[We consider this subject important in relation to infanticide. When, in a doubtful case, a medical jurist attempts to estimate the probability of a child having come into the world living or dead, he assuredly ought to be prepared with a knowledge of the results which have been derived from statistical enquiries relative to live and still birth. If this kind of knowledge answer no other purpose, it must have the effect of rendering him cautious in the expression of an opinion. The subject, however, is not without interest to the general practitioner in numerous other points of view. In the following extracts we shall not confine ourselves strictly to foreign sources, being anxious to render our view of the subject as complete as we can.]

I.

Bohemia. In 1835, the births were in this kingdom, 160,871, of which 2,561 children were still-born. This nearly gives a ratio of only one child born dead out of every sixty-three births; an extraordinarily low proportion.

Lower Austria. From 1st November, 1835, to the end of October, 1836, the births were 49,658; of which number, 1,215 were still-born children. This is nearly in a ratio of one in forty-one. The still-births were twice as numerous among *legitimate* as among *illegitimate* children; and, with regard to *sex*, the still-born males were to females as about four to three among the legitimate births. Among the still-born illegitimate children, the sexes were nearly equal.

Presburg. In the year 1835, there were born 1,385 children; of which fifty-five were born dead. This is a ratio of about one in twenty-five.

Innsbrück. From the 1st November, 1834, to the end of October, 1835, the births in this town amounted to 314, of which seventeen were still-born; a ratio of one in eighteen. The still-born males, even this small number, were to the

females as two to one.—*Wildberg's Jahrbuch, loc. cit.*

II.

Geneva (City). During the ten years from 1814 to 1823, there were born, as a mean annual average, 511 children; out of which number thirty-four were born dead, giving a ratio of one to fifteen for the still births. In the ten years from 1824 to 1833, there were born, as an annual average, 581 children; of which thirty were born dead, about one in nineteen. The mean annual births were, however, for the whole period of *twenty years* over which the observations extend, 556; and the mean annual number of still-births was, for the same period thirty-two, about one in seventeen. Of the mean annual births, the males were to the females as, 284 to 262; in the still-births as eighteen to fourteen. We learn by this that, as the preponderance of total births is on the side of the male sex, so is the preponderance of still-births. It is to be observed, however, that the number of children born dead was liable to great yearly fluctuations, being sometimes as high as one-eleventh, and sometimes as low as one-twenty-seventh of the total births.

In a medico-legal view, it is interesting to ascertain the ratios of the still-born among *legitimate* and *illegitimate* children, whenever this is practicable; since the great majority of alleged cases of child-murder lie among the *illegitimate*.

Out of 9,833 *legitimate* births, during the whole period of twenty years, 517 children were born dead, or one child was born dead in every nineteen legitimate births. Out of 1,092 *illegitimate*, there were 129 born dead, or one in eighty-four cases.

These results, deduced from observations on nearly eleven thousand births, show that the still-born are more than *twice as numerous* among illegitimate as among legitimate children. This exactly what we might expect, since the circumstances under which illegitimate children are born tend to render their coming into the world alive very uncertain. The want of care and attention at the time of delivery, which generally takes place in secret, as well as the anxiety of mind under which the mother is commonly labouring, are facts that perhaps sufficiently explain the difference observed. The result of the Genevan observation is, it will be seen, entirely opposed to that deduced from the statistical survey of Lower Aus-

tria. Notwithstanding that, in the two cases, the total births of the illegitimate children are nearly *equal*, and that, in respect to legitimate children, the total births in Lower Austria are *five times as numerous* as those of Geneva; and, therefore, admitting only one-fifth of the possible error which would attach to those of Geneva, we are inclined to place greater confidence in the Genevan result, not only from the very high probability which attends it, but also from the circumstance that observations extending over a long series of years, are much more to be trusted than those which are confined to a single year.

Among the illegitimate, it was found that there was a slight preponderance of male over female births, as well as among those children which were born living as among those which were born dead. The number of still-born males, taking the total births, was much greater than that of females. The ratio for the whole period of the Genevan tables, twenty years, was as four to three. This difference has been ascribed, and perhaps with justice, to the generally greater size of the head and body in the male; conditions which necessarily expose the child to greater risk during delivery. As a summary of the still-born to the total births, the following statement may be taken:—

1 male born dead in . . .	15.59 births.
1 female	18.60 —
1 child	16.91 —

Paris. To his remarks on Geneva, the author of the report, M. Mallet, has appended a statistical summary, derived from observations, made during a period of *thirteen years*, namely, from 1819 to 1832, in the capital of France. It is as follows:—

1 male born dead in . . .	16.48 births.
1 female	19.67 —
1 child	17.90 —

Marseilles. According to the statistical survey of the department of the Bouches du Rhone, in the city of Marseilles there is one child born dead in sixteen births.—*Ann. d'Hygiène et de Méd. Lég. Janvier, 1837.*

III.

Prussia. In the recently published volume of the Statistical Society of London, we have met with a valuable paper founded on the researches of M. Hoffmann, of Berlin. It represents a statistical view of the births and deaths in the

Prussian states during a period of *fifteen years*, from 1820 to 1834. It is entitled to our consideration, not only from the reputation of the compiler, but from the fact of its comprising several *millions* of births, extending over a long period of time. We shall confine our extracts to that portion of the paper which is relevant to the question now under examination.

In the fifteen years, there were born in the Prussian states, 7,593,017; Of these, there were born dead 257,068. This gives a ratio of rather above one child born dead in every 29·14 births; that is to say, the still-born formed rather more than 3·31 per cent. of the total births.

This vast compilation also shows the same striking difference in the mortality of male and female children during birth which we have already had occasion to point out. M. Hoffmann refers this difference to the same causes as ourselves. In the above period of fifteen years there were born, of males 3,906,544, and of females, 3,686,473; of which were born dead, males 147,705, and of females 108,363. These numbers give a general ratio of males born dead to females of 1·35 to one; or, for every one hundred still-born females there were 135 still-born males.

The influence of legitimacy or illegitimacy is not noticed in this paper, probably from the great difficulties which must have attended the collecting of satisfactory evidence on this point, among so many millions of births.—*Trans. Stat. Soc. Lond.* 1837. Vol. i. Part 1., p. 132.

IV.

From October 1835, to October 1836, in the Lying-in Charity of Guy's Hospital, there were 630 births, and among these, thirty-four children were born dead, in about *equal proportions* of the two sexes. It is worthy of remark, that only eight out of the total number of deliveries were premature; an important circumstance, and one which ought always to be ascertained, to allow of fair statistical comparisons; since it is beyond all question that the ratio of live to still births must vary for the different periods of gestation at which a child is born. The ratio of the still-born here amounts to one-eighteenth of the total births.

Out of 766 applicants to the Charity during the year, it was ascertained that 643 had already given birth to 2,460 children; of which 133 were still-born—a ratio of one in eighteen. It is curious

thus to find that the ratios should be alike, although, as will be perceived, the births from which they were deduced were four times as numerous in the one case as in the other. This fact, in our view, furnishes at the same time strong intrinsic evidence of our having reached a near approximation to the truth.—*Dr. Ashmell in Guy's Hospital Reports*, IV. April, 1837.

[Our readers will have perceived that some of the results differ very widely, but, if we except Bohemia (one to sixty-three), and Lower Austria (one to forty-one), which numbers representing, as they do, merely *one annual result*, and differing so materially from all the others in our list, we do not hesitate to exclude from our calculation, we shall have a mean result of one-twentieth; i.e., that *one child out of twenty is still-born*. This result, it is to be observed, is deduced, at the lowest computation, from nearly *eight millions* of births.]—*British and Foreign Medical Review*.

BIRMINGHAM EYE INFIRMARY.

Report of the Cases attended by R. Midlemore, Esq., from January 1, to December 31, 1836.

The following Report is contained in the Transactions of the Provincial Medical and Surgical Association, published within these last few days.

Simple acute conjunctivitis, 116. Chronic conjunctivitis, 45. Acute conjunctivitis, with pustule or ulcer on the cornea or conjunctiva, 98. Acute conjunctivitis with puriform secretion, 55. Purulent conjunctivitis of new-born infants, 45. Irritable conjunctivitis, 53. Strumous conjunctivitis, 46. Effusion of various kinds beneath the conjunctiva, 13. Disease of the semi-lunar membrane and lachrymal caruncle, 4. Corneitis, 26. Vascularity of the cornea, 7. Pannus, 4. Opacity of the cornea, 44. Staphyloma of different kinds, and of various parts, 13. Ossification of the cornea, 1. Impaction of foreign bodies in the cornea and conjunctiva, 22. Sclerotitis, 13. Ulceration of the sclerotica, 3. Morbid growth from the cornea and sclerotica, 2. Pterygium, 3. Simple acute iritis, with or without ulcer of the cornea, onyx, or hypopium, 34. Chronic iritis, 3. Syphilitic iritis, 3. Strumous iritis, 5. Pro-

lapse of the iris, 4. Vacillation of the iris, 8. Choroiditis, 6. Varicose ophthalmia, 3. Retinitis, 2. Cataract, 29. Fungoid and other tumours within, and upon the surface of, the eye-ball, 7. Amaurosis of various kinds and in different degrees, 50. Diseases of the lachrymal apparatus, 21. Strabismus, 7. Ophthalmia tarsi, 71. Lippiudo, 7. Hordeolum, 4. Entropium, 5. Ectropium, 8. Inflammation of the eye-lids, 12. Ptosis, 1. Ulceration of the eye-lids, 6. Tumours in the eye-lids, 20. Wounds of the eye and its appendages, 30. Adhesion of the eye-lid to the eye-ball, 4. Congenital defects, 6.

Irritable Ophthalmia.

"In three examples of irritable ophthalmia, which have fallen under my observation during the past year, and which occurred in poor women, who had continued to suckle for an injudiciously long period, in the hope of deferring their subsequent pregnancy, one eye only was affected in each case; and, on inquiry, I found that the subjects of the malady suckled only with the breast of the side corresponding to the diseased eye. I do not know a more decided proof of the asserted connexion subsisting between protracted lactation and the irritable form of ophthalmia, which occasionally affects the eyes of females during that period."

We do not know that this can be considered *very* decided evidence of the connexion between lactation and ophthalmia. The best evidence is the frequent coincidence of the two affections, such frequency of coincidence or of sequence constituting, in fact, the ordinary evidence of cause and effect, or of the relations of one thing to another.

Carcinomatous Growth from the Cornea and Sclerotica.

Joseph Wilkes, aged 49, residing at Redditch, has been suffering for several weeks from a painful tumour arising from the surface of the eye. It is about the size of a shilling, of a red colour, firm texture, and very uneven surface; it is firmly attached to the surface of the sclerotica and cornea, but chiefly to the former; it is not very painful when touched. The conjunctiva is inflamed, but the cornea and iris are not so affected. There is very copious lachrymation, and considerable intolerance of light. The patient is employed as a waggoner; and he states that the disease has come on gradually, and

from no cause with which he is acquainted.

Mr. Middlemore was desirous of removing the whole anterior part of the eye-ball. He was over-ruled, but no doubt he was right. He dissected away the morbid growth from the surface of the membranes to which it adhered. In about two months after the patient's return home, the growth re-appeared, and has since rapidly increased. But the patient will not submit to another operation.

The growth, when examined, was found to be hard, and interspersed with firm white bands and spots; its surface was vascular, and had a rough craggy appearance. It more nearly resembled cancer of the eye-ball than any other disease.

Melanotic Growth from the Semilunar Membrane.

"I have now a patient in attendance at the Eye Infirmary, in whom there is a filmy prolongation, of a melanotic character, of the membrana semilunaris; and, just at the temporal side of the lachrymal caruncle, there is also a dark-coloured tumour of the size of a large pea. It appears, though much darker, a good deal like a portion of iris recently prolapsed through an opening in the cornea. The disease has existed for several years, but has lately much increased owing to her having scratched it whilst rubbing her eye. I have told this poor woman that nothing but surgical operation is likely to relieve her, but she will not, at present allow me to remove the diseased part. I have never before seen a case precisely similar to this, during the whole course of my practice.

Since the preceding paragraph was written the tumour increased in size so very rapidly that the patient was anxious to have it removed. This was readily accomplished by means of the small curved scissors, as it was but slightly adherent to the semilunar membrane, and quite unattached to the sclerotica. It was covered by the conjunctiva, and appeared to have been chiefly developed in the subconjunctival cellular membrane. The tumour itself was not organized: it consisted of a firm substance of an irregular dark colour, its external surface being densely black, its middle and posterior portions being of a dark brown colour, intermixed with lines and streaks of an extremely black appearance. The whole of the tumour became comparatively pale after it had been immersed in spirit of wine three or four days."

Opening a small Abscess.

"If you consult those books which treat of abscess, you will find it laid down as a general rule, that where the abscess is of small size, it ought to be left to nature to effect an opening, because this, it is said, will be small, and consequently leave but an inconsiderable cicatrix. According to this view, small abscesses are to be left to themselves, provided they be not too indolent, nor advance too rapidly. But I reject this method; for if the aperture made by nature be small, why should not that made by art be made small likewise? It is only necessary for this purpose that we use an instrument with a narrow blade, and that we make a simple puncture."—*Lisfranc. Med. Gaz.*

To prevent Scars in the Neck.

"Abscesses of the neck ought to be opened by means of a simple puncture. I do not now allude merely to small abscesses; I have opened, in this manner, purulent depots of considerable size, and although the extent of the incision was not in proportion to the collection of matter, yet was all the pus evacuated, while the cicatrix which remained did not exceed that of a leech-bite. This precept is of great importance, not only to the welfare of the patient, but to the reputation of the surgeon."

If there is a lodgment at the lower part, a small counter-opening is necessary. The incision, in any case, should always be made transversely, in the direction of the natural folds of the skin.—*Ib.*

How to open a large Abscess.

"The bistoury is to be held in the first position; the two last fingers, separated from each other, and extended, are to be placed, if possible, beyond the tumour, as a *point d'appui*; the tissues which are penetrated must be divided in a perpendicular direction: the middle finger placed on the blade of the instrument, serves to regulate the depth of the incision. This is very important, for if the instrument cuts ill, or if the texture be hard, we are under the necessity of pressing more strongly on the parts to be divided; and without the precaution of having the finger as I have described, we should incur the risk of plunging in the instrument too far. Besides, it is easy to push the bistoury farther in, if necessary, by drawing back the finger on the blade of the instrument. We must do all gently: thus, when the blade arrives in the collection

of pus, the hand will perceive the fact, because the knife is now passing through a less resistance than before. The only exception to this is where there are muscular contractions of a nature to interfere with the resistance. I cannot well give you a measure of the slowness necessary in this proceeding; but always remember this fundamental principle in operative surgery—*tuto is better than cito.*"—*Ib.*

It is refreshing to hear a man of the admitted dexterity of Lisfranc, of a dexterity of Lisfranc, of a dexterity probably quite unequalled, denouncing the stop-watch mode of operation. A master of celerity himself, he points out the folly, we might almost say the wickedness, of making it the paramount consideration.

How to open a deep Abscess in the Neck.

"Take the neck as an example. I there make an incision parallel to its axis, and which divides, layer by layer, successively, the skin; the cellular membrane, and, if necessary, the superficial aponeurosis. I next take a blunt probe, and limit the extent to which it is to penetrate the textures, by holding it between the thumb and forefinger. I then introduce this to the bottom of my incision, and make it pass on by separating, or rather pushing, aside the fibres of the parts beneath. Whenever the instrument has entered the abscess, there is a cessation of resistance, besides which I perceive drops of pus oozing along the sides of the instrument. I then push it upwards and downwards, so as to enlarge the opening, and thus the matter finds a ready exit."—*Ibid.*

JOINT STOCK COMPANY OF
GOWER STREET.

CHAIR OF CHEMISTRY.

The election of this Chair has at length been decided in favour of Dr. Graham of Glasgow, and late Professor of the ANDERSONIAN UNIVERSITY in that city. Out of the numerous candidates who laid their pretensions before the council, Drs. Graham and Phillips were the only individuals selected; and the difficulty there was in estimating the abilities of these gentlemen may be conceived by the fact of each having eight votes. Lord Brougham, however, having the casting vote, as chairman, gave it in favour of the Scotch professor. In the present crowded state of our columns we have not space but merely to announce the appointment; neither can we, for the same reason, give insertion to the letter of *Scotus*.

NOTES OF LECTURES ON
PHYSIOLOGY.

BY DR. FLETCHER.

*Delivered in the Argyle Square School
of Medicine, Edinburgh.*

No. XXXI.

THERAPEUTICS.

Evacuant Medicines—Errhines—Mode of action—Diseases in which they are useful, and those in which they are dangerous—Sternutatory effect of looking at the sun—Sialagogues—Local and general sialagogues—Condiments—Medicines which produce ptyalism—Demulcents—Difference between demulcents and expectorants—Demulcent purgatives—Expectorant purgatives—Mucilaginous demulcents—Mistura mucilaginosa of the Edinburgh Infirmary—Oleaginous demulcents—Gelatinous demulcents—Pectic acid—Farinaceous demulcents—Expectorants—The only four Balsams of the Pharmacopœia—Emetics—List of indigenous emetics—Purgatives—Laxatives—Cathartics—List of purgatives which admit of ounce doses—Drastic purgatives—Saline purgatives—Resinous purgatives—List of medicines which produce liquid stools—Medicines which act on different parts of the intestines—Carminatives—Origin of the term—Families of plants which furnish them—Diuretics—Animal, vegetable, and mineral diuretics—Emmenagogues—Tonic, antispasmodic, and purgative emmenagogues—Effects of dancing, riding, hipbaths, electricity, and sexual intercourse—List of emmenagogue plants—Hierapicra—Secale cornutum—Diaphoretics—Diseases in which they are most used—Uncertainty of their action—Necessity of a hot regimen—Contrary rule with diuretics—The best diaphoretic—Advantages of combination—James's powder and Dover's powder—Diaphoretics for fat patients—Effects of venesection—Epispastics—Rube-facients—

No. 15.

Vesicants—Suppurantia—Caustica—Effects of combining cantharides with vinegar—Munro on vesication with boiling-water—Best mode of applying it—Blistering with a tea-kettle in sciatica—Vesicating with gun-powder—Tartar Emetic ointment—Difference between escharotics and caustics—Proper mode of applying nitric acid and muriate of antimony—Revulsives—Ancient notion of peccant matters—Supposed benefit of a profuse discharge—Revulsives which produce no discharge—Origin of the term "Counter-irritation"—Mode in which counter-irritants act—Sympathetic conveyance of irritation—Stimulating treatment of ophthalmia, sore-throats, and gonorrhœa—Mode in which galvanism and acupuncture act—Best mode of blistering—Spontaneous hæmorrhage—Critical discharges—Supposed incompatibility of two contemporaneous irritations—Uroscopists and urosmancers—Medical chamber-pots—Coc-tion.

(1.) *Errhines*.—These medicines are used in diseases of the cerebrum, the eyes, the nose, the gums, and the mucous membranes about those parts. They act by what is called revulsion; though Hippocrates thought it was by relieving the brain of phlegm. They are dangerous in apoplexy, epilepsy, hæmorrhage, and aneurism. The principal of them are, nicotiana tabacum, veratrum album, asarum Europæum, lavandula vera, euphorbia officinarum, mentha (pulegium, vera, and piperita), salvia officinalis, momordica elatærum, hyssopus officinalis, inarubium vulgare, melissa officinalis, origanum (vulgare and majorana), rosmarinus officinalis, teucrium (marum and Chamæpitys), iris florentina, and saccharum officinarum. Dr. Duncan says that looking at the sun acts as a very good errhine.

(2.) *Sialagogues*.—These are either local in their application, as all condiments and essential oils, or general, as nitric acid, hydrocyanic acid, mercury,

gold, antimony, and all medicines which produce ptyalism. To the former class belong—piper nigrum, capsicum annuum, nicotiana tabacum, citrus aurantium, cochlearia armoracia, pistacia leutiscus, polygala senega, pterocarpus draco, myrtus pimenta, eugenia caryophyllata, angelica archangelica, anthemis pyrethrum, laurus cassia, myristica moschata, and daphne mezereum. Sialagogues are used in diseases of the ears, the eyes, and especially of the gums.

(3.) *Demulcents*.—Demulcents increase the follicular secretions, are bland, and are used in the beginning of diseases. Expectorants, on the contrary, increase the perspirable secretions, are acrid, and are used at the end of diseases. Purgatives may be divided in the same way; some (the oils and sulphur for instance) being demulcents, while others (as the resins) are expectorant, and produce watery stools. Demulcents are divided into four classes:—1. Mucilaginous demulcents, as the gums and mallows. The principal are malva sylvestris, althæa officinalis (from which is prepared the *mistura mucilaginosæ* of the Edinburgh Infirmary), linum usitatissimum, glycyrrhiza glabra, pyrus cydonia, prunus domestica, daucus carota, inula helenium, tussilago farfara, anchusa tinctoria, marrubium vulgare, ficus carica, acacia vera, and astragalus tragacanthus. 2. Oleaginous demulcents; are olea Europæa, amygdalus communis, cocos butyrea, adeps suillus, adeps ovillus, cetaceum, and cera. 3. Gelatinous demulcents; as isinglass, calf's-foot jelly, Iceland and Irish moss, and cornu cervi. These demulcents are said, by Duncan, to contain pectic acid. 4. Farinaceous demulcents; as avena sativa, triticum hybernum, and hordeum distichum.

(4.) *Expectorants*.—The principal of these are antimony, ipecacuanha, all the balsams, most of the turpentine, and many of the gum-resins. Storax, benzoin, balsam of Peru, and balsam of Tolu, are the only four balsams in the pharmacopœia. Besides those we have mentioned, the expectorants comprehend squill (*scilla maritima*), seneka, or rattlesnake root (*polygala senega*), uva ursi, amygdalus Persica (peach leaves), assa-fœtida, sagapenum, ammoniacum, acetic acid, oxymel, all acescent fruits, asarum, lichen Islandicus, Irish moss, melissa officinalis (balm), mentha sativa, or viridis (common mint, or spearmint), mentha pulegium (pennyroyal), salvia officinalis (sage), marrubium vulgare (horehound),

hyssopus officinalis, datura stramonium (thorn-apple), bubon galbanum, copaifera officinalis (copaiba), myrrh, balm of Gilead (*amyris*), alcohol, æther, benzoic acid, ammonia, and its carbonate, volatile oils, tar, stram, and tobacco-smoke.

(5.) *Emetics*.—The sulphates of zinc and copper, the preparations of antimony, squill, and digitalis purpurea, are the chief of this class. According to Dr. Graham, the indigenous emetics are the seeds of the white-mustard (*sinapis alba*), the common violet (*viola odorata*) horse-radish (the root of the cochlearia armoracia), chamomile-flowers (*anthemis nobilis*), the ranunculacæ, asarum, and arum maculatum (wake robin), common mustard (*sinapis nigra*), tobacco (*nicotiana tabacum*), and carbonate of ammonia may also be mentioned among the emetics.

(6.) *Purgatives*.—These may be divided into three orders:—1. Laxative; as cassia fistula (the pulp of its fruit), tamarindus Indica (the common tamarind), the fig (*ficus carica*), the prune (*prunus domestica*), fraxinus ornus (the ash-tree from which manna is obtained), morus niger (the mulberry), grapes and resins (from the vitis vinifera), sulphur, molasses, or treacle, honey and calomel. 2. Cathartic; as jalap and scammony (*convolvulus jalapa* and *scammonia*), castor-oil (*ricinus communis*), rhubarb (rheum), and the five following, which are given in ounce doses;—sulphate of magnesia (Epsom salt), sulphate of Soda (Glauber's salt), phosphate of soda (tasteless purging salt), tartrate of potash (soluble tartar), and tartaric acid of potash and soda (tartarized soda, or Rochelle salt). 3. Drastic; as gamboge, elaterium (extracted from the wild cucumber, *momordica elaterium*), scammony, croton oil (*croton tiglium*), and cucumis colocynthis (*colocynth*, or bitter-apple.) Besides those we have enumerated, we may mention among the purgatives, the pulp of the fruit of dog-rose (*rosa canina*), *sinapis alba*, *viola odorata*, elder-berries (*sambucus nigra*), dandelion root (*leontodon taraxacum*), saccharum officinarum (sugar), olea Europæa (olive oil), pinus sylvestris (oil of turpentine), pistacia terebinthus (Chian turpentine), *amyris Gileadensis*, *copaifera officinalis*, euphorbium (*euphorbia officinarum*), Venice turpentine (*pinus larix*), Canadian turpentine (*pinus balsamea*), catharticum (purging-flax), rhamnus catharticus (buckthorn), senna leaves (*cassia senna*), broom-tops (*spartium scoparium*), *Geoffroya inermis* (cabbage-tree bark), *arctium lappa* (burdock), *menyanthes*

tri-oliata (buckbean), *spigelia marilandica* (Carolina pink), *gratiola officinalis* (hedge hyssop), *aspidium filix mas* (male fern), *helleborus niger* (Christmas rose), *helleborus fetidus* (bear's-foot), *colchicum autumnale* (meadow-saffron), *veratrum album* (white hellebore), *rosa centifolia* (damask rose), *rumex aquaticus* (water-dock), *magnesia* and its carbonate, sulphate of potash, cream of tartar (supertartrate of potash), common salt (muriate of soda or chloride of sodium), and blue pill (*pilulæ hydrargyri*). Saline purgatives act on the upper part of the intestinal canal; resinous purgatives, and sulphur, on the lower. *Colocynth* acts on the whole canal. *Elatarium*, gamboge, cream of tartar, and Epsom salt, produce liquid stools.

(7.) *Carminatives*.—These medicines derive their name from *carmen*, a charm, on account of their prompt operation. They are principally furnished by the cruciferae, labiatae, and umbelliferae. The chief of them are fennel and dill-seeds (*anethum fœniculum* and *graveolens*), angelica root, carraway seeds (*carum carui*), coriander seeds (*coriandrum sativum*), cummin seeds (*cuminum cyminum*), the seeds of the carrot (*daucus carota*), anise seeds (*pimpinella anisum*), common hyssop (*hyssopus officinalis*), lavender flowers (*lavandula spica*), *melissa officinalis*, mint, pennyroyal, peppermint (*mentha piperita*), common and sweet marjoram (*origanum vulgare* and *majorana*), sage, and rosemary (*rosmarinus officinalis*.)

(8.) *Diuretics*.—These are taken from all the three kingdoms. The animal kingdom furnishes the Spanish fly (*cantharis vesicatoria*). Alcohol and the spirit of nitrous æther, are the most powerful of the inorganic diuretics; and to them may be added, diluted mineral acids, muriate of iron, corrosive sublimate, blue pill, tartar emetic (*antimonii tartaras*), the carbonate, bicarbonate, acetate, tartrate, and supertartrate of potash, sal polychrest (*sodæ et potassæ tartaras*), nitrate, chlorate, hydrosulphuret, and ferrocyanate of potash, subborate of soda (common borax), and muriate of baryta. The vegetable diuretics are, squill, colchicum, fox-glove (*digitalis purpurea*), tobacco (*nicotiana tabacum*), *lactuca virosa* (strong scented lettuce), *leontodon taraxicum*, *gratiola officinalis*, volatile oil of turpentine, and of juniper (*juniperus communis*), *copaiba*, gamboge, brom-tops, and cajepout oil (*malealeuca leucadendron*).

(9.) *Emmenagogues*.—All tonics, antispasmodics, and purgatives are emmen-

agogues. To these may be added various kinds of exercise; such as dancing, and riding on horseback, hip-baths, electricity and sexual intercourse. The plants which have enjoyed the greatest celebrity as emmenagogues, are *juniperus sabina* (savine), *crocus sativus* (saffron), black hellebore, *rubia tinctorum* (madder), *ruta graveolens* (rue), *sinapis alba*, *valeriana officinalis*, *artemisia absinthium*, *tanacetum vulgare* (tansy), *aristolochia serpentaria* (Virginian snake-root), *canella alba*, and *aloes socotorina*. The two latter form *hiera picra* (*pulvis aloes cum canella*), which has been much celebrated as an emmenagogue. We may add gamboge and the fetid gums; and especially the spurred rye (*secale cornutum*.)

(10.) *Diaphoretics*.—This class of medicines is much used in rheumatism, diabetes, and diseases of the skin. After the administration of diaphoretics, a hot regimen is to be prescribed; while a cold one is to be employed when diuretics are taken. The best diaphoretic is warm water, and it assists the action of the rest. In the list of the latter are antimony, mercury, alcohol, the salts of ammonia, volatile oils, sulphuric and nitric æther, wine, musk, castor, camphor, *laurus comphora*; bay-leaves and berries, *laurus nobilis*, mezereon or spurge-olives, *daphne mezereum*; virginian snake-root; *cascarilla*-bark, *croton cascarilla*; *contrayerva* root, *dorstenia contrayerva*; *sarsaparilla*, *similax sarsaparilla*; sweet-flag, *acorus calamus*; *guaiacum officinale*; *ruta graveolens*; *sinapis nigra*; opium; *polygala senega*; *copaifea officinalis*; *sambucus nigra*; *cephælis ipecacuanha*; *valerian*, *valerian officinalis* or *sylvestris*; *elecampane*, *inula helenium*; leopard's bane, *arnica montana*; *arctium lappa*; *rhododendron chrysanthum*, yellow-leaved *rhododendron*; cayenne pepper, *capsicum annuum*; night-shade, *solanum dulcamara*; *hyssopus officinalis*; *melissa officinalis*; *mentha pulegium*; *rosmarinus officinalis*; *salvia officinalis*; *sassafras*, *laurus sassafras*; Dover's powder and James's powder. Dover's powder consists of eight parts of sulphate of potash, one part of ipecacuanha, and one of opium. James's powder consists of equal parts of peroxide of antimony, and persulphate of lime. Diaphoretics are very uncertain medicines. Their action is much assisted by combination, and, if the patient be fat, by venesection.

(11.) *Eptispastics*.—This class may be subdivided into four others; *rubefacientia*, *vesicatoria*, *suppurantia*, and *caustica*.

1. The rubefacients include rectified spirit of wine, æther, ammonia, stavesacre (delphinium staphisagria), buttercups (ranunculus acris), ruta graveolens, guaiac (guaiacum officinale), sinapis alba, cochlearia armoracia, amyris elemifera, cajepout oil, oil of cloves, (eugenia caryophyllata), galbanum, sagapenum, ammoniacum, opoponax gum (pastinaca opoponax), pellitory of Spain (anthemidis pyrethrum), capsicum annuum, cinnamom (laurus cinnamomum), saffraas, camphor, daphne mezereum, euphorbia gum (euphorbia officinarum), black and long pepper (piper nigrum and longum), Venice turpentine, savine oil, arum maculatum, ginger (gingiber officinale, and the onion and garlic (allium cepa and sativum). 2. Vesicatoria; such as cantharides, and strong acetic acid. If these two be combined, their action is immediate. Munro was the first to use boiling water for the purpose of raising an instantaneous blister. It is best done by pouring boiling water on a cloth in a basin, and then inverting the latter on the part which it is wished to vesicate. A bleb may be raised along the course of the sciatic nerve, by conducting along it the spout of a boiling tea-kettle, or by laying a train of gunpowder over it, and then firing it. 3. Tartar emetic ointment is an excellent example of the suppurantia. 4. Caustica may be subdivided into escharotics and caustics proper; the first of which act on diseased, and the latter on sound parts. The principal caustics are nitrate of silver, sulphuric, nitric, and muriatic acids, potash, lime, corrosive sublimate, sulphate and acetate of copper, and muriate of antimony. In applying muriate of antimony, its extent should be confined by plaster, while nitric acid should be guarded by wax.

(12.) *Revulsives*.—It was formerly thought that medicines produced revulsion by drawing the "peccant matter" from one part of the body to another more within the controul of the physician, and therefore evacuants were considered to be beneficial in proportion to the discharge they occasioned. But many revulsives produce no discharge at all, and in these cases a new irritation was said to be substituted for an old one; whence arose the term counter-irritation." We may have two thousand irritations, the ganglionic nerves (which convey irritation) being complete in themselves; but we cannot have two sensations, because the sensorium is one and indivisible. Counter-irritants or revulsives act by causing a

new irritation, which is conveyed by sympathy to the diseased part; the inflammation of which (inflammation being *diminished* irritation) is relieved by this *increased* irritation. This is well seen in the treatment of ophthalmia, sore throat, and gonorrhœa, by stimulating collyria, gargles, and injections; and it is thus that galvanism and acupuncture cure inflammation. Blisters do most good when they are employed as rubefacients, without producing any discharge at all.

It was observed, from the earliest periods in the history of medicine, that spontaneous discharges of blood, or of the various secreted fluids of the body, frequently attended the cessation of inflammation; and it was therefore to be expected that the earlier medical authors would speak of the remedies by which these discharges, whether of blood or of the various secretions, were promoted, under the general term of evacuants; and would ascribe the advantage derived from them to the depletion which they occasioned. It could not, however, be long concealed from observation, that equal benefit was sometimes derived, in inflammatory diseases, from remedies which produced no discharge; and it became necessary, therefore, to establish it as a law of the animal economy, that the constitution could not suffer from two preternatural irritations at the same time; and that thus, when a secondary irritation had been set up, the primary one had been alleviated or removed. At this time, it must be remembered, inflammation was supposed to consist, not in diminished but in increased irritation. It has, accordingly, been almost the uniform practice of medical men to refer the advantages derived from the remedies called revulsive, to one or other of the causes we have mentioned. Even in the present day it is not uncommon to find medical practitioners dwelling, with great emphasis, on the number of liquid stools caused by a purgative medicine, or on the quantity of discharge produced by a blister; as if the efficacy of the remedies were to be estimated by these circumstances. Still more frequently, on the other hand, do we observe them attributing the benefit to be derived from such remedies as do not produce any sensible discharge, either to their effecting new determinations of blood (which is only a modification of the evacuation doctrine), or to counter-irritations, or to the abstraction of stimuli, of some kind or other, from the part affected. It is my intention

to trace, as shortly as possible, the origin of the vague surmises above alluded to, and to assign my reasons for thinking that both these explanations of the beneficial action of the remedies in question should be exploded; the benefit of these remedies being due to the stimulus which they indirectly communicate to the inflamed vessels.

It is stated as a naked truth by Hippocrates, that all inflammatory diseases are capable of being resolved, either by a flow of blood or other fluids, or by a discharge from the bowels, the urinary bladder, or the skin; and it is highly probable that the observations of this fact, together with the remarkable changes which most of the natural excretions of the body undergo in inflammatory diseases, as well as the preternatural discharges which frequently take place, lead to the opinion that the observation of all this, gave rise to the celebrated humoral pathology, the doctrines of which still influence the reasonings and practice of modern physicians, more than they are willing to admit, or perhaps more than they are themselves conscious of. The changes which the natural excretions of the body undergo in inflammatory affections, are considerably more obvious, and therefore more immediately striking, than those effected in the solids. It is easy therefore to account for the minute attention which medical men, in former ages, were accustomed to pay, not only to the quantity but also to the quality of the stools, the urine, and the cutaneous exhalations, in forming their prognosis in inflammatory diseases. Esculapius is well known to have been branded by Aristophanes with the name of *Σκίροπαγος*; and it is familiar to everybody how fertile a theme has been furnished to modern satyrists by the descendants of Theophilus and Actæuius, the Uroscopists and Uromancers of former times; who, it must be confessed, with their graduated glass chamber-pots, and their subtle divisions and subdivisions of a fluid, of the real nature of which they were profoundly ignorant, into cremor, nubecula, encephorema, and hypostasis, were not quite unworthy of the sarcasms cast upon them. Nor was the regard which the ancient physicians paid to the cutaneous exhalations much less remarkable, or less susceptible of ridicule, for but little really useful was known about these exhalations before the discovery of the insensible perspiration by Sanctorius.

A minute attention to the urine and perspired fluids was in ancient times con-

sidered of importance in inflammatory diseases, because any change in these fluids was supposed to indicate the progress of the coction, and the consequent expulsion of the *ῥῆμα*, or morbid matters, upon the entrance of which into the body, such diseases were supposed to depend. An attention equally minute, at least, would of course be paid to the blood, to the supposed two kinds of bile, and to the phlegm, because by their immediate agency, this coction and expulsion were conceived to be effected. The occurrence of spontaneous hæmorrhages, as well as of diarrhœa, sedimentous urine, or a flow of sweat, in inflammatory diseases, was from the earliest times noticed as an almost certain forerunner of recovery; and a similar coincidence appeared frequently to occur also in the other fluids in question, which, unlike those previously named, were not among the natural excretions, but were formed, as was supposed, immediately from "the four elements," and constituted by their union the bulk of the body. Hence it was a very natural conclusion, that inflammation was excited by a superabundance in the affected parts of the body of one or other of these four fluids; and hence, also, appears to have arisen the celebrated ancient dogma, that the four kinds of inflammation then admitted (phlegmonous, erysipelatous, schirrhus, and leucophlegmatic) were caused by a preternatural influx of these fluids into the parts affected; each being severally despatched thither by the *πύρ*, the *φύσις*, the *ἐνόρμωσις*, the *πνεῦμα*, or the chief moving spring of the body (by whatever name it was designated) on an expedition against the morbid matters above-mentioned.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

General Principles of Disease.

Strong susceptibilities of a constitution to take on diseased disposition and action, whether of the whole as such, or a local effect of a constitutional disease, (which last I call an act of the constitution,) only require the impression of the immediate cause for the disposition and action peculiar to these susceptibilities to take place. These immediate causes may not be the same in two constitutions, although both may have a strong susceptibility for the same action; for what will produce the

action in one constitution may not produce it in another. One constitution will require one immediate cause and another another though both constitutions may have a susceptibility for the disease. Two men equally susceptible may be exposed to the cause of ague: one may have the disease, the other not. It is exactly similar with the mind: two men may be naturally or constitutionally equally susceptible of anger, but each must have his immediate cause; what will bring forth action in one will have but little effect on the other, and *e contrario*. It is the same thing with every effect of the mind.

Most susceptibilities are so much of a specific nature in themselves that each susceptibility shall be brought into action, in nineteen people out of twenty, in one way, and probably in the twentieth it has been prevented by what produced it in the others. This accounts for the same diseased action in people arising from so many different causes, and also accounts why such disease, though having a specific mode of action, may be varied in the same person in different ways, still more in different people, and even often require different modes of cure.

This theory may be illustrated by every disease that takes on full specific action; whether a full constitutional action, as an ague, or a local one, as the gout. As an ague is a well-known and well-marked disease, this theory will of course be illustrated by this disease.

Every constitution has more or less susceptibility to fall into an aguish habit; but there must be in all an immediate cause to produce the disease. The immediate cause may be such as will make nineteen people out of twenty fall into aguish action; but many constitutions, though they have a susceptibility of falling into an aguish habit, yet when the immediate cause takes place, may have no disposition to take on the full action of that disease; by which means the constitution is teased by what is called a badly formed ague. If the immediate cause be some local disease in the body, as diseased liver, spleen, &c., then the cure must be effected by the cure of the liver, &c.

This reasoning may be taken in another point of view. Suppose twenty people having different susceptibilities;—introduce something that shall endanger the constitutions of the whole number, and each shall take on the disease that he was at that time most susceptible of, whether ague, gout, or any other.

But often that which would become the

immediate cause in those already susceptible of action, or already predisposed to it, by repetition or continuance becomes the predisposing cause in others not susceptible. If two men, one susceptible as only to want the immediate derangement, the other not at all susceptible of an ague, be sent into the fens of Lincolnshire, the first shall have an ague immediately, because he only required the immediate cause of it; the other, if he does not get the better of the climate by habit, shall become aguish in time, because the country will become both a predisposing and an immediate or exciting cause.

We may substitute for the disease of ague some other disease, and the whole of the above reasoning will be perfectly applicable. But where it is the nature of the disease to take on local action, as in gout, there must not only be a universal disposition for such disease, which is the original, but there must also be a local preference, or rather a local susceptibility superior to the rest; and when the immediate cause takes place, so as to form the disposition, that part takes on the whole action, which relieves the constitution of such disposition, except it should produce another constitutional effect by a vital part taking it up, by which means it would affect the whole constitution similarly to any of the affections of this vital part, where a diseased disposition is formed, but does not take on the regular type of the disease, or does not take on the full and complete action; as in the aguish disposition not having gone through the regular stages of the ague, or gout not having formed a regular fit.

In those diseases that become local, as gout, some attention is to be paid to the seat of action; for if a vital part takes it up, it must be much worse than when there is only a constitutional affection.

The qualities of periodicity and regularity in constitutional diseases, or the power of a constitutional affection to become local, are, I believe, but little understood.

Susceptibilities for dispositions and actions appear to me to be the same with what are usually understood by temperament. Temperament is the state of the body fitting it for the disposition or action it is then in, whether it is only a state of susceptibility, of disposition, or action. The action is always the best test of that state; but, although the action is the best test, yet there are some circumstances attending animals that either dispose them for, or are concomitant upon, such and

such susceptibilities; and from these circumstances we can say beforehand, although only in a general way, what are the most predominant susceptibilities for certain actions in this or that animal. We see that even colour in animals depends on a difference in their temperaments, or is concomitant with temperament; for animals with fair skin and hair are more susceptible of cold than the dark, as also of pain. This is well known in the army, where we find that the power of bearing violence committed on the body is in proportion to the darkness of the individual. Fair people are more irritable in their minds, more susceptible of anger, and probably of all other passions. Fair people are also more susceptible of certain diseases than dark, as of scrofula. This may arise from their not being able to bear the vicissitudes of climate; for it is in changeable climates, especially where there is cold, moisture, &c., that scrofula is most predominant. The irritable inflammation also is more common in the fair than the swarthy. As the fair are less able to resist cold than the dark, it might be supposed that the dark are less able to resist heat, therefore more ready to run into diseases which warmth has a tendency to bring on. But from the estimate made by Dr. Young in the Island of St. Vincent's, it would appear there is some reason to suppose the contrary; from which it would appear that the dark-coloured are rather fitter for all kinds of climates.

Of diseased Disposition.—Dispositions are natural or unnatural, including diseased. The natural belong to the healthy animal, therefore are not to our present purpose.

Dispositions may be unnatural (and of course the actions arising from them unnatural,) and yet not diseased.

Unnatural dispositions and actions we shall divide into three kinds, or they may arise from three causes, which are remote.

1st. The disposition of restoration, in consequence of some injury done, which is also a consequence of every disease which is curable.

2nd. The disposition arising from necessity, as the thickening of parts from pressure, ulceration of every kind. This includes a great variety.

3rd. Diseased dispositions of all kinds, which also includes a vast variety.

From this division we see that there are two preternatural dispositions that are not diseased, so much so that the first may be reckoned a disposition of health;

therefore there is but one preternatural disposition to action which can be called diseased, namely, the disposition to destruction, and which is to be cured by substituting the first disposition.

Diseased dispositions may arise from fault in the animal powers themselves, or some extraneous matter in the constitution or circulation, as in the case of many poisons, or from many substances acting on the stomach called poisons, or from some substances being applied externally to the body which disagree with animal life in general, as too much cold, to much heat, &c.

Every diseased disposition most probably has its allotted time for action after the impression, or after the formation of the disposition. This is remarkably the case in specific diseases; but yet this will differ according to the susceptibility. The same with poisons: the small-pox is about six, seven, or eight days at a medium; the measles the same. The venereal disease has a medium, although it varies. But some specific diseases shall remain a considerable time before the action takes place; and this will be much longer in some than in others, according to the nature of the diseased disposition and parts. In cancer it is often very tedious. I have seen instances where it was years after all continuance of the cause was removed, before the glands in the armpit had taken on diseased action after contamination.

A girl at St. George's Hospital, fourteen years of age, born in the West Indies, left that part of the world when ten years of age. About a twelvemonth ago she had an eruption on the skin in several parts of the body, especially on the face, arms, and hands. The eruption arose like warts, or like large moles, about the size of half a crown piece, above the surface of the skin, irregular in their base, some standing single, others running into one another, of a browner colour than the common skin, which was clear and of a firmer texture.

Now this was a West Indian disease; therefore I say that the girl was contaminated in the West Indies. The impression was made there which was the first cause, and the disposition was formed; but the disposition did not come into action for three years after. The removal to a cold climate, though it could not remove the disposition or prevent its effects, yet protracted them.

It may be further remarked, in specific diseases and in poisons, that if the specific

disease or poison is such as is capable of contaminating different parts, whose powers or readiness to act is different, the same disease will show itself at different intervals in these places in the same person, though perhaps every part is contaminated at the same time. Thus we have the venereal disease appearing in different parts at different intervals in the same person, arising from the natural susceptibility for action in some parts being greater than in others. The skin and tonsils being most susceptible of contamination, as also of action, are therefore affected soonest; the bones and tendons less so, and are therefore later in taking on the action. The disposition simply does not seem to affect either the constitution or the part, for either shall go on well with all their natural functions, and powers of restoration when injured or affected with diseases of every other kind, although at the same time in the disposition of some other disease.

Dispositions of one kind may be restored after being destroyed for a time by a more powerful impression, or such as the constitution is more susceptible of, which shall supersede the first disposition, and go on with its actions; and when its action is completed, the first disposition shall again take place, as will be illustrated when we come to talk of actions simply.

Action.—I have explained that a disease is a disposition for a wrong action, and that the action is the immediate effect of the disposition, and that either the actions, or the effects of those actions, produce the symptoms which are generally called the disease, such as sensations, which are commonly pain of all kinds, sickness, alteration visible or invisible in the structure of the part or parts that act, and sympathy.

The animal, or part disposed to act, generally takes on action, which is of three kinds: natural, restorative when injured, and the diseased; each arising from the corresponding class of dispositions, and therefore divisible into the same.

The actions of health arise from a disposition to act properly, that is, according to the combined laws of the machine, which may be either universal or only partial; for a man may be wholly in health, or only so in part. The actions of restoration are for the falling back into the above natural actions, and which will be according to the nature of the injury done and the parts combined. The dis-

eased actions are many, but may be ranked under the following heads:

1st. Improper actions of natural parts, as spasms of muscles; irregularity in the times of action of a compound part. The nerves have the credit of being the remote cause of all these.

2nd. Unnatural or improper actions of the vessels; and these may be either attended with an increased or diminished action.

The ultimate and visible effect of disease is action; but this is not the disease, for the action is only an effect, a sign, or symptom of disease. But the disposition being only discovered by its effects, we are apt to go no further in our inquiry, the cause being to many only an object of curiosity. However the effect must be attended to, for it is this which leads us to the cause. These actions may arise from poisons, or substances improperly applied to the surface; from cold; from substances taken into the stomach: these usually give a sensation, to the animal, so that it can judge that the parts are diseased. But sometimes the action is too slow to give an alarm to the part; or the disease is felt through the irritation; or by a part remote from the diseased part sympathizing, as worms in the intestines, producing convulsions, an itching at the nose, &c. When the hip or loins are affected, the sympathising part, before the disease is felt in the original seat, is the knee. Passing a bougie has caused sickness before it was felt in the urethra, as has a clyster before the rectum was sensible of any inconvenience.

Often the internal feeling of health is the forerunner of disease. People just before a disease shall be in better spirits, and feel strong, so as to take notice of it themselves.

A gentleman had better health before a spitting of blood came on.

A boy had more spirits than usual the night before he was attacked with the cold fit of fever.

Perhaps the cause of disease gives the first feeling of health or vigour; the animal powers are called up on the first alarm of the disease; and when they sink, which is the second stage, they produce cold, or shivering, which is generally supposed to be the first symptom. In children I have often observed that the smell is affected before diseases. The first impression here is made on the olfactory nerves.

Some diseases come on extremely rapidly, producing at first very violent

symptoms, called acute; others come on slowly, and do not produce any sensible first symptom.

I have already observed, that all the actions in a healthy state are only produced by their proper stimulus; but sometimes we have actions without proper stimulus, which are diseased actions. In all organs I have observed there is a regular succession of action, as in the secretion of different substances, according to the wants of the parts which become the stimuli; but they may perform this office without the stimulus. The vessels are very active parts, and have often wrong actions, producing diseases in a great variety of parts, and are peculiarly active in the operations of disease.

Too great action will produce disease, according to circumstances. As the powers are equal, or greater, the action is universal or local: if universal, as in inflammatory fever, it will either produce resolution or death; if local, as in inflammation, either resolution or suppuration; or if the action is greater than the power, irritability; or it may keep up a constant inflammation; or if very violent, produce mortification. Too great action will often in the end, produce too little action; but not often *vice versa*. General action, or fever, may produce local, as inflammation; or local will produce general, as fever. They often attend one another from accident, and then they generally increase one another.

Too little action arises from a disposition to act within the necessary bounds of health, which produces real weakness and a bad state of health, with debility, without any visible state of disease, as we often see in fine ladies. If the part debilitated be not necessary to life, it only produces its effects on that organ. Too little action may subject the person to many more diseases than what the active are subject to. Even the habit of indolence in the mind, joined with inactivity of the voluntary actions, which is generally produced from an indolent state of the mind, produces the same effects, especially as we see in women. So that weakness is attendant on many diseases, and although somewhat necessary to many, yet it is not actually the disease itself. For instance, weakness attends the scurvy, and is necessary before the full effects of the specific disposition, namely, the action, can take place. The same in locked jaw, scrofula, &c. Weakness becomes one of the causes of irritability, as will be explained. Weakness, too, pro-

duces an increase of the disease. It may be local or universal, for many parts of an animal body may be weak, while others are strong; and if the weak parts are not essential to life, then the effect is only debility in performing the function, and the vital parts may not suffer. If the nerves are weak, the voluntary parts suffer; if the stomach, then the whole will suffer, or there may be a weakness which includes the whole without destroying it. It sometimes seems that the suspension of action for a time, increases the power afterwards; and lessening the power of action, increases the real strength at other times.

All diseased actions are simple.—A disposition of one kind may and shall exist in a part or whole, while an action of another kind is going on; and when the action ceases, the disposition, or dormant action, if we may be allowed to call it so, shall then come into action.

There are certain natural actions arising in an animal body in consequence of every irritation, whether appearing as a spontaneous injury or from accident. These common accidents I shall illustrate by inflammation.

Inflammation, then, is one of these simple actions; but we find inflammation may be joined by a specific quality which shall not alter its apparent mode of action, yet shall cause its ultimate effect to vary; thus, though the mode of action is altered the action itself is not altered.

It appears to me that every disposition must be simple, and therefore be only capable of producing a simple action. Parts so disposed may be irritated by something that alters the disposition. If the old disposition be destroyed, a new one must be produced; but if the disposition be only altered in part, there may be the two dispositions in the same part, the old in part and the new in part. But it is possible that a new disposition may be formed out of the two, different from either of the two which formed it; still it must be considered as a simple disposition.

This is plain in the cure of the venereal disease; a third disposition, namely, the healthy, arises out of the two, that of the disease, and that of the remedy. This is likewise shown in the action of Dover's powder, for neither vomiting nor sleep is produced, but a third action, namely, sweating.

But a constitution or part may have equally a susceptibility of a variety of diseases, as venereal, scrofula, &c.,

some of which may have a common cause, others a specific, as lues; yet the constitution can have, at the same time, only one specific action. As there are susceptibilities for dispositions, so there must be also dispositions for actions; yet two of these cannot exist at the same time in the same part or constitution.

Two children were inoculated for the small pox. Their arms were inflamed; but about the third or fourth day from the inoculation symptoms of fever arose, and the measles appeared, and went through their progress as usual. During this time the inflammation in the arm was arrested, but when the measles were completely gone, the smallpox took place, and went through its progress.

Here a disposition for the measles had taken hold of the body, but although it had done that previously to the smallpox, yet it was not in such a way as stopped the progress of the smallpox. The smallpox matter was capable of contaminating, and produced inflammation, which went to a certain length, but the moment the measles changed their disposition into action, as the two actions could not go on together, the action of the smallpox was suspended till the measles had gone through its action, and the moment the constitution got free of this, the smallpox began to act again.

A lady of rank was inoculated by Mr. Sutton. A few days after a fever came on, of the languid or putrid kind, but without any eruption, except a few petechiæ on the breast; she went through the process of a low fever, and afterwards the smallpox commenced; yet when the pustules matured they spread wide and were very large; also a different set of eruptions succeeded, so that thirty days passed before the skin was clear of the eruptions.

These cases show that but one mode of action can take place at the same time; yet I could conceive that two actions might produce a third one, which might have been a new poison, as the last case in some measure seems to show.

Of wrong actions.—I have already mentioned, under the animal œconomy, the two different kinds of action in an animal:—1st. The natural powers of growth, modelling, &c.; 2nd. The powers peculiar to each part, voluntary or involuntary. Now, the first may act improperly; it may push forth unnatural and unnecessary growth in some parts, and too little in other parts. They may also act in such a manner as to obstruct the neces-

sary actions of the machine, as by unnecessary masses called tumours, increase of the bones, &c. The second may also act wrong, that is, may act without the necessity for action, as in spasms, locked jaw, over secretions, palpitations of the heart, &c. This is in every respect similar to the former, only the improper action is on a different part. If, then, improper actions fall on a part of importance to the machine, they produce disease; or they may act too little, and thus produce diseases of a different kind.

Diseased actions, like the actions of health, become accustomed to impressions, and we see many of them subject to the same laws. This is of two kinds,—first, where the diseased part becomes less and less affected by stimulus, from a continuance of the application; second, where the whole body, or a part, becomes more easily affected by the stimulus, from a repetition of the application.

People constantly exposed to the cause of certain diseases become less affected, or less liable to be affected. Perhaps the best way to prevent being affected by some infectious diseases would be to live constantly where the infection was. People coming out of the country into the town are more liable to be infected by certain infections, as the smallpox, than those who live constantly in large towns. The constitution having once felt the stimulus of the smallpox, is not afterwards affected by it; yet I can readily conceive that if a man were to live two hundred years he might arrive at that period when he would again be susceptible of the impression.

THE ANATOMIST.

ARTERIES.

THE AORTA,

Is divided into three portions, viz., the arch of the aorta, the thoracic aorta, and the abdominal aorta.

THE ARCH OF THE AORTA,

Sends off five branches.

A. *Arteria coronaria dextra*, which sends a branch to the right auricle, a branch to the anterior part of the right ventricle, and a branch to the posterior part of the right ventricle.

B. *Arteria coronaria sinistra*, which sends a branch to the left auricle and a branch to the left ventricle.

C. *Arteria innominata*, which divides into the right carotid and right subclavian arteries.

D. *Left carotid artery*.

E. *Left subclavian artery*.

THE COMMON CAROTIDS

Divide into two branches.

A. *External carotid artery*.

B. *Internal carotid artery*.

THE EXTERNAL CAROTID

sends off ten branches, viz.—

A. *Superior thyroid*, which sends off 1st, a hyoidean branch; 2nd, a superficial branch; 3rd, a laryngeal branch; and 4th, a thyroidean branch.

B. *Lingual*, which sends off, 1st, a hyoidean branch; 2nd, the dorsalis linguae artery; 3rd, the sublingual artery; and 4th, the ranine artery.

C. *Facial*, which sends off, 1st, the inferior palatine; 2nd, the tonsillar; 3rd, the glandular; 4th, the submental; 5th, the inferior labial; 6th, the inferior coronary; 7th, masseteric; 8th, superior coronary; 9th, the lateral nasal; and 10th, the angular.

D. *Muscular*.

E. *Occipital*, which gives off the cervicalis descendens, the inferior meningeal, and the superficial.

F. *Posterior auris*, which gives off the muscular, the glandular, and the stylo-mastoid.

G. *Ascending pharyngeal*, which gives off the pharyngeal branches, and the meningeal branches.

H. *Transverse facial*.

I. *Superficial temporal*, which gives off, 1st, the anterior auris; 2nd, the capsular branches; 3rd, the middle temporal; 4th, the posterior temporal; and 5th, the anterior temporal.

K. *Internal maxillary*, which gives off 1st, the meningeal media; 2nd, the inferior maxillary; 3rd, the pterigoid; 4th, the deep temporal; 5th, the masseteric; 6th, the buccal; 7th, the dental; 8th, the infra-orbital; 9th, the descending palatine; and 10th, the nasal.

THE INTERNAL CAROTID

sends off five branches.

A. *Arteriæ tympani*.

B. *Arteriæ receptaculi*.

C. *Ophthalmic artery*, which sends off, 1st, the lachrymal; 2nd, the centralis retinæ; 3rd, the supra-orbital; 4th, the ciliary branches; 5th, the muscular; 6th, the posterior ethmoidal; 7th, the anterior

ethmoidal; 8th, the palpebral; 9th, the nasal; and 10th, the frontal.

D. *Posterior communicating artery*.

E. *Anterior cerebral*, which sends off, 1st, the anterior communicans; 2nd, the arteria corporis callosi; and 3rd, the middle cerebral, which furnishes the arteria choroidea.

THE SUBCLAVIAN ARTERY

sends off five branches.

A. *Vertebral*, which gives off, 1st, the arteria medullæ spinalis transversæ; 2nd, the meningeal; 3rd, the inferior cerebellar; 4th, the arteria medullæ spinalis; and 5th, the arteria basilaris; from this artery arises the superior cerebellar artery, and the posterior cerebral, two in number.

B. *Internal mammary* which gives off 1st, the anterior intercostal; 2nd, the mediastinal; 3rd, the comes nervi phrenici; 4th, the musculo-phrenic; and 5th, the superior epigastric.

C. *Thyroid axis*, which gives off, 1st, the inferior thyroid; 2nd, the cervicalis ascendens; 3rd, the supra-scapular; from which arises the superior acromial, the supra-spinal, and the infra-spinal; 4th, the posterior scapularis, which gives off the glandular, the superficial cervical, and the posterior scapular.

D. *Cervicalis profunda*.

E. *Superior intercostal*.

THE AXILLARY ARTERY

sends off seven branches.

A. *Acromial thoracic*.

B. *Thoracica suprema*.

C. *Thoracica alaris*.

D. *External mammary*.

E. *Subscapula*, which sends off an anterior and a posterior branch.

F. *Posterior circumflex*.

G. *Anterior circumflex*.

THE BRACHIAL ARTERY

sends off four branches.

A. *Profunda superior*, which sends off, 1st, an ascending branch; and 2nd, the musculo-spiral branch.

B. *Nutritia humeri*.

C. *Profunda inferior*.

D. *Anastomotica magna*.

THE RADIAL ARTERY

sends off ten branches.

A. *Recurrent radial*.

B. *Muscular*.

C. *Superficialis volæ*.

D. *Anterior carpi radialis*.

E. *Dorsalis carpi radialis*.

- F. *Dorsalis pollicis.*
- G. *Dorsalis indicis.*
- H. *Princeps pollicis.*
- I. *Radialis indicis.*
- K. *Palmaris profunda.*

THE ULNAR ARTERY

sends off eight branches.

- A. *Anterior recurrent.*
- B. *Posterior recurrent.*
- C. *Interosseous*, which sends off, 1st, the anterior recurrent; 2nd, the anterior interosseous; 3rd, the posterior interosseous; 4th, the posterior recurrent; and 5th, the posterior descending branch.
- D. *Muscular.*
- E. *Carpi ulnaris anterior.*
- F. *Ulnaris posterior.*
- G. *Arteria communicans.*
- H. *Palmaris superficialis.*

PALMAR ARCHES.

The deep palmar arch is formed by the palmaris profunda of the radial, uniting with the arteria communicans from the ulnar; it sends off five small branches to supply the interossei muscles.

THE SUPERFICIAL PALMAR ARCH

is formed by the arteria palmaris of the ulnar, uniting with the superficialis volæ from the radial. It sends off four branches.

- A. *Branches to ulnar edge of little finger.*
- B. *Branch to cleft between little and ring fingers.*
- C. *Branch to cleft between ring and middle fingers.*
- D. *Branch to cleft between middle and index fingers.*

THE THORACIC AORTA

sends off five sets of branches.

- A. *Pericardiac.*
- B. *Mediastinal.*
- C. *Bronchial.*
- D. *Œsophageal.*
- E. *Intercostals*, each divides into, 1st, the posterior branches; and 2nd, the anterior branches.

THE AORTA ABDOMINALIS

sends off the following branches:—

- A. *The two phrenic arteries.*
- B. *The celiac axis.* From this axis arise—1st, the superior gastric artery, which divides into a superior and an inferior branch; 2nd, the hepatic artery, which gives off the superior pyloric artery, the gastro-duodenal artery, which divides into the arteria pancreatica duodenalis,

and the arteria gastro-epiploica dextra. The hepatic artery then divides into the left hepatic and right hepatic arteries, from the last of which proceeds a small branch to the gall-bladder, called arteria cystica; 3rd, the splenic artery, which sends off the pancreatica parvæ, the pancreatica magna, the vasa brevia, splenic branches, and the gastro-epiploica sinistra.

C. *The superior mesenteric artery*, which gives off, 1st, the colica dextra, which divides into a superior and an inferior branch; 2nd, the colica media, which divides into a right and left branch; 3rd, the ileo-colica, which divides into a superior branch, a middle branch, and an inferior branch, and, lastly, the mesenteric branches, from fifteen to twenty in number.

D. *Two capsular.*

E. *Two renal.*

F. *Two spermatic.*

G. *Inferior mesenteric*, which send off, 1st, the colica sinistra, which divides into an ascending branch and a descending branch; 2nd, the sigmoid artery, and 3rd, the superior hæmorrhoidal artery.

H. *Ureteric arteries.*

G. *Lumbar arteries.*

K. *Sacra media.*

THE COMMON ILIAC ARTERIES

divide into two branches, viz.,
The internal and
External iliac arteries.

THE INTERNAL ILIAC ARTERY

sends off eleven branches in the female.

A. *Arteria ilio-lumbalis*, which sends off, 1st, ascending branches; 2nd, external branches; and 3rd, descending branches.

B. *Sacro-lateral sacral.*

C. *Middle hæmorrhoidal.*

D. *Vesical.*

E. *Umbilical.*

F. *Uterine.*

G. *Vaginal.*

H. *Obturator*, which sends off, 1st, the branches within the pelvis; and 2nd, branches without the pelvis.

I. *Gluteal*, which sends off, 1st, a superficial branch; and 2nd, a deep branch.

K. *Ischiatic*, which sends off, 1st, the coccygeal branch; 2nd, the arteria comes nervi ischiatici; and 3rd, the muscular branches.

L. *Pudic*, which sends off, 1st, the externa hæmorrhoidal arteries; 2nd, the perinæal; 3rd, the transversalis perinei; 4th, the arteria corporis bulbosi, which gives a branch to Cowper's gland, and a

branch to the corpus spongiosum; 5th, the arteria corporis cavernosi penis; and 6th, arteria dorsalis penis.

THE EXTERNAL ILIAC

sends off two branches.

A. *Epigastric*, which sends off, 1st, the spermatic artery; and 2nd, the muscular artery.

B. *Circumflexa ilii*.

THE FEMORAL ARTERY

sends off the following branches.

A. *Superficial epigastric*.

B. *Pudenda superficialis*.

C. *Circumflexa ilii superficialis*.

D. *Profunda femoris*, which sends off 1st, the circumflexa externa, from which arise the ascending branches, the circumflex branches, and descending branches; 2nd, the circumflexa interna, from which arise arterial branches to the muscles of the hip joint, and a branch to the interior of the hip joint; 3rd, the arteria perforans prima; 4th, the perforans secunda; 5th, the perforans tertia; and 6th, anastomotica magna.

THE POPLITEAL ARTERY

sends off seven branches.

A. *Superior muscular*.

B. *Articularis superior externa*, which sends off a superficial branch, and a deep branch.

C. *Articularis superior interna*, which sends off a superficial branch, and a deep branch.

D. *Azygos branch*.

E. *Articularis inferior externa*.

F. *Articularis inferior interna*.

G. *Inferior muscular*.

HISTORICAL ACCOUNT OF THE INTRODUCTION OF TOBACCO INTO ENGLAND.

By T. S. C. S. P.

In offering the following little compilation to public notice, the Editor presumes his labour will not be considered useless, when he avows his object to be a desire to communicate information and afford amusement to those who indulge in a habit of almost universal prevalence. It is a matter of surprise that the use of tobacco, in the short period of 300 years, should have become general over the entire habitable globe, comprehending all

classes of people, from the savage to the most refined. Being introduced into England in an age of great men, and rendered fashionable by one of the most accomplished of that or any other age, it was, for a long time, considered an elegance and a mark of good breeding; while the means taken to suppress its use had a contrary effect, and it became so generally diffused, that it is now equally the comfort of the labourer and the artisan, as the elegant luxury of the peer and the prince. In fact, while the cottage and the palace acknowledge its cheering influence, the revenues of the kingdom are considerably enhanced by the increased consumption of it as an important article of commerce.

There is perhaps no article on which so much diversity of opinion has been expressed as this, philosophers, poets, kings, and physicians have written upon its use and abuse, the Editor, therefore, without entering into any controversy upon its merit or demerit, is free to declare that some of his happiest hours have been passed while enjoying the social pipe with a respected friend, and in moments of doubt and difficulty, his scattered ideas have been concentrated, by the refreshing and invigorating pungency of a pinch of snuff: he purposes, therefore, only to lay before the reader a general history of tobacco (collected from various sources, as the amusement of his leisure hours), accompanied by a few anecdotes connected with it; and in order that the information may be within the reach of the humblest of its devotees, it is published at a price, which would justify its purchase, even if used in lighting the pipes of those who may have been interested or amused by the perusal.

According to the best authorities tobacco was not known in Europe until after the discovery of America by the Spaniards, at which time it was in general use among the natives, and was invariably used in their religious ceremonies, the priests having delivered pretended answers from the world of spirits, while under the influence of a peculiar intoxication produced by inhaling the smoke of tobacco, which thrown upon a fire lighted for that purpose. It is said by some writers, that the first time it was seen smoked as a luxury, was at a friendly interview between Grijalva, a Spaniard, and the cacique or chief of Tabasco, an island in the Gulf of Mexico, in 1518, from whence the herb took its name. While it is asserted by others, to have been derived from the is-

land of Tobago, discovered by Columbus in 1496, who thus named it after the pipe used by the islanders, in smoking the herb then termed *Kohiba*; the herb and pipe bore the same name at the other extremity of the Carib Archipelago, in St. Domingo. Be this as it may, it is certain that the Spaniards first introduced the use of tobacco into Europe.

The Chinese pretend to have been tobacco-smokers for many ages, but there is no reason to believe they were at all acquainted with the herb till procured by them from India, to which country the seeds of the plant were first taken by the Portuguese in the year 1599. But there is no doubt that the habit of smoking was known at a very early period, for in the *Anthologia Hibernica*, vol. i. p. 352, Dublin 1793, is a print of a *Dudeen*, viz. short stump of a pipe, which was found at Brannockstown, county Kildare, sticking between the teeth of a human skull. A memoir accompanies the print, in which we are told, on the authority of Herodotus, lib. i., sec. 36; Strabo, lib. vii. 296; Pomponius Mela, 2, and Solinus, c. 15, that the northern nations of Europe were acquainted with tobacco, or an herb of similar properties, and that they smoked it through small tubes—of course long before the existence of America was known.

It may therefore be fairly concluded that other substances were smoked by these nations, since all historians agree that America is the source from which this peculiar plant originally sprang.

In 1519, the Spanish General, Cortez, sent a present to his king, Charles, comprising a variety of commodities, as a specimen of the productions of the land he had conquered, among them was included a quantity of tobacco, which thus, for the first time, found its way into Europe, but it does not appear to have attracted much notice until several years after that period.

In 1561, Jean de Nicot, of Nismes, Lord of Villemain, then ambassador from Francis II. to the Court of Portugal, procured some seeds from a Dutchman, and sent them to his queen, Catherine de Medicis, who used it medicinally in the form of snuff. About the same time the Cardinal Santa Croce, the Pope's Nuncio, returning from his embassy at the Spanish and Portuguese courts, carried some of the plants with him to Rome. The use of it became rapidly diffused over both France and the Papal States in the shape of snuff. But the practice of smoking it did not commence until some

years afterwards. The French dignified it by a variety of names, as *Herbe de la Reine*, *Herbe de la Grande Priere*, &c. But the generic name assigned to it by the celebrated Swedish naturalist, Linnæus, is *Nicotiana*, from the French ambassador before mentioned.

The universal habit of smoking, prevailing in the east, has induced many persons to imagine that, the use of this herb was known in Turkey and Persia before it was imported from America into Europe; but upon reference to works of an earlier date, in which oriental customs are described with great minuteness, no mention of it is to be found, neither is it noticed by old travellers in those countries, which would undoubtedly have been the case, had it then existed.

The Persians appear to have obtained it from India, whence it was supplied by the Portuguese, who had settlements in the Persian Gulf for nearly thirty years after they had introduced it into India; and whence also they imported large supplies after the expulsion of the Portuguese from those settlements; as appears from the following relation of Sir Thomas Herbert, in 1628, who being that year in Persia, says, "It seems that forty camels, entering Cashin, laden with tobacco out of India, the drivers being ignorant of a late prohibition, the king sometimes commanding and restraining, as reasons of state invited, Mamet Ally-beg, the favourite, wanting his *Piscak*, i.e. present for his connivance, commanded the penalty to be executed, which was to crop their ears and snip their noses; offering withal to his angry justice, a dismal sacrifice of forty loads of tobacco, which were put into a deep hole which served as a pipe, and being inflamed, in a black vapour, gave the citizens *gratis*, for two whole days and nights, an unpleasing incense."

The Turks appear to have received it about the same time as the Persians, probably from the same source, or more immediately from Europe, by means of the Venetian and Genoese traders in the Levant, who began to find it a marketable commodity. Sandys, who was at Constantinople in 1610, speaking of it as a custom lately introduced, says:—"They also delight in tobacco. They take it through reeds that have joined unto them great heads of wood to contain it,—I doubt not but lately taught them, as brought them by the English; and were it not sometimes looked into (for Morat Bassa not long since commanded a pipe to be thrust through the nose of a Turk,

and so to be led in derision through the city), no question but it would prove a principal commodity. Nevertheless, they will take it into corners, and are so ignorant therein, that that which in England is not saleable doth pass here among them for most excellent." This later remark is exceedingly curious when we consider the refinement introduced into the art of smoking by the orientals, and that the idea of the personal appearance of a Turk or Persian is inseparable from the appendage of a long pipe, which has now become indispensable to him.

The use of tobacco has been introduced wherever Europeans have found their way. In the Sandwich Islands, says Kotzebue, "tobacco is now so generally used, that young children learn to smoke before they walk, and grown-up people carry the practice to such an extent, that they have fallen down senseless, and often die in consequence."

Tobacco was transported soon after its discovery to the West Indies, where it has been extensively cultivated particularly in the Island of Cuba.

Hume says, "that tobacco was introduced into England by Sir Francis Drake's fleet on their return from the attack on the Spanish provinces in the West Indies in 1585," so says Camden, adding "it immediately began to grow into very general use, and to bear a high price; a great many persons, some for luxury, and others for their health, being wont to draw in the strong-smelling smoke with insatiable greediness through an earthenware tube, and then to puff it forth again through their nostrils: so that tabacca-taverns (*tabernæ tabaccanæ*) are now as generally kept in all our towns, as wine-houses or beer-houses." This last extract appears to confute the vulgar error that it was introduced by Sir Walter Raleigh, although there can be no doubt that Sir Walter's example contributed much towards its more general use, and he probably introduced a greater variety of the herb; Malcolm has preserved a tradition which existed in the Parish of St. Matthew, Friday street, that Sir Walter Raleigh used to sit at his door smoking with Sir Hugh Middleton in the reign of Elizabeth, he adds, "The custom was probably promoted, through the public manner in which it was exhibited, and the aromatic flavour inhaled by the passengers, exclusive of the singularity of the circumstance and the eminence of the parties. Indeed, the two last motives are alone adequate to establish a custom ten

times more loathsome than King James describes tobacco-smoking to be."

It was known in England as a curiosity, before the time mentioned by Camden, but it is certain that Sir Walter Raleigh took great interest in the promotion of its cultivation and consumption in this country. He also introduced the culture of it in Ireland, on his estate at Youghal in the county of Cork; and it has since been cultivated to a large extent in various counties of that kingdom until it was restricted by certain legislative enactments for the protection of our colonial trade.

On the discovery of Virginia by Sir Walter Raleigh, Elizabeth consented to plant a colony thither, and tobacco began to be cultivated as the principal staple commodity; the following singular circumstance which occurred in the beginning of the 17th century, will give some idea of the value of the article. There being a scarcity of females in the colony, the Virginia company, which was established in 1606, sent out a number of respectable young women to supply the settlers with wives. These ladies were actually changed for 120 pounds of tobacco each, being the amount of the expenses of the voyage.

The cultivation of tobacco in Virginia, is thus described by Mr. Thomas Glover, in 1676,

"In the Twelve days after Christmas they begin to sow their seeds in the beds of fine mould, when the plants be grown to the breadth of a shilling, they are fit to replant into the hills, for in their plantations they make small hills about 4 feet distant from each other, somewhat after the manner of our hop-grounds; these hills being prepared against the plants be grown to the fore-mentioned bigness, (which is about the beginning of May) they then in moist weather draw the plants out of the beds, and replant them in the hills, which afterwards they keep with diligent weedings. When the plant hath put out as many leaves as the ground will nourish to a substance and largeness as will render them merchantable, then they break off the top of the plant. If the ground be very rich, they let a plant put out a dozen or sixteen leaves before they top it; if mean, then not above nine or ten, and so, according to the strength of their soil; the top being taken off, the plant grows no higher, but afterwards it will put out suckers between their leaves, which they pluck away once a week, till the plant comes to perfection, which it

doth in August. Then in dry weather, when there is a little breeze of wind, they cut down what is ripe, letting it lie about four hours on the ground, till such time as the leaves, that stood jutting out, fall down to the stalk, then they carry it on their shoulders into their tobacco-houses, where other servants taking of it, drive into the stalk of each plant a peg, and as fast as they are pegged, they hang them up by the pegs on tobacco-sticks; so nigh each other that they just touch, much after the manner they hang herrings in Yarmouth: thus they let them hang five or six weeks, till such time as the stem in the middle of the leaf will snap in the bending of it; then, when the air hath so moistened the leave as that it may be handled without breaking, they strike it down, strip it off the stalk, bind it up in bundles, and pack it into hogsheads for use."

Doubless the mode of culture varies according to the soil and climate of the various countries whence it is raised, and also must be greatly improved since Mr. Glover wrote.

Mr. Strahan, in a paper on the culture of tobacco in Yeylan, 1702, Phil. Trans. vol. xxiii. describes what he considers the origin of the cigar, as follows:—

"The natives of Zeylan cultivate two sorts of tobacco, both of which they call *Dunkol*. The signification is a smoking leaf, for *Dun* is smোক, *Kol* a leaf, the one they call Hingele *Dunkol*, or Singele *Dunkol*, for they make no distinction of H and S; the other is called *Dunkol Kapada*, which word *Kapada* signifies zelding, and is derived from the Portuguese; which tobacco is very intoxicating, and much stronger than the former: it is the same plant, the difference is only that the Singalee tobacco has little attendance, while a great deal of pains is taken with the other until it be fit for use."

"The souldiers, who delight to smoke a big pipe full, and that frequently in one day, do smোক the common sort, some of the *kapada* among it; the Singalee, who smoke not so much at once, neither so frequently, do take a piece of *kapada* and roll it together, then roll a piece of dry leaf of the wattukan trees about this, and kindle it at one end and suck at the other, until it be consumed."

However, there is reason to believe, that the Spaniards and Portuguese both, smoked the leaf rolled up as a cigar soon after the discovery of the herb, in the first place from its portable nature and manifest convenience, and secondly because

smoking it in that manner is the prevailing fashion in those countries at the present time.

The practice of smoking had become so universal in the year 1600, that in a note on the "Criminal Trials," vol. i. p. 361. it is stated that the French ambassador of that time in his dispatches, represented the peers, on the trials of the Earls of Essex and Southampton, as smoking tobacco copiously while they deliberated on their verdict.

M. Joverin, describing a tavern dinner at Worcester in 1659, says:—

"Moreover, the supper being finished, they set on the table half a dozen pipes and a packet of tobacco for smoking, which is a general custom, as well amongst women as men who think that without tobacco one cannot live in England, because, say they, it dissipates the evil humours of the brain."

Smoking appears to have been carried to an extraordinary excess by our ancestors, and indeed in every country into which it had found its way; and although it met with strenuous opposition by powerful authorities both abroad and at home, it seems to have gained ground with singular pertinacity, its votaries persisting to cherish the habit, in defiance of the severest penalties inflicted, amounting in some cases to mutilization and death, as will be seen by the following detail.

Its principal opponents were the priests, physicians, and Sovereign Princes, the former declaring it sinful. In 1590, Shah Abbas forbade the use of tobacco in Persia by a penal law; but the luxury had become so firmly rooted amongst the inhabitants, that many fled to the mountains where they concealed themselves rather than forego the pleasure of smoking. In 1625, the Grand Sultan, Amurath IV. prohibited smoking, as an unnatural and irreligious custom, under pain of death. In Russia, the Grand Duke of Moscow prohibited the entrance of tobacco into his dominions, under the penalty of personal chastisement for the first offence, and death for the second; and the Muscovite who was found snuffing was condemned to have his nostrils split, and his hostility against tobacco was so great, that a particular court of law was established in 1634, for the punishment of smokers, which court was not abolished until the middle of the eighteenth century. Pope Urban VIII. excommunicated by a bull of 1624, all persons who took snuff in churches, which bull was re-issued in 1690 by Pope Innocent. In Switzerland

also it was made a subject of public prosecution, and all smokers were cited before the Council at Appenzel, and severely punished, the police regulations of the canton of Berne, in 1661, placing the prohibition of smoking in the list of the Ten Commandments, immediately under that against adultery.

Louis XIV. also endeavoured ineffectually to discourage the use of snuff-taking. His grooms of the bed-chamber were obliged to relinquish it when they were appointed to that office; and the Duke of Harcourt was supposed to have died of apoplexy in consequence of having, to please his Majesty, left off at once a habit which he had carried to excess. An amusing anecdote in connection with the king's opposition, is related of Fagon, his physician; in the midst of a violent speech on the pernicious effects of tobacco, the orator made a pause; and taking his snuff-box from his pocket, refreshed himself with a pinch, in order to enable him to resume the argument.

In England, Queen Elizabeth published an edict against its use, giving as a reason, that her subjects, by indulging in the same luxuries as barbarians, were likely to degenerate into barbarism, however, no persecution in consequence of that edict appears to have occurred during her reign; but in that of James who succeeded, it seems to have become the fashion to decry it, the king himself setting the example, by writing the celebrated "Counterblaste to tobacco," and at the same time imposed a duty intended as a prohibition, of six shillings and eight pence per pound on the importation, and enacted that no planter in Virginia should raise more than 100 pounds of it in one year. There is a tradition in Scotland that he ejected the clergyman of Gullen a district of East Lothian, for the simple reason of his being an immoderate smoker. The following extracts from James's book which was published in 1603, are both curious and interesting:—

"It is a custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs, and, in the black stinking fume thereof, nearest resembling the horrible Stygian smoke of the bottomless pit." "Such," says he in a strain of amusing irony, "is the miraculous omnipotence of our strong-tasted tobacco, that it cures all contrarious sorts of diseases, in all persons and at all times. It cures the gout in the feet; (which is miraculous) in that very instant when the smoake thereof, as light, flies up into the head,

the virtue thereof, as heavy, runs down to the little toe. It helps all sorts of agues. It makes a man sober that was drunk. It refreshes a weary man and yet makes a man hungry. Being taken when they go to bed, it makes one sleep soundly, and yet, being taken when a man is sleepe and drowsie, it will, as they say, awake his brain, and quicken his understanding. * * * * O omnipotent power of tobacco! And if it could by the smoke thereof cast out devils, as the smoake of Tobias's fish did, which I am sure could smell no stronger it would serve for a precious relike, both for the superstitious priests and the insolent puritans to cast out devils withall."

The contrast between the manners of his day, and those of the present generation is thus shown:—

"And for the vanities committed in this filthy custom, is it not great vanity and uselessness that at the table, a place of respect, of cleanness and of modesty, men should not be ashamed to sit tossing of tobacco pipes, and puffing of the smoke one to another, making the filthy smoke and stink thereof to exhale across the dishes, and infect the air, when very often men that abhor it are at their repast. * * * But not only meal time, but no other time nor action, is exempted from the public use of this uncivil trick. And it is not a greater vanity that a man cannot welcome his friend now, but straight they must be in hand with tobacco. No, it is become, in place of a cure, a point of good fellowship, and he that will take a pipe with his fellows, though by his own election he would rather *feel* the savour of a stink is accounted peevish and no good company, even as they do with tippling in the old eastern countries. Yea, the mistress cannot in more mannerly kind entertain her servant than by giving him out of her fair hand a pipe of tobacco."

And again:—

"But herein is not only a great vanity, but a great contempt of God's good gifts, that the sweetness of man's breath, being the good gift of God, should be wilfully corrupted by this stinking smoke."

It is probable, however, that the disgust of the royal author, had no influence beyond those who were in immediate attendance upon the court.

Lilly mentions a clergyman of Bucks, who was so attached to smoking, that when he had no tobacco, he would cut the bell-ropes and smoke them.

The London Medical

AND

Surgical Journal.

Saturday, July 15th, 1837.

THE LATE KING'S ILLNESS.

THE BULLETINS.

It is with no small degree of satisfaction that the information which we from time to time presented to our readers, and the opinions which we ventured to publish on the nature of the illness of our late beloved Monarch, have proved to be correct; and it is no small source of gratification to a journalist, to look back and find that all the statements which he hazards, and which were so contradictory to those given by his contemporaries, have been proved, by the late melancholy result, to be worthy of credit. As far back as our number published on the third of June, we stated that his Majesty was attacked with ailments of a serious character, and that, besides a very profuse mucous expectoration, occasionally mixed with blood, there was great embarrassment in breathing, irregularity and diminished frequency of the pulse, anasarca swellings of the extremities, and though all these alarming symptoms were occasionally mitigated under the judicious treatment and practical sagacity of Sir Henry Hallford, no change took place in the general character of his Majesty's ailments which could have led that able physician to hesitate in pronouncing the fatal character of his Majesty's malady; and the post-mortem appearances afford the most satisfactory evidence of the opinion which was given by the renowned president of the College of Physicians, of the condition of the thoracic viscera. Much dissatisfaction has been expressed by the

public in general, on account of the information contained in the official bulletins which have been issued on the late melancholy occasion; but in justice to the medical attendants of his late Majesty, it is but proper to state the particular circumstances under which such documents are framed, and the purposes which they ought reasonably to be expected to fulfil. If the condition of the Royal sufferer be such that the bulletin must be framed to meet his eye, the bulletin signers have a just claim on the indulgence of the public for the imperfect, not to say false, document which they may consider themselves necessarily compelled to present to the public. And in the case of the late King, we can state positively, that on one occasion his Majesty had commanded that the manuscript of the bulletin should be shown to him before its publication, and that the words "continued to do the business of the country" were added to it by himself. But should the condition of a member of the royal family be such as to render it impossible that any public intimation of his malady could ever reach his eye, the nation would then have a just right to expect something like an intelligible, if not a strictly true, statement of his disease. And hence it may be observed that there is a tone of veracity in the bulletins which were published during the last eight days of his Majesty's illness, which could not be produced in those of his "distinguished" medical attendants. It is indeed an interesting circumstance, that during his Majesty's last illness, he not only attended to executing the high and important functions of the state, but transacted many minor duties; and though in itself trifling, it is a fact worth noticing in a Medical Journal, that the King, up to a few days of his death, was graciously pleased to condescend to *fee*

the medical attendants, giving a check upon the Privy Purse for £25 for each of their visits from London.

Though the reports which were published in the daily papers, of his late Majesty having conferred the honour of Knighthood on Drs. Chambers and Davies, have been fully contradicted, yet there is no doubt of Dr. Chambers at least (for we cannot answer for the order of the divine Dr.) having received the Guelphic *order*, as he wore it at the last dinner party at the College, where,—

“He bore his *blushing* honours thick upon him.”

DISTRIBUTION OF SUBJECTS FOR DISSECTION.

It is gratifying to be able to state, to those interested in the pursuit of Anatomical Science, that several new regulations are about to be carried into effect at the Home office, to secure the equal distribution of subjects to the various Anatomical Schools in the metropolis—regulations which have resulted from the anxiety of the Inspector of Anatomy, since his attention has been most particularly directed to the point. This will at once remove all the necessity for memorializing government, and must be a satisfactory reply to the complainants in Edinburgh, of the unjust mode by which the bodies were distributed to the different schools of the Scottish metropolis. The present measure will also relieve Messrs. Grainger, Quain, Partridge, and Tatum, the official representatives of the Anatomical Committee, from their heavy and responsible duties, which they so willingly took upon themselves *solely* for the public weal.

REDUCTION OF HOSPITAL FEES.

There is every reason to believe that the fees of the Middlesex, Westminster, and Charing Cross Hospitals will be reduced to the standard of the North London Hospital. This policy would be wise, and it is only surprising it has not been acted on long ago. The modern taste is in favour of cheap commodities, and the time is gone by when any other will suit the medical student. Certain are we that the fees would be doubled by the proposed plan, for fair competition is most beneficial to trade of every kind.

REPORT OF THE COMMITTEE OF THE WESTERN MEDICAL SOCIETY OF THE COUNTY OF CORK,

FOR THE YEAR 1837.

The committee of this society in coming forward at the commencement of the session for the year 1837, cannot refrain from congratulating the members, on the steady and permanent improvement of the association since its establishment in the year 1829.

The society had its origin under, it may be said very unfavourable auspices, and and many serious difficulties were thrown in its way; but though prejudices may have arisen, and many doubts of success may have been entertained, these have in a great measure been dissipated, and from the many highly respectable and influential names lately attached to our list of members, we have every reason to expect that its interests will still farther advance, and that the objects contemplated at its formation will be more fully and adequately attained. By some untoward circumstances and by the indulgence of selfish and unworthy feelings, the early development and advancement of this society has been checked; its nature and character have been misrepresented and misunderstood.

Prior to the formation of this society, there was no *nucleus* in the country, no starting point, no source from whence to

originate projects of vital and serious import to the medical profession. Its claims were unsupported, its interests neglected, and had not this society been established, a large and respectable body of our profession would have been materially injured, its interests compromised, and, eventually, the profession at large must have been subjected to the most baneful and injurious results.

The Western Medical Society originated in the very best motives, and its establishment has been attended with the very best consequences; and, the objects contemplated, by the original members, have never been lost sight of,

The society has tended to promote a "more general intimacy and acquaintance amongst the members of the profession" and has ever endeavoured to "diffuse a more kindly feeling." It has enabled the profession "more effectually" to come before the government of the country, and through the means of this association, application has been made to the legislature, for important and deeply interesting objects.

Our last session closed with a dark cloud impending, and to dispel this cloud was our first public effort made. It was not made for the purpose of personal aggrandizement, nor for the purpose of protecting the pockets of individuals. It was not made for the purpose of supporting abuses, or covering the delinquency of any who may have been wilfully neglectful of the important duties committed to their charge; but for the purpose of upholding the character and dignity of that profession to which we belong, and to prevent its interests from being trampled on and destroyed.

By the promptitude and decision of this society, and by its well directed operations, the 18th clause of the New Grand Jury Bill has been repealed, through the instrumentality of the Western Medical Society, two most important meetings of the profession in this county were convened in the city of Cork, and from these originated the most numerous and respectable provincial medical meeting ever assembled in the south of Ireland. At this meeting of the profession of the province of Munster, our talented and highly esteemed deputies (Doctor Nugent and Surgeon Phelan) were appointed. These gentlemen were authorized to proceed to London in order that they might watch the progress and ascertain the nature of any legislative measures to be brought before parliament, to protect the interests

of their brethren superintending the charitable institutions of this country, and also those of the profession at large. By the immediate and constant communication of the deputation with many members of the Government, and with most of the influential members of the House of Commons, the degradation about to be inflicted upon a large and respectable portion of the profession has been averted; and the establishment of a system of poor laws, in this country, which has been attended with so many evil consequences in England, and which has been so loudly complained of by our brethren there, has been prevented. And had not this deputation gone forward, the government of the country, in all probability, would never have contemplated a separate legislative enactment for the medical charities of Ireland. By the interviews of our deputies with the Chief Secretary and Mr. Nicolls, these objects have been attained, and by a letter lately received from one of the deputation, we have every just ground for expecting that such measures will be passed as will fully tend to the promotion of the interests and uphold the respectability and independence of our profession.

But although the 18th clause of the New Grand Jury Bill for Ireland may have been repealed, and although the government of the country may have given their assistance and rectified the evil in that instance, much still remains to be done. An extensive field for further exertion lies before us; and whilst the medical profession throughout the kingdom has felt the impetus of past efforts, we must not now relax. There never was a period so pregnant with interest to the medical body as the present, and it behoves every member of that body to rally round the standard of its independence. The medical profession has its enemies, those enemies are on the alert, and we regret to say, that they have found encouragement in the public press of the day. By some, it may be considered a degradation to notice the anonymous drivellings lately exhibited to the public through the medium of a certain English journal, and it might be deemed more prudent and wise to permit the imputations cast upon the whole body of the profession in the south of Ireland to pass unheeded and unthought of. This we would have done, but for the obstinate perseverance and vicious pertinacity with which those malicious charges have been so unreservedly preferred. Misrepresentations

tations have been advanced with the most unblushing hardihood, our motives have been impugned, and we have been stigmatized as acting under the basest and most unworthy feelings. The tongue of slander has been let loose, and the voice of calumny and vituperation has smothered itself in all the mire of anonymous and unaccountable malignity. The shaft, however has fallen stingless and unhurtful. The odium attempted to be fixed upon us, we hurl back upon our accuser, and we commit the secret assassin of the character and reputation of the medical profession in the south of Ireland to the gloomy and miserably degrading enjoyment of selfish malice; and to the gratification in the most contemptible obscurity, of those morbid and mischievous inclinations which must have given rise to a tissue of the most calumnious misrepresentations that were ever permitted to violate the pages of a British periodical.

This society came forward at the close of the last session, in order to remedy an evil universally complained of. To a generous, candid and discerning public, it freely and openly appealed, and that appeal was freely and satisfactorily responded to.

To the council of the British Medical Association for their best endeavours to promote the objects of the deputation, we return our warmest thanks. From it the deputies received every possible assistance, and by a resolution unanimously adopted on the 14th day of March last, pledged itself to use every effort to further the objects of their mission. These efforts have been crowned with success, and the 81st clause was repealed as early as was consistent with parliamentary regulations, and our remonstrance and petitions were thereby proved to be neither frivolous nor vexatious.

It is cause of the highest gratification to find that during the last session, societies of the same character and founded upon the same principles as ours, have been established in other counties throughout the Kingdom, and of their good will and co-operation we have been assured; and we look forward with the pleasing anticipation to the formation of provincial medical associations in Ireland.

In conclusion, to every member of this society, we appeal and earnestly solicit their assistance and exertions to further our common interests, to promote the advancement of science, and to maintain that position in society which must natu-

rally belong to the members of a liberal and enlightened profession.

Signed in behalf of the Meeting,
MATTHEW O'HEA, M.D., Chairman,
S. WOOD, A.M. M.B., Secretary.

Bandon,
June, 23rd, 1837.

TUNNELS.

REPORT ON THE PRIMROSE HILL TUNNEL
ON THE LONDON AND BIRMINGHAM
RAILWAY,

*By Dr. Paris, Dr. Watson, Mr. William
Lawrence, Mr. R. Phillips, and Mr.
Lucas,*

We the undersigned visited together, on the 90th February, 1837, the tunnel now in progress under Primrose Hill, with the view of ascertaining the probable effect of such tunnels upon the health and feelings of those who may traverse them.

The tunnel is carried through clay, and is lined with brickwork. Its dimensions, as described to us, are as follows: height 22 feet, width 22 feet, length 3,750 feet. It is ventilated by five shafts, from 6 to 8 feet in diameter, their depth being 35 to 55 feet.

The experiment was made under unfavourable circumstances. The western extremity of the tunnel being only partially open, the ventilation is less perfect than it will be when the work is completed. The steam of the locomotive engine also was suffered to escape for twenty minutes, while the carriages were stationary near the end of the tunnel; even during our stay near the unfinished end of the tunnel, where the engine remained stationary, although the cloud caused by the steam was visible near the roof; the air for many feet above our heads remained clear, and apparently unaffected by steam or effluvia of any kind; neither was there any damp or cold perceptible.

We found the atmosphere of the tunnel dry, and of an agreeable temperature, and free from smell; the lamps of the carriages were lighted; and, in our transit inwards and back again to the mouth of the tunnel, the sensation experienced was precisely that of travelling in a coach by night, between the walls of a narrow street. The noise did not prevent easy conversation, nor appear to be much greater in the tunnel than in the open air.

Judging from this experiment, and

knowing the ease and certainty with which thorough ventilation may be effected, we are decidedly of opinion that the dangers incurred in passing through well-constructed tunnels are no greater than those incurred in ordinary travelling upon an open railway or upon a turnpike-road; and that the apprehensions which have been expressed that such tunnels are likely to prove detrimental to the health, or inconvenient to the feelings of those who may go through them, are perfectly futile and groundless.

REPORTS ON THE TUNNEL ON THE LEEDS AND SELBY RAILWAY.

Report of Dr. Davy, and Dr. Rothman.

After careful inquiry, and an examination of this tunnel, we are of opinion that it has no injurious influence on the health of the passengers. We have come to this conclusion from finding:—1st. That the air in the tunnel at the time of passing is not appreciably vitiated. Chemically examined, its composition appears to be the same as that of the atmosphere, even after repeated transits of the locomotive engines.

2nd. That the temperature of the air in the tunnel, though more uniform than that of the external air, does not vary so much from it as might have been anticipated. In the warmest weather in which observations have been made, the air of the middle of the tunnel was only eight degrees lower than that of the atmosphere, the latter being seventy degrees. In February the greatest difference we found was also eight degrees, the atmosphere then being at 56 degrees. We were assured that, during the severest weather of last winter, the temperature of the tunnel never fell to the freezing point.

3rd. That the humidity of the air in the tunnel, judging from the few experiments which we have been able to make, will be more uniform than the temperature. That it will generally be somewhat greater than that of the external air, but never sufficiently so to cause the precipitation of aqueous vapour in the carriages, or on the persons of passengers.

4th. That we have not been able to detect, in any part of the tunnel, traces of acid, or other irritating or noxious effluvia. The tunnel, at present, is passed through in darkness, which, though not dangerous, is to many persons unpleasant. This seems to require correction, and it is understood

to be in contemplation to attach lamps to the carriages.

The noise made by the engine and train of carriages did not seem to us much greater in the tunnel than in the open air, nor to form any reasonable ground for complaint. Annexed to this report is a certificate by Dr. Williamson, a high medical authority in Leeds, generally in accordance with the opinions above expressed. He has even arrived at the conclusion, which we see no reason to doubt, that travelling on the railway is often beneficial to persons in delicate health, particularly in certain cases of slight pulmonary disease.

The tunnel in question is situated very near the terminus of the railway in the town of Leeds. It is 700 yards in length, 17 feet high, and 22 broad. Its direction is nearly east and west. The inclination of the floor is 1 in 300. It has three shafts at irregular distances, which now serve the purpose of ventilation. The westernmost is somewhat the deepest; the depth of this is 23 yards, measured to the floor of the tunnel. The tunnel is bricked throughout its whole extent. It is traversed by 20 engines daily, and on an average by 350 passengers. The average time of passing is about a minute and a quarter. The steam is generated by coke of the best quality, under a pressure of 56 lbs. With regard to our sensations in passing through the tunnel, with the windows of the carriage purposely left down, we experienced nothing unpleasant, either from smoke, vapour, or currents of air. The temperature in the carriage was agreeable, and everything felt dry.

We would conclude by observing, that the opinions we have expressed of this tunnel we hold to be applicable to all other tunnels, the circumstances of which are similar; and to tunnels of greater length, if they are higher and have a sufficient number of shafts to secure an adequate ventilation.

DR. WILLIAMSON'S REPORT.

In reference to the effects of the transit through the tunnel of the Leeds and Selby Railroad on the health of passengers, I have to state that, in the whole of my experience, both in private practice and in my official connexion with the Infirmary, and with the other medical institutions of this town, I have, indeed, frequently recommended delicate persons to make excursions on the railroad for the benefit of

their health, and have known very decided advantages to accrue from such excursions to persons even labouring under the slightest forms of pulmonary irritation.

I conceive that the vapour, smoke, and the gaseous results of combustion can never exist in such proportions as materially to deteriorate the air; and that there is no humidity or deleterious emanation, peculiar to the tunnel, which can be appreciably detrimental to animal life.

I believe that persons of irritable bronchial membrane may respire in the air of the tunnel for a considerable period without feeling the slightest inconvenience or sustaining any injury.

RESEARCHES ON NEPHRITIS, OR INFLAMMATION OF THE KIDNEYS.

By PROFESSOR CHOMEL.

The diagnostic of the inflammation of the kidneys sometimes offers great difficulties. In its acute form nephritis has a great resemblance with several other abdominal affections, such as partial peritonitis, inflammation of the stomach and intestines, nervous colics, acute rheumatism of the psoas and iliac muscles of the lumbar region. Sudden and acute pains, mostly near the kidneys, pelvis, and ureter, their progress or extension from the kidney to the bladder. The numbness of the opposite thigh, pain on pressure near the kidney exclusively, in men painful contraction of the testicle; the pains are so intense, that patients sometimes utter the most piercing shrieks, and make the strangest contortions; they retain the power of bending and raising the body without greatly increasing the pains; nausea, vomiting, accompany the exacerbation of the pains, which are irregular; they decrease or increase, entirely disappear, and then come on with almost unbearable intensity: there is marked alteration in the secretion of the urine, for instance, suppression, or mixture with blood or gravel; such are the signs best calculated to fix the judgment of the practitioner, and their union leaves no doubt as to the seat and nature of the disease.

If the accidents arise a second or third time; if without having had nephritis, the patient has already voided blood or gravel with urine, in all these antecedent facts, the practitioner has new signs, which may

enlighten him, and arrest his attention at the commencement of the disease. But in most cases the evil is not accompanied by all these symptoms, and the diagnostic offers difficulties which compel the physician to suspend his judgment, not only in the early stages, but even sometimes after the termination of the disease.

In cases, for instance, in which, after having observed the rational signs of nephritis, and particularly the speedy progression of acute pain from the kidneys to the bladder, in the direction of the ureter, these accidents completely disappear, without any foreign body being found in the urine, or without any show of blood, it is often very difficult to determine whether there has been inflammation of the kidneys, or rheumatism of the lumbar muscles and psoas. If we read attentively the history of Boerrhave's disease, as related by Van Swieten, we shall find in the sudden invasion of pain, in the nausea that accompanies it, in the vesical tenesmus, much reason to doubt that he was correct in supposing that he had only a lumbago.

As in nephritis, urine furnishes the best means for establishing a diagnostic, too much attention cannot be given to this fluid. It will not suffice to recommend that the urine be not thrown away for four and twenty hours, but it must be examined immediately, before it may be thickened by cold; if any sediment be found, it should be put into water, and kept till the arrival of the medical attendant, who, by the consistence and aspect, will judge of its importance.

By this continued and attentive observation, during the course of acute inflammation, a just opinion of the character of the disease may be formed; while by neglecting these means, doubts may exist.

It is also of the highest importance, in cases where circumstances may lead to the suspicion of nephritis, to pay particular attention to the produce of some other excretions; thus the urinary odour of cutaneous transpiration may become a sign of some importance, in case of complete occlusion of one of the ureters, or simultaneous inflammation of both kidneys; the urinary odour of the pus escaping by fistulous course accounts for the origin of this fluid: in cases similar to that of Fanton, where the pus ran into the colon, and was excreted by the anus; and that of Dehaen, where the left lung and the kidney formed a large sac, a more attentive examination of the pus, either by the smell, or by chemical reactives might

probably conduce to discover the origin of the fluid. I say probably, because the alteration of the kidney might be carried to so high a degree, that the secreted fluid would not contain any of the characteristics of urine.

The diagnostic of chronic nephritis is, in many instances, most difficult, especially in those in which the cause that has given rise to inflammation, has at the same time produced complete occlusion of the ureter. Nephritis may also be mistaken for a disease of the spleen, or of the pancreas, caries of the vertebrae, chronic rheumatism, enkysted tumour; and in females a disease of the ovaria.

The seat of the pain, a tumefaction, more or less apparent, and the sensation of weight in the region of the kidneys, which according to Galen, the patient would only feel while lying in the stomach, vomiting, engourdissement of the flank and the corresponding thigh; and in man, even the painful stricture; and later on, atrophy of the testicle, are not symptoms sufficiently certain to fix the diagnostic in cases, not confirmed by the examination of the urine.

If the presence of pus or blood in the urine leads to a suspicion of an affection of the kidney, it must be remembered that an ulceration or cancer of the bladder, or calculi in the viscera, an abscess opening in its cavity, an engorgement of the prostate, may also give rise to these symptoms; and before an opinion is given, it is therefore necessary to ascertain all past circumstances, to explore the urethra and bladder in both sexes.

Prognostic.—Whatever may be the form or degree of intensity of nephritis, it is always a serious disease.

It is of a far less alarming nature when the inflammation is caused by external violence, or when it is not very intense. But when it arises without any apparent cause, and is owing to the presence of calculus in the pelvis or ureter; the disease itself, when it does not threaten the existence of the patient, is of a nature to inspire a fear that the disease will appear in different forms, more or less often; that it will eventually cause suppuration of the kidney, and the death of the patient.

When the disease has become chronic, and the kidney suppurates, or there is hectic fever, death is generally the result of this malady. But there are examples of individuals who have survived this complication of alarming symptoms. Accompanied by our friends, MM. J. Cloquet and Louis, we saw a patient reduced to the last stage of marasm, by suppuration

of the kidney, combined with hectic fever, which lasted three months; yet he regained the appearance of almost perfect health.

Forestus relates the case of a priest, aged 45, who, during three months, voided urine mixed with pus, sometimes with blood, and who, owing to this affection, became very thin. Mild regimen, composed chiefly of milk, restored him to health. Forestus mentions two other cases, in which suppuration of the kidneys was treated with equal success.

But a much more remarkable fact, which leaves no doubt as to the possibility of the cure of nephritis, with suppuration and destruction of the tissues of the kidneys, occurred at the *Hotel Dieu*, in 1835.

Jean Latour, aged 71, a comb-maker, of robust constitution, and general good health, was brought to the *Hotel Dieu*, the 30th of July, 1835. Three days before, he had suddenly felt violent pain in the head; hemiplegy to the right, and fainting. There was total absence of motion and feeling on the whole of the right side of the body; the patient was bled in the arm, and cupped on the nucha, the inferior limbs were covered with revulsives, and aperient injections were administered.

The patient died on the 4th of August, without any indication of the pathological alteration of the right kidney, nor any account of the succession of symptoms to which this alteration certainly gave rise.

When the body was examined, there was white *ramolissement* of the brain outside rather above the left *corpus striatum*, being fifteen lines long, to eight in height and width, and without the least trace of sanguine effusion. There was also a considerable sub-arachnoidien œdema.

The heart was nearly double its usual size, and the left ventricle alone formed three parts of the mass. There was concentric hypertrophy, and the cavity was very small. There were also bony plates in the aorta. But the most important alteration in the present instance, was that of the kidneys.

The left kidney was twice its normal size; it was red, and perfectly healthy in every respect. Instead of the right kidney was found an irregular mass, which, carefully dissected, offered a sort of membranous sac, nearly the size of a pigeon's egg, formed by the calices, the pelvis, and ureter, and containing about half an ounce of clear fluid. Round these membranous sacs there were no traces of coriaceous and streaked substances. An abundant

cellular tissue, yellow, and mixed with greasy flakes, united these parts.

The *suprarenal* capsule is very distinct, and in its natural state. Two inches from the pelvis, the ureter, which is three times its usual size, is closed by an oval calculus, black, hard, and which entirely obliterates it. Above the obstacle the ureter is small, but still free, opening as usual into the bladder; this latter organ is perfectly healthy.

This fact, as we have already observed, leaves no doubt as to the cure of calculous nephritis, with suppuration and destruction of the renal tissue, and it will be easy to prove it. The presence of a calculus in the ureter, the dilatation of this tube above the calculus in the ureter, the dilatation of this tube above the calculus, and its narrowness below, do not permit us to say that the anatomical conditions of the kidney were congenital. If this patient had only the rudiments of a kidney, it would be quite impossible for a calculus to have been formed, or that a calculus caught in the urethra could give rise to alterations in the diameter of this tube.

The supposition of impeded development, or malformation being inadmissible, we are obliged to recognize a diseased kidney in the small membranous kyst, where the renal vessels meet, and from whence the pelvis issues. As a kidney cannot be reduced to the state of a membranous point until it has undergone a dilatation that has made its own tissue disappear, and that this dilatation, and destruction never exist without occlusion of the ureter, and suppuration of the kidney, it results, in the first instance, that the kidney to which we allude, had undergone this alteration, and secondly, that this alteration is not necessarily dangerous.

Treatment.—The treatment of acute nephritis is in general founded on the same principles as that of other inflammations: general bleeding and cupping on the renal region, repeated according to the intensity of the affection, and strength and age of the patient; baths, hip baths, soothing poultices, or fermentations; mucilaginous injections; cooling beverage, such as whey, emulsions, decoctions of barley, marshmallow, linseed, are the means generally employed.

Independently of indications common to nephritis, and other phlegmasiæ, there are some which peculiarly appertain to nephritis. The degree of heat in the whole body, and most particularly the lumbar

region, caused by lying on a soft bed would be very injurious.

The well known utility of placing the inflamed organ in a state of repose, furnishes another and special indication. The abundant beverage recommended in other phlegmasiæ, would in nephritis increase the action of the kidneys, the patients should therefore only drink sufficient to allay their thirst, and in very small quantities at a time, particularly when the suppression of urine gives reason to fear the complete occlusion of the ureters. The beverage should be tepid, if cold, the secretion of urine would be increased.

Another important point in the treatment of acute nephritis is, to insist on the patient remaining as quiet as possible. As the presence of a calculus is almost always the cause of the disease, the least change of position in the patient might suffice to bring on sudden and intense pain. There are, however, exceptions to this precept of complete immobility; it is not applicable in cases where the intensity of the pain naturally leads the patient to roll in bed, or on the floor. In these exacerbations, immobility is not only impracticable, but might be prejudicial. Indeed, while it is most important not to move during the cessation of pain, there is no reason for remaining still when the pain is so intense as scarcely to admit of increase.

Narcotics, sometimes employed with advantage in several other phlegmasiæ, particularly in dysentery, are mostly indicated in acute inflammation of the kidneys, on account of the pain, which generally surpasses that which takes place in other inflammations; consequently while we have recourse to antiphlogistics, we must not hesitate, when the pains are very great, to make the patient take every hour, or every half hour, half a grain, or even a grain of opium, either in pills, or in draught; it is generally preferable in a draught, because it acts more speedily; but if the nauseous flavour of this remedy increases the coming, pills are more desirable, and injections are still better. The decrease of pain, or a commencement of narcotism, show when the use of opium should be continued or suspended.

If an active revulsion towards the skin appears requisite, the special seat of the inflammation necessitates some precautions in the choice of the means employed to produce it. The use of cantharides must be avoided, which even externally in some persons produce, in the urinary

passages, accidents analogous to those we purpose to combat. Consequently when it is necessary to produce rubefaction, or vesication, we must scrupulously abstain from topical cantharides, and employ some other, such as flour of mustard, or ammoniacal pomatum.

When nephritis has given way to these remedies the patient must not remain in ignorance as to the possibility of a recurrence of the disease, if he be again placed in the same conditions as when the disease was first developed. When the accidents have completely ceased, without gravel having been found in the urine, or without a calculus falling in the bladder, the patient should be recommended, if he has felt symptoms of acute nephritis, to follow the regimen prescribed to individuals who have actually had calculi in the kidneys.

The regimen consists principally in the use of vegetables, cooling and diuretic beverage, especially alkaline waters, taken in large quantities; abstaining from heating liquors and food, and violent and prolonged exercise, and remaining night and day in a cool temperature.

If after one or two attacks of acute nephritis, suppuration be formed in the kidneys, the case must be considered very serious, and the assistance of art merely tend to alleviate the pain, and prolong existence.

At all events, in some instances, there has been cure when suppuration of the kidneys existed. In these cases milky or vegetable diet; the establishment of one or more setons in the lumbar region; change of scene, climate, country air; alkaline mineral water, are means generally employed with the greatest chances of success, according to the state of the cases.

When the pus formed in the kidney tends to break out, it is advisable to open the abscess, whether deep or superficial, and seek for the calculus, and extract it, however deep it may be situated.

In a case of this sort J. L. Petit was so fortunate as to cure an individual in whom he had taken a three-branched calculus from the lumbar region, and who, after the operation, had a urinary fistula. If the calculus be strongly adherent, the fistulous passage should be kept open by proper dressings, until the calculus could be withdrawn.

With regard to suppuration of the kidney, this disease is always of long duration; whatever may be its issue, it is necessary to keep up the strength of the pa-

tient, notwithstanding the state of the fever; but the nourishment must be mild and of easy digestion.

I must again repeat, that at all periods of calculous nephritis, the disease is calculous; inflammation is but a secondary phenomenon. We must, therefore, always insist on alkaline waters, in as high a dose as the digestive organs will permit, with the double view of dissolving the calculi that may exist in the urinary passages, and to prevent the formation of new calculi.

Waters taken from their source are always preferable, because the patient can not only drink them, but can also have the advantage of baths. It is true there are some calculi which resist the dissolvent action of the alkali, but this calculi is very scarce, if compared to those dissolved, softened, or separated by reactives.

Some persons have given the name of albuminous nephritis to a disease described by Dr. Bright, under the name of granulous disease of the kidney. We have not mentioned this disease in the memoir, because we did not wish to mingle in common considerations two distinct pathological alterations.—*Continental and British Med. Rev.*

LUPUS TREATED BY CAUTERIZATION AND ARSENIATE OF SODA.

By M. BAUDELLOCQUE.

Hospital for Sick Children.

Since last October there are two children in the hospital with lupus on the nose. Though the treatment has been varied and active, yet these affections are not yet cured; however there is every reason to believe that the continuation of the same means may suffice to remove them entirely, as the improvement is great.

The two little girls have been subjected to nearly similar treatment. Both had a large scab on the extremity of the nose; the suppuration, caused by the ulcers under the scabs, escaped in several places. The scabs came off; it was found that the lobule of the nose was nearly destroyed by several ulcers with uneven edges, extending along the nose. These ulcers were touched in several parts with nitrate acid of mercury, and hydrochloride acid;

but the new scabs came off, and it was evident there was no improvement.

M. Baudelocque prescribed arseniate of soda, the sixth part of a grain. This dose was gradually increased to a quarter, then a third, then half. One of these little girls had violent colics, and the medicine was suspended; the other child did not suffer in the same way. Caustic iodine was substituted for the above mentioned caustics; but the scabs were speedily formed again, and ulcers were found in the same state when the scabs came away. Mr. B. then tried the effects of a caustic, of which arsenic was the basis: the following is the recipe of this composition.

Quick lime four ounces, sulphuret of arsenic an ounce, to be pounded; second lixivium magistrale, two tumblers; boiled till it thickens; to be kept well covered.

Mr. B. found this paste a valuable caustic in bad ulcers. It has been frequently employed in the hospital for children, and never gave rise to symptoms of absorption of arsenic; it was applied three times to the two young patients we have named.

When the scabs came away, the ulcers were covered with this paste, taken up with a spatula. The caustic soon acted, and caused great pain. The children complained sadly all day, and a large dark scab was formed by the following morning, which was three weeks coming off. But shortly after the cauterization, a few drops of sanies escaped, which showed that the ulcers were not cicatrized. A third application of caustic was made, and as the scabs seem quite dry, and there has been no further discharge, it is to be hoped cicatrization has taken place.

During this treatment, arseniate of soda has been administered, though suspended several times, either for the colics, as we have already stated, or for acute ophthalmia, with which one of the children was affected. No change has been made in the regimen, and every week an aperient draught was given.—*Id.*

ON THE ORIGIN OF CANCEROUS TUMOURS IN THE BREAST,

And the means of preventing this fatal termination.

By M. LISFRANC.

The 7th of November, 1836, a woman left the hospital de la Pitié, where she had been for several weeks, with an in-

flammation of the breast. Several abscesses were opened by M. Lisfranc. The wounds were gradually healed, yet there remained various small engorgements; when the woman insisted on leaving the hospital.

M. Lisfranc observed, that engorgements of this description were very common after parturition; but, unfortunately, females gave very little attention to them; sometimes they were removed by the assistance of nature alone; but they were also known to remain indolent for many years; give no pain, cause no uneasiness; but when menstruation ceased, these indurations, hitherto so indolent, became very painful, and were transformed into as many scirrhus tumours.

Most of the females, who have their breasts amputated, admit that neglected engorgements have been the origin of scirrhus.

When the surgeons are called to remove engorgements, after they have existed two or three years, they find the greatest difficulty in bringing on a resolution; whereas, if they be recent, a few sanguine evacuation, poultices, and baths, remove them in a few days. The greatest attention should therefore be given to these engorgements, as by a simple medication, a cruel and fatal disease, which baffles the powers of art, may be prevented.

These considerations on the cause of most of the scirrhus indurations of the breast, lead us to examine this important question:—

Which are the engorgements of the breast we should endeavour to resolve?

Many practitioners have unhesitatingly declared, that these indurations should be extirpated with the bistoury, and others recommend attempting resolution. M. Lisfranc thinks that between these two extremes there is a more rational method, and that distinctions must be established before any step is taken.

Many patients, of lymphatic constitutions, admit they have had swelled glands of the neck, under the arm, and in the groin; some have glands of this description in the breast, which have gone off unaided.

These circumstances may lead to the presumption that the engorgement of the breast, at present existing, may be a lymphatic engorgement. Cold abscesses are as liable to be developed in the breasts, under the arm, and in the groin, as elsewhere. The engorgement of the lym-

phatic ganglia developed under the influence of this cause, may, in the first instance, be overcome by milder means than extirpation; and even admitting that this induration may one day degenerate, and be transformed into a cancer, is it not rational to attack it by all the dissolvents known in medicine, before we have recourse to an operation, which, however slight it may be, is always attended with danger, and what objection can be raised against this proceeding?

An engorgement of the mammary gland does not suddenly increase; the constitution is not from one day to another invaded by diathesis; and if the dissolvents are judiciously employed; if the stages of the disease be carefully followed, is it not full time to have recourse to an operation, when medicinal means are found to be important. At all events, the utmost that will have been lost, is a little time, and surely this is nothing, when the object is to avoid a cruel operation.

It must not be forgotten, that there are cases in which it would be rash to attempt to use dissolvents; if the tumour be recent, not very large, no inequality on the surface, not hard, resolutives should be employed. If, on the contrary, the tumours are as numerous as four or five, hard, voluminous, adherent; if there be engorgement in the armpit; if on certain parts of these tumours, there be ramollissement, dissolvents instead of arresting the course of the disease, would hasten the carcinomatous degenerescence, and the operation must be performed without delay, if it be not too late.

M. Lisfranc does not attempt to obtain the resolution of scirrhus tumours; he is not aware whether the engorgement of the breast is complicated with inflammation, or whether they are produced by inflammation; but it is certain that in many cases resolution has been obtained when there was sufficient cause to show the necessity of extirpation.

In following the rules prescribed, in seizing the characters indicated, dissolvents and antiphlogistics may be employed, but if there be reason to suppose that success will not attend these measures, they must on no account be resorted to, however desirous the patient may be to make the trial, in order to avoid an operation.—*Id.*

OBSERVATIONS

ON

FURUNCULUS PANULATUS.

By M. ALIBERT.

These boils were very long since designated by the name of *furunculi panulati*, because when the tumour broke there was an oval perforation. M. Alibert did not think it right to change this denomination.

These furunculi are very long coming out; they sometimes remain for years in a state of *crudity*; they dry up in their s, here of irritation, and when scratched are gradually reduced to dust; they may grow on all parts of the body, and after they disappear, there remains for a long time an ecchymosis similar to that which preceded their apparition. The furunculi panulati ought not to be confounded with various eruptions met with in the facial tegument.

The following case is a striking example of the furunculus panulatus:—

A man of a sanguine constitution, fat and strong, is accustomed to hard labour; he has never had any syphilitic disease, nor any other disease of the skin than the present one. Eighteen months ago, a red spot appeared on the lateral side of the nose, on the right: this point was like an ecchymosis, but, after many weeks, a small hard tuberculus appeared; it gave no pain, it could be pressed under the finger. This tubercle remained *eighteen months* stationary, gave little suppuration, and disappeared. Some other tubercles occurred, and remained a very long while. Some are still existing; pressed by the finger they give no pain, but what is constant is the red spot, sometimes bluish, which lasts long before and after the tubercles.

M. Alibert employed, with some advantage, nitratis argenti, for the cauterization of the furunculi panulati.—*Id.*

A LETTER

ON THE

BETTER REGULATION OF MEDICAL CHARITIES;

IN REPLY TO A CIRCULAR ISSUED BY THE ROYAL COLLEGE OF SURGEONS.

By EDWARD BEWLEY, Surgeon.

“As to the medical attendants on most of the public charities, they cannot, by any alteration in the existing laws, be

much worse circumstanced than they are at present. They are, notoriously, most inadequately remunerated. Take a country dispensary for example. In the greater number of these, a gentleman of talents and education is expected to devote four hours of every alternate day to attendance on the poor; to visit (often at night) such as are unable to attend the dispensary, at a distance of five miles from his own residence; and to endure all the hardships of protracted midwifery cases, during which he is frequently obliged to remain the whole night in filthy hovels—all for sixty pounds a-year! This is actually the average salary of a qualified surgeon in such institutions; in a few instances it may be somewhat more, but in others it is considerably less. And for this paltry sum he must keep at least one horse, and maintain a respectable appearance in society. In fact, no one would accept of such a situation, were it not with the hope that it may prove a stepping-stone to practice; but in this expectation they are frequently, I might even say, generally, disappointed. The public, in its wisdom, prefers the man who seems independent, though he may, in reality, be a person of inferior acquirements.

“The surgeon of the county infirmary is situated under far more favourable circumstances. His very position places him at the head of the practice in the county; his duties are but trifling when compared with those of the dispensary surgeon; and he is much better paid. I have no doubt that there are many highly respectable members of our profession, in every respect fully qualified for the office, who would gladly undertake the charge of a county infirmary for half the present salary; and I am confirmed in this opinion by the well-known fact, that the situation has been frequently purchased for a large sum of money. Taking all these matters into consideration, I am therefore not at all disposed to look with a jealous eye on the proposed reduction of the salary—provided due regard be had to existing interests.

“It appears that the sum of £100 a-year, which is to be withdrawn from each infirmary, is to be appropriated to the payment of medical inspectors. The duties of these officers, as mentioned in your circular, are so vague and undefined, that I am hardly prepared to give an opinion as to whether their appointment may be objectionable or not. I can very well conceive that such an office, entrusted to intelligent and well-educated

men, might be productive of the most beneficial results, both to the public and to the profession. If they were disposed to act in harmony with their brethren, they might be the means of promoting union among the whole body of medical men, a ‘consummation devoutly to be wished.’ In a statistical point of view, also, their services might be made invaluable. But I am sure I only echo the sentiments of the entire profession, in strongly protesting against the interference of the inspectors in the treatment of the patients entrusted to the care of the medical attendants of hospitals and dispensaries. So monstrous a power would nullify itself—it could never be enforced—it would never be submitted to.

“The next clause of the act to which you refer, is that requiring all surgeons of hospitals, &c., to be members or licentiates of some college of surgeons. From this I infer that it is proposed to throw open our county infirmaries to qualified surgeons, without any regard to the college from which they have obtained their diploma. This, rightly considered, is perfectly fair and equitable, and strictly in accordance with the principles which should actuate a legislature, in the framing of laws for the government of scientific institutions in a free country. But I must acknowledge, that I do not consider the mere possession of a diploma from any college, except that to which I have the honour to belong, as a real qualification. I do not say this invidiously, or from *esprit du corps*; but because the examination of candidates for the diploma of the College of Surgeons in Ireland is held publicly, and is much more severely and searching than that of any other similar body. I should therefore deem it highly advisable, if our college is to be deprived of its privilege of providing surgeons for the county infirmaries, that a board for the public examination of candidates should be established in lieu of it. Of course, I mean that this board should examine candidates for all medical appointments under the controul of government.

“I now come to the consideration of that paragraph of your circular, in which you detail the instructions which your deputation in London has received; and here you must pardon me if I enter somewhat more fully into the subject than at first sight may appear necessary. Passing by, for the present, the first sentence in the paragraph, or that which refers to your praiseworthy exertions for securing to the

medical officers of charitable institutions "a permanent, defined, and adequate salary," I shall proceed at once to offer a few remarks on the concluding sentence. In this it is stated that "they (the deputation) have been instructed to exert themselves to have some standard of education established by law, to constitute the qualification to fill the situation of hospital or dispensary surgeon or physician." I take it for granted that the above quotation means, that you conceive it necessary that candidates for those situations ought to be obliged to produce a certain number of certificates of their having heard certain lectures, delivered by certain professors; of attendance at certain hospitals for a certain length of time; and of their having practised dissections at certain medical schools for a certain number of seasons. If this be a correct interpretation of your meaning, I must beg leave most respectfully to express my dissent from the doctrine, that any specific number of such certificates can constitute a legitimate or genuine qualification. It is well known to every teacher, that one person, either from industry or his natural talents, will be able to acquire a considerable portion of knowledge in a short period of time, say a year; while in another, through idleness, inattention, or inherent stupidity, the same degree of knowledge will require ten years for its acquisition. Where, then, is the utility in establishing a "standard of education?" Is it just that he who really possesses the requisite information, should be debarred the attainment of his legitimate reward, merely because he cannot produce the full number of certificates required by law? Or, on the other hand, should the idler or the booby, who has dozed away his time in the lecture-room, or heedlessly lounged through the wards of an hospital for a certain number of years, bear away in triumph the honours and emoluments to which he is not fairly entitled, because he is possessed of the required certificates? Assuredly not.

REVIEW.

The Philosophy of Human Nature in its Physical, Intellectual, and Moral Relations: with an attempt to demonstrate the order of Providence, in the three-fold constitution of our being. By Henry M'Cormac, M.D. London: Longman, Rees, Orme, Brown, Green, and Longman. pp. 564. 1837.

Doctor M'Cormac is already well known to our readers as an author of considerable observation, much research, and persevering industry, from his able work on continued fever (a review of which appeared in this Journal about two years since).

We are again happy of having it in our power to speak favourably of Dr. M'Cormac's abilities; his present volume, although it does not possess much originality, or great demonstrative depth, possesses sufficient to amply compensate the reader for its careful perusal. The simplicity of the style, the order and arrangement observed throughout, the numerous familiar illustrations brought forward, and the importance of the work in a moral and religious view to the legislator and the philanthropist, must render it acceptable, not only to the profession which has the good fortune to have the author enrolled amongst its members, but also to the general reader.

After enforcing the necessity of studying our nature in its three-fold division in regard to the body, the intellect, and the feelings and affections, and consigning to the "night of time," the doctrine of "innate ideas," our author proceeds to show that "all the ideas which we are capable of experiencing, flow in the first instance from sensation; a truth of great importance in education, as well as in laying a foundation for the argument from analogy, in favour of the similar origin of the affections, feelings, and moral judgments," our demand upon the legislator and philanthropist, for a wise and universal education, is thus demonstrated:—

"If our knowledge—if our qualities whether for good or for ill, are in no case inborn, it necessarily follows, not only that all are capable of superior intellectual and moral culture, but that all have an unequivocal right to receive it."

We cannot better express the views and philanthropic desires of Dr. M'Cormac, than by permitting him to speak for himself:—

"I experience an unflinching confidence in the fulfilment of the superior destinies of our race. It is a long-cherished conviction, and one which I shall carry to the grave. God is just and merciful: he has implanted capabilities that can never be exhausted. The grievous errors which mark our career, must be ascribed to defective training, deteriorating circumstances, and insufficient personal exertion. Even the wisest and best probably, afford but an imperfect criterion of

what, under happier auspices, all might become. At birth, we are innocent, and, with proper management, might remain so through life. What a glorious prospect does it not unfold to mankind, when they shall acquire wisdom enough to apply the principle to the full extent. There need then be no ignorance, no want of feeling, and no crime; and why, but because all shall be cultivated, and because it is impossible for such unhappy results to accrue, when the causes which lead to them are lopped away for ever. All other public measures dwindle into insignificance, when contrasted with the efficacy of universal training. In ten short years, the machinery of instruction might be brought into operation, and a moral revolution gradually accomplished."

The difficulties which present themselves to the accomplishment of this desirable end, our author thus boldly puts forward:—

"There are too many jarring interests and conflicting opinions, however, as well as too low an estimate of the dignity of human nature, to permit a provision of such boundless utility to be carried into effect. Even so, then, until the world consent to work this great good, so long shall desolation, and sin, and misery prevail. It is not intellectual cultivation alone, that will do the work; the feelings, affections, and moral principles must be developed, while the physical condition of the community at large must be elevated."

Yet great and many as jarring interests and conflicting opinions may at present be, a golden era is expected by Dr. M'Cormac:—

"Let existing obstacles, however, be what they may, the time must work round when they will fade into nothing, and when the human race shall assert with one voice, their indefeasible rights never to be deprived of them again. Step by step mankind approach a consummation of virtue, knowledge, and happiness, which the world has not yet seen. We might be faint hearted indeed, were this mighty change to devolve on human agency alone; but the path has been marked out by superior skill, and the operation of circumstances, under the control of an all-directing Providence, must finally lead us to the happy goal."

"A consummation devoutly to be wished."

We have not space to enter more fully into our author's opinions; the general style of the work may be gathered from the following:—

"How well adapted is the organ of vision to convey expression? How speaking is the eye of intellect; or powerfully does it reflect the impulse of every passion—of love, of hatred, and of scorn! Yet how vacant is the eye of apathy and ignorance; but, above all, how dull and unmeaning is the eye of the dead! There is no limit to the impulses which this organ conveys from the soul, and none to those which it can bring back. The language of the eye includes a host of ideas and feelings innumerable: how poor would speech become without its aid; how vast its addition to human intercourse. Does it not yield an expression of friendship, love, parental affection, filial reverence, mute obedience, exultation, curiosity, heroic daring, ardent hope, and devout submission, to which no tongue could give utterance? Such copious access to God's creation and the face of human kind, yields scope for boundless gratitude. For how desolate is the darkness of the poor blind, who can never hope to look abroad, till the great veil is lifted up that sends life from immortality?"

"The mind itself, is the ultimate vehicle of every kind of emotion, whether pleasurable or painful; the satisfaction produced by music however, is owing partly to association, and partly to the structure of the ear. How could the gratification which is yielded by delightful melody, or full rich harmony, be ascribable to the former alone? Nothing can render the discord in itself pleasing; the distinction is marked out by nature, and cannot be invaded. Whatever instrument be selected, the great requisites are execution, expression, and lastly, scientific knowledge. Method may direct, but cannot create feeling; yet, without this, no one can be a musician. There may be execution, but the soul of music—the quality, without which, the art is but the husk or shell, is wanting. Faultless execution is necessary to do justice to feeling, imagination and judgment: for of what avail is it to feel, if we cannot reproduce our emotions? Without the foregoing requisites, the most admirable compositions fall dead upon the ear; with them, indifferent, and even imperfect productions, tell."

"Governments are abstractions of popular power; owing their existence to it, but acting independently. Their influence on morality, though of a mixed and inferior nature, is very great. It is enough to excite mournful reflections,

when we consider what governments might do, and what they omit doing; how education is limited and perverted, and how the diffusion of knowledge is shackled and restricted. If they represented the enlightenment of community, these things could not be. It is a problem worthy of solution, how it happens that the governments of Europe and of the world, exert an almost irresponsible power; or how it is, that everywhere the best interests of the many, are more or less misunderstood and opposed? How long is this state of things to last, or when shall governments concentrate their energies for the common enlightenment and happiness of mankind? It is difficult to propagate truth without enlisting under the banners of a party; but there can not be the party of humanity—a party advocating without restraint, the principles which concern the well-being of our race? Among the inferior passions, truth and excellence have a fierce and implacable opponent in party-feeling. Even the powerful enginery of governments is controlled by its agency. In mischief-working, however, it must yield to fanaticism, which at times, is an epitome of everything that is base. When the two are combined, iniquities the most demoralizing, result. It is not that these vices are so destructive in themselves, as that they become the vehicle and the pretext for personal enmity, and every form of human malignity. Truly, if humanity prove noble and admirable under some aspects, it is base and despicable under others. How then, shall we adequately denounce those destructive qualities, that convert the milk of human kindness into gall and bitterness. and sow the heart with sin and misery? Party-feeling in its worst features, is indeed a wide remove from that rational and benevolent patriotism which wills and works the good of all—of family, country, and humanity."

BOOKS FOR REVIEW.

Medical Essays, by J. Hungerford Sealy, M.D., &c. No. II. The Imagination, its History and Effects. London, 1837. 12mo. pp. 91.

The Teeth a Test of Age, considered in reference to Factory Children. By E. Saunders. London, 1837. 8vo. pp. 76.

What Asylums are and ought to be; being the substance of Five Lectures de-

livered before the Managers of the Monroseye Royal Lunatic Asylum. By W. A. F Browne, Surgeon. Edinburgh, 1837. 8vo. pp. 231.

TO CORRESPONDENTS.

Bibliopole.—The account of the reading-room of the College of Surgeons is very amusing; could our correspondent favour us with any particular conversation?

A Finsbury Elector.—Our correspondent must apply to a contemporary hebdomadary.

An Attorney.—The particulars of the will may be seen at Doctors' Commons. If our memory is accurate, the sum did not exceed £10,000, either to the solicitor, apothecary, or the physician.

Crito.—We are not quite certain who christened the New College, and we have reason to suspect that neither Mr. Richard Quain, nor Dr. T. Thomson, has stood sponsors. The name, in all probability, has been chosen from the striking resemblance between the ubiquitous professor and the great Sydenham.

Erasmus.—We have reason to believe that the luminous discourses of the "modern Sydenham," will not only be delivered at THE COLLEGE in Sussex-street, THE COLLEGE in Webb-street, but also in several of the other renowned Colleges of the Metropolis.

Cyclops.—The remarks will find ready admission into a contemporary.

Paul Pry must favour us with his name confidentially.

Post Mortem ought to have known better the etiquette of the Court, and been aware that Mr. Balderson's name could not have been officially appended to the account of the post mortem examination at Windsor. When Sir Astley Cooper requires the attendance of a junior, it is entirely for his *private* accommodations, and for the purpose of securing morbid specimens.

North London Hospital.—We are unavoidably obliged to defer, an account of the fatal case of Lithotripsy. For the same reason we cannot find room for the Talia-cotian operation.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

London Medical and Surgical Journal.

NOTES OF LECTURES ON PHYSIOLOGY.

By DR. FLETCHER.

*Delivered in the Argyle Square School
of Medicine, Edinburgh.*

No. XXXII.

THERAPEUTICS.

Revulsive Remedies—Humoral pathology
—Influence of the blood in inflammation
—Doctrines of coction and crisis—*Ubi
irritatio ibi fluxus*—Spontaneous influx
of the blood—Natural evacuations and
artificial drains—Medicines for dis-
lodging morbid matters—Origin of
blood-letting—Cholagogues and mel-
enagogues—Herodotus, on the opinions
of the ancient Egyptians—Their prac-
tice of taking emetics and purgatives
every month—Opinions and practice of
the Greeks and Romans—Employment
of diuretics by Hippocrates—Dr. Bay-
nard on diaphoretics—Back doors and
sally-ports of nature—Unsparing use of
Epispastics—General employment of is-
sues—Early employment of bloodletting
—Universally prevalent in savage na-
tions—Pliny, on venesection by the
hippopotamus—Ancient prevalence of
errhines and siatogogues—The brain a
depot of phlegm—Remedies which pro-
duce no discharge—Supposed incompat-
ibility of two irritations—Arbitrary
and gratuitous doctrine of Hippocrates—
Stahl, Hoffman, and Cullen, on the chi-
meras of humoral pathologists—Acids,
alkalies, fermentations, and efferves-
cences of the Arabians and chemical
pathologists—Lentor, remora, and error
loci of the iatro-mathematicians—
Spontaneous accumulations, cachochy-
my, and spissitude of the fluids—Solidist
views of inflammation—Improved no-
tions of Belingheri, Lubbock, Allan,
and Foster—*Anima of De Gorter*—Ar-
cheus of Van Helmont—Cullen on
spasm of the capillaries—Hunter on the
seat of inflammation—The talented vaga-
bond, John Brown—Experiments of
No. 16.

Wilson Phillip, and Hastings—Slower
circulation of blood in inflamed parts—
Dr. Parry on increased momentum of
blood—Dr. Thomson on the capillary
circulation—Bell on electrical repul-
sion—Pring, on capillary attraction—
Vague pathology of the French school
—Inflammation is really diminished ac-
tion, preceded by increased action—
Revulsive remedies do not act by pro-
moting evacuations, or withdrawing
stimuli—Loss of balance between the
weight and the moving powers—Double
character of the blood—Source of
Brown's fatal error—Insane opposition
to blood-letting by Erasistratus and his
successors—Pernicious practice of Ra-
sori, Tommasini, Bordu, Balfour, and
Maclean—Necessity of lightening the
load, as well as increasing the stimulus—
Arteriotomy, leeching, cupping, scarify-
ing, and venesection.

It is not a little remarkable that although, in the present day, we with one consent reject the notion, that any other fluid than the blood is concerned in producing inflammation; and although we have, in a great measure, discarded the doctrines of coction and crisis, we still frequently so far adopt the old axiom of "*Ubi irritatio, ibi fluxus*," as to speak of the accumulation of blood in an inflamed part, not as a necessary consequence of the dilated state of its capillary vessels, but as produced by a spontaneous influx of this fluid, in furtherance apparently of some definite end.

Whatever may have given rise to the humoral pathology, the almost necessary result of it was an attempt, on the part of physicians, to immitate these apparently salutary processes of nature, and to substitute artificial drains, for those spontaneous evacuations which appeared so beneficial. Hence the origin, on the one hand, of emetics, purgatives, diuretics, diaphoretics, and epispastics, as the means of directly dislodging the supposed "morbid matters," and thus obviating the

necessity of their coction and expulsion by any of the four fluids we have mentioned, blood, yellow bile, black bile, and phlegm. This likewise was the origin, on the other hand, of blood-letting, cholagogues, melanagogues, errhines, and sialogogues, as the means of evacuating a portion of these four fluids, when their preternatural accumulation, however salutary when moderate, had become excessive.

The ancient Egyptians, according to Herodotus, supposed that the elements of all diseases entered the body with the element; and from the Egyptians, the Greeks derived all the germs both of medicine and philosophy. Now it is sufficiently well known that it was a prevalent custom with the Egyptians to take emetics and purgatives every month, for three days in succession, as a preventive of diseases in general; and the use of these remedies was hardly less common among the Greeks and Romans; nor does it appear to have once entered into their heads to conceive that the advantage derived from them could be unconnected with the discharge which they occasioned.

The same thing may be said also of the notions at first entertained of diuretics, the employment of which was common with Hippocrates; and of diaphoretics, which were so much relied on, in after time, as a means of obviating inflammatory diseases; the pores of the skin being regarded (as remarked by Dr. Baynard) "as so many back-doors and sally-ports, by which nature drives out the enemy that has crept into her garrison." It was in a similar manner that the advantages of epispastic remedies were in general explained; and how unsparing were the ancient humoral pathologists in the employment of these remedies is very generally known, although they were entirely outdone in this respect by the modern sectaries of the same school. In the days of Willis, it is said there were few persons who had not, on some part of their body, issues of one kind or other, which he compares to the trenches by which fenny lands are drained; and so sore an evil had the extensive use of blisters of cantharides (a short time revived by Mercurialis) become about the time of Dr. Baynard, that he ventures to surmise that "the devil himself, old B-e-l-z-e-bub, is nothing but a *great cantharid*, they act so according to his nature, to plague mankind wherever they are applied."

While emetics, purgatives, diuretics, diaphoretics, and epispastics were sup-

posed to do good by obviating the necessity for accumulations of the fluids, and thus preventing inflammation, blood-letting, and the other means of immediately evacuating these fluids, were considered to be not less efficacious in controlling this accumulation and the consequent inflammation when they had become too violent. Blood-letting appears to have been one of the earliest remedies to which physicians had recourse in the cure of inflammatory diseases; nor is there any nation in modern times, however savage, which does not employ it in one form or other. It is said by Pliny to have been suggested by the example of the hippopotamus, which is reported to open a vein with its teeth, as often as it finds itself indisposed. No doubt, however, mankind was first prompted to its use by the benefit observed to arise in inflammatory affections from spontaneous hemorrhages. Of blood-letting, however, it is not necessary to say anything further in this place; since, though formerly undistinguished from the other evacuant remedies, it is not commonly included, in modern times, among the remedies called revulsive; and since the benefit derived from it is without doubt, really dependent chiefly on the evacuation produced.

The last head of evacuant medicines, the introduction of which requires to be mentioned, is that of errhines and sialogogues; for the chologogues and melanagogues were inseparably connected with purgatives, of which we have already treated. How liberal was the employment of errhines and sialogogues in ancient times must be well known to all who are familiar with the writings of Hippocrates, as well as with how much consistency they were prescribed by the ancient physicians, who, of course, always looked upon them in the light of evacuants alone. The nostrils and mouth were formerly considered as the natural emunctories of the brain,—the great depôt of the phlegm of the body; and fluxes of phlegm from this organ were looked upon as the cause, not only of catarrh and pyalism, but of laryngitis, bronchitis, tubercles of the lungs, anasarca, rheumatism, and gout. Hence it followed, that whatever produced a discharge of mucus or saliva, would be a powerful means of relieving any one of the diseases in question.

We have hitherto spoken only of those remedies for inflammation which were introduced in order to effect artificially that which when natural seemed

advantageous, and the chief or sole beneficial action of which, was almost universally attributed to the discharges which they occasioned. But it was soon found that some remedies which give rise to no sensible evacuation at all (particularly those applied to the surface of the body) were of equal service in inflammatory diseases, to whatever causes the *introduction* of these remedies might have been owing. It became necessary, therefore, to frame a specific law in order to meet this emergency, and it was accordingly enacted, by "the father of medicine," that if two irritations are set up in the body at the same time, the stronger will overcome the weaker. This doctrine, arbitrary and gratuitous as it certainly is, and altogether false, as there is every reason to believe it to be, it has been received since the time of Hippocrates, almost unquestioned; and so long as inflammation was believed to consist in increased, and not in diminished irritation (as was the case till very lately) it was no doubt a very convenient doctrine, and if it did not really explain anything, it answered at least all the purposes of an explanation.

We owe it to Stahl, Hoffmann, and Cullen, that the chimeras of the ancient humoral pathologists, modified as they were by the acids and alkalies, the fermentations and effervescences of the Arabians and their progeny, the earlier chemists, and by the lentor, the remora, and the error loci of the iatro-mathematicians, were at length rejected in favour of the doctrine that inflammation, the "head and front" of most diseases, arose not from a spontaneous accumulation, a cacochomy, or a spissitude of the fluids, but from some preternatural affection of the solids of the body. And not less do we owe it to Vacca Berlinghieri, Lubbock, Allan, and Foster, supported recently by Wilson Phillip, and Hastings, that the notions of Stahl, Hoffmann, and Cullen, modified as they were by John Hunter, have been corrected in their turn. It is only within these few years that the persuasion, for a long time universal, that inflammation consisted in increased irritation or action of the vessels affected, has been very generally superseded by the opinion that, in this state, the affected vessels are acting below par, and that it is on this account alone that the blood becomes accumulated in them.

According to Stahl, and his pupil De Gorter, it was an increased muscular contraction of the capillary arteries, operating by forcing too much blood into the ves-

sels immediately beyond them, that constituted inflammation. This increased muscular action was excited by the supposed anima, which was a lineal descendant of Van Helmont's archæus; as the latter was of the *πυρ, αὐτίς*, &c., of the ancients. Hoffman and Cullen, equally with Stahl and De Gorter, attributed inflammation to increased muscular contraction, or spasm of these capillary arteries; but, differing from them, they imagined that this spasm, while it excluded the blood from the vessels immediately beyond them, produced inflammation by occasioning an accumulation of it in the vessels on the opposite side. It was observed, however, by John Hunter, that capillary arteries themselves, and not the vessels on either the distal or the proximal side of them were the immediate seat of inflammation. He could not conceive that the effect of increased muscular contraction of these vessels, could be that of overloading them; and yet he was unwilling to resign the notion of an increased action of some kind or other. He was therefore obliged to presume that in inflammation, their elasticity or active tendency to expand, more than counterbalanced their muscular contractibility, or active tendency to contract; and thus actively produced that dilatation and accumulation of blood which constituted this state.

Perhaps it was John Brown—the vagabond and despised, but talented, John Brown—who was the first to suggest the doctrine, that a diminished power of any kind of action, in the capillary arteries, as necessarily followed any inordinate exertion of this power, as fatigue of the voluntary muscles followed any unusual exercise; and that as all the positive exciting causes of inflammation operated in calling forth this inordinate exertion, a necessary consequence was, that the fatigued capillary arteries subsequently acted too little, and thus did not actively produce, but passively allowed, of such an accumulation of blood in them, as established the state in question. This theory—for in Brown's hands it was a mere theory—has since been amply corroborated, and it may be almost said proved, by the reasonings of Vacca Berlinghieri, and the other authors above mentioned, particularly Wilson Philip and Hastings. By a series of well-conducted experiments on the intestines of rabbits, the web of the feet of frogs, and the fins of fishes, it was satisfactorily shown by these pathologists, that inflammation (always understanding

by this term, the condition of a part indicated by "rubor, tumor, calor, and dolor"), was at all times to be induced by diminishing the irritation or action of the capillary arteries, and relieved by increasing it. It was also proved that, from the greater quantity of blood contained in these capillary arteries in a state of inflammation, they absolutely transmitted, in a given time, precisely as much blood as in health; the flow of blood through them was, from their increased calibre, necessarily slower than natural. This view of inflammation has accordingly, of late years, been pretty generally adopted; notwithstanding that some celebrated authors (as Dr. Parry) have contended that "an increased momentum of the blood in a part, is essential to local inflammation;" and others (as Dr. Thomson) have endeavoured to show that "inflammation is sometimes attended by an increased, and at others by a diminished velocity of the circulation through the capillary arteries." Nor has this view of inflammation been modified, in any considerable degree, by the notion of Mr. Bell, that a part of the phenomena of inflammation may depend upon a want of electrical repulsion between the vessels and their contents; or that of Dr. Pring, that it may arise from a power of attraction exercised by the capillary arteries. The latter hypothesis, indeed, seems to be little more than a renewal, in another form, of the notions of Hunter, and to have been invented chiefly for the purpose of rendering a little more tangible, the doctrines of the old "fluxus" school, formerly alluded to, and still so vaguely followed by many of the French pathologists, who continue to speak of a "concentric afflux of the fluids," and a "more considerable determination of the fluids," as if the dilatation of the capillary arteries were the consequence of this influx, instead of this influx being the result of their dilatation.

From what has been said we may consider it as proved, or at least as rendered highly probably, that inflammation (as indicated by redness, swelling, heat, and pain) essentially consists in an incapacity in the affected vessels (owing to their diminished irritation or action), to transmit, in a natural manner, the blood which they receive. As, however, this diminished action of the capillary arteries, has always been preceded by a proportionately increased action, of which it is the consequence, we may, if we please, consider the latter (as is habitually done by some pathologists) as constituting the first stage

of inflammation. Hence we may still speak of inflammation, in one stage at least, as a stage of increased irritation. This we may do with no less propriety than we describe a fever as including the cold stage (or that of oppression), as well as the hot stage (or that of excitement). This, however, is a mere *logomachia*, and turns altogether on the definition which we choose to give of inflammation; a state which if we consider it (as is almost universally done) to be essentially indicated by redness, swelling, heat, and pain, is manifestly to be referred to *diminished* irritation, however *increased* may have been the irritation by which it was preceded. It is also to be borne in mind, that the increased action of the heart, and the violent febrile symptoms, which are usually attendant on any considerable inflammation, render it extremely difficult to divest the mind of a certain association between increased action and inflammation; and it was probably this constant concatenation of increased *general*, with diminished *local*, action (the former of which is much more easy to be recognized than the latter), that first gave rise to the idea that inflammation consisted in increased action. The real question, however, is what is the condition of the immediately inflamed part, and not what is the condition of the rest of the body, when any considerable part of it is in a state of inflammation. It may easily be conceived that the local affection may be that of preternatural collapse, while the general affection is that of excessive excitement; nor would it perhaps be difficult to explain how these two states are not only compatible, but in the relation of cause and effect to each other. It is not, necessary however, to prosecute the subject further.

If then, the modern explanation of the proximate cause of inflammation, be not only different from those formerly adopted, but diametrically opposite to them, it is evidently impossible that the explanation of the manner in which the remedies of inflammation operate, can be the same. The notion can be no longer tenable, that revulsive remedies operate, on the one hand, by promoting evacuations, or, on the other, by withdrawing stimuli. It must have been apparent, from the foregoing remarks, that inflammation consists chiefly in a loss of balance between the weight to be moved, and the powers destined to move it; and it must be equally obvious, that the only means of relieving this state must be such as are calculated

to restore this balance, either by removing a portion of the superabundant weight, or by adding to the deficient moving powers. The only remedy which directly fulfils the former of these indications, is blood-letting; and it is pretty certain that this remedy is only or chiefly beneficial from the evacuation which attends it. It is often not sufficiently considered, that the blood, in relation to the vessels which contain it, sustains the double and, in some respect, opposite characters of a load and a stimulus. In the former character the blood tends to oppress the vessels; but the latter it excites them to relieve themselves from such oppression. It appears to have been from regarding the blood in the character of a stimulus only, that poor Brown was led into the fatal error of decrying blood-letting in inflammatory diseases. The insane opposition to blood-letting by other authors, from Erasistratus to Van Helmont, is unworthy of being remembered. The pernicious practice to which this determination by Brown gave rise, has probably, in his hands, and those of his followers (such as Rasori, Tommasini, Borda, Bal four, and Maclean), slain its thousands and tens of thousands, and has branded the name of Brown with an opprobrium, by the sweeping vortex of which his real merits have been almost overwhelmed. If a porter be oppressed by his burden, the most direct and effectual means of relieving him, is unquestionably to take from him part of his load. This is precisely what we do by blood-letting in inflammation. It is done directly when the abstraction of blood is by arteriotomy, leeching, cupping, or scarifying; and indirectly (that is, through the medium of the heart) when it is by venesection. The general inadequacy of all other remedies to remove violent inflammation, till blood letting has been premised, might have been reasonably anticipated from a knowledge of the real nature of inflammation; just as no means short of diminishing the load, would enable a porter to carry a burden to which his physical strength was incompetent.

But when the requisite portion of this burden has been removed, what is the most feasible means of facilitating the conveyance of the remainder? Undoubtedly that of adding energy to those powers by which this conveyance is to be effected. This is to be done, in the case of inflammation, by employing remedies which are either immediately or intermediately stimulant. When the inflammation is seated

in a superficial part (as in the case of ophthalmia, cynanche tonsillaris, or erythema), the local applications which are commonly resorted to, and which are found most beneficial, are such as (in the form of collyria, gargles, and lotions) immediately irritate the dilated arteries, and thus promote their action; and in inflammation of a deep-seated part, some of the most efficacious local remedies (such as calomel, electricity, and acupuncture) operate manifestly as direct and powerful stimulants. That such is the action of caloric in all its forms, from ignited moxa down to the simplest fomentations, can hardly be doubted; in spite of the ingenious surmise of Baron Larrey, that the benefit occurring from moxa is owing to the evolution of a something,—“a very active volatile principle,”—during the combustion of the substance employed. Such a suggestion displays exceedingly well the infinite vagueness, with which the action of remedies directly stimulant, has been usually attempted to be explained. Their actions could not be easily recognized with the theories already in vogue with respect to the action of remedies reputedly revulsive, but in reality indirectly stimulant (either that they effected an evacuation, or abstracted a stimulus); but nevertheless, there was an unwillingness to oppose those theories. Had they been abandoned, however, in favour of the simple views we have enforced, the action of moxa, as well as of the other remedies in question, would have been explained in a manner at once consistent and satisfactory.

LECTURES ON SURGERY.

BY JOHN HUNTER, F.R.S.

OF SEDATIVES AND STIMULANTS.

Perhaps there is no idea of any principle, simply as an idea, more correct than that conveyed by the word sedative, stimulus, irritation; yet I think it is probable that there is no idea so little understood in practice; and it may be a very difficult task, and next to an impossibility, to say what real state the body or part is in, or can be brought into, or be affected in either one or the other way. This arises from our imperfect knowledge of the true state of the body or parts, or of their œconomy; for what might act as a sedative at one time, might be a stimulant at another, or even an irritant; or

what might be a sedative to one part, might be either a stimulant or irritant to another, which we shall see to be really the case, for whatever will excite action, even the common action of parts, will be a stimulus, and whatever will excite actions beyond the real strength of the body will be an irritant; and this cause of excitement beyond the common action may be no more than what at another time would act as a sedative.

For example, without heat, probably no action could take place either in common vegetable or animal matter. Heat admits of becoming an exciter to action; but as heat, in so far as it can, only excites natural actions, and, in due proportion to the strength of the parts, it may be called sedative; for we may suppose that by sedative is not meant an unnatural reduction of action, (for which, indeed, we have no expression,) but the production of a natural action from too great an action. It may increase or diminish action, according to circumstances. But to ascertain the precise degree of heat suitable to every state of body or part, so as neither to increase nor diminish action, is probably impossible.

When animals are extremely weak, their actions should be suitable to their strength. Or if an animal is only moderately weak in the whole, considered as a whole, yet there will be parts that will be very weak, and if those parts are under disease, care should be taken that those parts are not thrown into action above their strength.

The temperature of the body, or parts respecting heat and cold, should be in proportion to this weakness, which will regulate the action, and to apply warmth at such time would be applying a stimulus; and if the body was still more reduced, warmth might become an irritant; or if the body was not able to act up to this stimulus, it would be an irritant.

To lower actions suitable to the state of the constitution, whatever this may be is the use of a sedative; but in some constitutions it may be requisite to bring it even lower. So it is often necessary to produce fainting; but this cannot be called a sedative; it is probably only weakening.

Irritability.—There is no word perhaps more improperly applied than irritability; it is often used for stimulus, and stimulus often used in place of it.

Indeed we must allow that there is a resemblance between them in several of their properties, both exciting actions of

the living parts; but they differ very much in the consequent action, as, indeed, irritability appears to be nearly allied to susceptibility.

I have already explained, when on the œconomy, that stimulus excites or increases natural actions; but an irritation either excites an unnatural quantity of a natural action, or an entire new one; and susceptibility is the readiness with which they can be excited.

Some constitutions are so easily excited or, in other words, so susceptible of diseased impression, as to take up actions so readily as to make them appear natural, which in others are only brought on by disease. That a natural action may be increased beyond its natural bounds we see every day. Salivation is an instance of this. That irritation produces new action is perhaps more evident than the former. Accidents of all kinds are of this kind. Blisters act on this principle. In short, every new action which takes place may be said to arise from an irritation produced in the part, or something similar. Irritations are often producing salutary effects, and therefore may be said to terminate in a stimulus, which is owing to a kind of irritation, such as those which are in consequence of many accidents, which new action produces a restoration of the part injured, as in wounds, compound fractures, &c.

There are new modes of action taking place every day that would appear to arise spontaneously (therefore from no possible irritating cause, which, on the contrary, most probably arises from this new mode of action). The immediate cause may be so slight as hardly to approach to an irritation. Such constitutions are called irritable, which is only saying that one part may be irritated by what would have no effect on another. Those unnatural spontaneous actions often arise from a want of power to act properly, with a strong disposition to action, which is the reason why weakness, or want of power, becomes the cause of irritation, which produces new action, which new action will be according to this want of power and the nature of the part combined.

Necessity often becomes the cause of irritation, as when a small opening is made into a large cavity, and not allowed to heal by the first intention, the whole becomes under the necessity of taking on a new action to restore the whole; therefore irritation often produces salutary effects.

Many of the preternatural actions are so slow in their motions that we can hardly make them accord with our ideas, which ascribe them to irritation, especially in those that seem to arise spontaneously, as the formation of many wens, encysted tumours, &c.

Irritation may be divided into common, specific, and poisonous: 1st, Common, is that which will affect all animals; 2nd, That which will affect only the same species; 3rd, Is also very much confined to species; one only, as far as I know, being excepted,—the bite of a mad dog. So that the disease of one animal, although communicable to another of the same species, is not so to one of another species. Smallpox, chickenpox, venereal disease, measles, whooping-cough, jail-distemper, itch, scrofula, are peculiar to the human. The disease of black cattle is confined to them; the rot to sheep; glanders to horses; mange to dogs.

OF SYMPATHY.

I have endeavoured to show that there are two principles in the higher animals, namely, life and the action of the nerves, which last is called sensation and volition; or rather, perhaps, there is but one principle, life, which becomes the basis of the other and of every action of the body. I also endeavoured to point out that sensation arose from feelings in the mind, which produce action in the body. I attempted to show that the more simple actions arose independently of sensation or the actions of the nerves; that the nerves, from their specific actions, only become the cause of many actions, but are not the principle of those actions; that from their termination in the brain they produce sensations there from which is formed mind, and that they also give rise to the will, and form the basis of reasoning. I showed that the mind becomes the cause of many involuntary actions in the body, as reason becomes the cause of the voluntary; and that thus the actions of life, of the nerves, of the mind, and of the will arise from impressions being made on each so as to affect their principles.

In speaking of the general principles of disease, I divided the living power into susceptibility of impression, impression, dispositions arising in consequence of such, and action consequent on disposition; all which I observed were immediate or primary. But there is a secondary susceptibility, disposition, and action arising from, or in consequence of, all, by

necessity, called sympathy; actions, as it were, playing amongst themselves, each becoming a stimulant to the other, or each being affected by the other.

By this principle of action, called sympathy, an action arises without an immediate impression in a secondary way, either acting in conjunction with the part immediately impressed, or taking the whole action on itself. This action without immediate impression is one of the most complicated principles in the animal body, especially the more complicated animals, because it is the compounding of actions.

Sympathy may be divided into two species: 1st, A local with a local disease; 2nd, A universal with a local. The first may be called local sympathy; the second universal. But all sympathies must arise from a local cause. Sympathy is not confined to the same actions of the same person, but it is transferable from one person to another.

In the investigation of this subject, we shall find all the principles of action in an animal, even in the most complicated, have a connexion with one another; for instance, the living principle, the action of the nerves, and the mind: and that the same principle in one part shall be affected by the same principle in another; and this is the simplest kind of sympathy I can conceive. Thus, the living principle of one part sympathizes with the actions of life in another part, as must be the case in all animals which have no nerves. The nerves of one part sympathize with the actions of the nerves in another, which may produce sensation. The mind sympathizes with the mind, which of course can only take place in animals that have mind, and perhaps not in all of them; and it is more than probable that such minds as are capable of sympathy are capable of other complications of affections. Probably what might be called the disposition to action of one principle in one part may produce action of another principle in another part. Thus sensation in another part may be produced, while simple life only is affected in the part immediately impressed. This would appear to be owing to the nature of the sympathizing part. Thus, if an injection is thrown into the urethra in a man, it shall not give pain in the urethra, not even the common sensation of the part, yet the stomach shall be affected and sickness produced, which last is a sensation. I have known a stimulus in the rectum, which did not produce pain in

the part, produce sickness and pain in the small intestines, and even stop digestion. Such pain certainly arises from action in the part. On the contrary, simple pain in the finger shall produce a greater action of the living principle in another part, as making the heart beat oftener.

The principle of sympathy itself I shall call a genus, of which the above make three species, namely, sympathy of the actions of life, of the nerves, and of the mind. Each of these have their varieties in action, each being susceptible of varieties of impressions, affections, and actions, and all being capable of sympathizing with one another.

It may admit of dispute, and probably will be difficult to settle, whether there is sympathy between sensation and sensation simply; for, sensation must arise from some impression made on a part, or some action of nerves similar to those arising from impression. Therefore every sympathy which only produces sensation must still arise from impression on, or action of, the nerves; and the same with the sensation in the sympathizing part. Sensation is only the natural consequence of such action, for sensation is only the intelligence of action, either from impression or arising from the spontaneous action of the nerve itself.

I suspect that all those which would appear to be sympathies of sensation only without action, are a delusion of the mind, a wrong reference of the mind to some other than the part affected, which I shall explain when upon the subject of delusion.

From what has been said above, it must appear that sympathy is a principle in animal bodies so intimately connected with every possible impression, affection, and action, that we cannot have a proper conception of the animal economy respecting diseases without taking this principle into consideration. It is one of the secondary principles when applied to the body itself, being the effect of some impression, affection, or action in some other part of the same body. Sympathy arises from every part of the body being ready to fall into affections and actions in consequence of an impression, affection, or action having taken place in some other part. Sympathy is one part taking part in the impressions, affections, and actions of another part.

Sympathy is not confined to actions of the same persons amongst themselves, but it is transferable from one person to

another, in whom it cannot be called a secondary action, as it arises from an impression being made on some of the senses.

Yawning is a species of sympathy; and all actions peculiar to country, places, family, &c., are so many sympathies. Dancing may be included among the sympathies, for it is not simply an imitative action arising from the will, but it is an irresistible impulse arising from a state of mind produced from musical sounds. If there were no sounds, or, in other words, not a sense of hearing, there would be no dancing; for seeing would not produce it, probably rather retard it. There is, first, sensation; then a state of mind formed in consequence of that sensation; and then the action of the limbs excited by that sensation.

The idea of sympathy may be stated differently: instead of saying a part sympathizes with another, we may say one part under stimulus or irritation is capable of stimulating another part of the same body into sensation, action, &c., which I think is the most natural idea or position.

Sympathy may be divided into two kinds, the natural and the diseased. The diseased is when sound parts sympathize with the diseased, and probably the diseased with the diseased, which is what I mean to explain.

The sympathy of one diseased part with the diseases of another part will include the idea of revulsion, as revulsion consists in the production of a disease in one part to cure a disease in another part; which shows that this one part, while under disease, can be affected by a diseased action being produced in another part, or the cessation of one action in consequence of another having taken place in another part.

Natural sympathy takes place more readily, and its actions are more strongly marked, in proportion as the powers of the machine are capable of repairing an injury received. On the other hand, it takes place more slowly, and is less evident, as the powers of life are more languid.

In many diseased states the condition of the whole body is often such that it more readily falls into sympathy at one time than at others. Thus we find people at particular periods much affected by slight causes, while at other times considerable mischief received will hardly affect them.

Some people are naturally more rea-

dily affected than others, as will be evident in disease.

Sympathy sometimes proves fatal, as in children from teething. But this depends in great measure on the parts sympathizing, or the number of parts that sympathize.

Sympathies are often not reciprocal: the liver never sympathizes with the shoulder, nor the urethra with the testis; nor when the glans penis is affected does any irritation pass to the bladder: but often they are, as, for example, between the head and the stomach.

Sympathies are generally simple; we hardly ever find two parts sympathizing with the same cause: however the spasmodic convulsion of both hands, or hands and feet, &c., as sometimes takes place, may be called a double sympathy.

Sympathy is common and uncommon. The first is where it takes place more readily between some parts than it does between others, as between the stomach and head, the stomach and the skin, the testes and the urethra. Sympathy may be called uncommon when parts sympathize with diseased parts that were never known to sympathize in health.

A gentleman had a sore on the inside of his thigh, which itched so intolerably that he could not avoid scratching it, and when he did, it always produced tightness in his chest and shortness of breathing, which he never had but at these times.

Lord Cavendish's father always felt pain in the left arm from a stone in the bladder. This pain was the only indication of a want to make water.

Sympathies are either similar to the cause or dissimilar. The similar can be but of two kinds: where the modes of affection or action of the sympathizer are either wholly similar to the modes of affection or action of the parts diseased, or the sympathizer has one of its modes of affection or action similar, and which is the one that sympathizes. Dissimilar sympathy may be of so many kinds that it is probably hardly possible to be completely master of the whole of the particular varieties.

Sympathy may be said to be either partial or universal. Sympathy is partial, from local diseases, when the causes of action in one part become the cause of action in a distant part, as when anything tickles the nose the muscles of respiration act; or it may be partial from a universal disease. But local sympathy with the constitution has its order of parts, as the

stomach sympathizes with the whole body in an incipient fever.

Sympathy is either natural or diseased. Natural sympathy always tends to produce some salutary purpose, as the breasts of women increasing with the size of the uterus during gestation.

As no part of the body is entirely independent of the rest, in all particular injuries the whole must sympathize more or less; but as every individual part has a more intimate connexion with some particular part than with others, these parts sympathize more readily.

Local or partial sympathies we call continuous, contiguous, or remote. Continuous is only an extension of the same action, as in most inflammations spreading from the centre; otherwise, in an injury, the part which received the first impression would alone become inflamed. Contiguous is where one part sympathizes with another where the parts are only in contact with each other, without any continuity of parts, as the contents of the abdomen with the abdominal muscles. Remote is where one part sympathizes with another part, though at some distance from it.

Universal sympathy is when the whole becomes affected in consequence of a local disease, and is of two kinds. One is where every part of the body sympathizes with any one part stimulated, as the sympathetic fever in consequence of local inflammation, as also eating substances that disagree with the stomach, convulsions from worms, teething, &c.; or, secondly, where particular parts, being stimulated, more readily produce universal sympathy than any other.

Constitutional sympathy may arise in many cases from local sympathy, and not from the effect of the first injured part. This is very remarkable when the sympathizing part is a vital part, though the first injured part be not vital. If the stomach sympathizes strongly with any part of the body, this sympathy of the stomach produces a morbid state of the constitution.

In universal sympathy there appear three stages, but all equally belonging to this principle: 1st, inflammatory fever; 2nd, hectic fever; 3rd, dissolution. These take their rise from the different stages of the local disease. There may be marked a fourth, which may be called nervous, spasmodic, or hysteric; but this is not particular to any one of the states of the local disease from which the others arise, but from peculiarity of constitution,

and sometimes it exists when the others do not.

Local or partial sympathy is found more in old than in young; whereas universal sympathy is more in young than in old. Sympathy is less determined in young persons, every part being then ready to sympathize with other parts under disease. This is remarkable in the teething of children, for in them universal sympathy seems the first mode of sympathy arising from local irritation.

When a local disease takes place in a part when the patient is very young, it is capable of giving a general disposition to sympathize, by which means symptoms become more uncertain than in those of more advanced age, often putting on the appearances of a great variety of diseases.

As the child advances, the power of sympathy becomes partial, their not being now in the constitution that universal consent of parts, but some part, which has greater sympathy than the rest, falls into the whole irritation; therefore the whole disposition to sympathy is directed to some particular part. The different organs acquire more and more of their own independent actions as the child grows older.

We find in children the symptoms from sympathy often more violent than those of the parts affected. In adults when cutting teeth there is only an affection of the part, or only a continued sympathy, that is a swelling of the cheek, &c. In adults the pain is often very great, but in children the pain is little, and the action of the part moderate, but the action in the sympathizing parts is very great, namely, in the voluntary muscles.

OBSERVATIONS ON EXTRACTION AND DISPLACEMENT OF THE CATARACT,

WITH TABLES SHOWING THE RELATIVE SUCCESS OF THESE OPERATIONS.

By J. ARGYLL ROBERTSON, M.D. F.R.S.E.,
Surgeon to the Eye Dispensary of Edinburgh, Lecturer on Surgery, &c.

[The following observations have appeared to us so judicious, and the facts contained in them are of such importance, and detailed with such a character of veracity, that we have much satisfaction in placing the whole memoir before our readers.—Eds.]

There are three distinct modes of operation by which cataract may be cured.

1st. By *Division*, or the breaking down of the opaque lens, so that it may be acted upon by the aqueous humour, dissolved, and by absorption removed from the eye.

2d. By *Extraction*, or the complete removal of the opaque lens from the eye, through an incision made in the cornea.

3d. By *Displacement*, or the removal of the opaque lens from the axis of vision, but still leaving it within the eye.

It is almost universally admitted, that when the cataract is of soft consistence, so that it may be broken with facility into fragments, or so fluid that it may be diffused through the aqueous humour, the operation of *division* should be resorted to, as inflicting comparatively little injury on the organ, and effecting a perfect and permanent cure, the lens being just as completely removed as it could be by the operation of *extraction*, and at infinitely less risk.

It is only generally admitted that, in numerous cases of hard cataract, the operation of *extraction* cannot be resorted to, and other operations must be adopted for its removal from the axis of vision, as in the following circumstances, viz.

1. When the section of the cornea could not be completed without wounding the iris, in consequence of the cornea being unnaturally flat, the iris unusually convex, or when adhesions exist between the iris and cornea.

2. When there exists a diseased condition of the cornea, that would be likely to interfere with the speedy closure of the incision, or would render that part peculiarly liable to inflammation if wounded.

2. When adhesions exist between the margin of iris and capsule of the lens, preventing the free dilatation of the pupil, or when the pupil is small and not dilatable to such an extent as would admit freely of the passage of the lens, whether this condition of the iris arise from natural conformation, or from its component fibres having been agglutinated and rendered immoveable by the interstitial deposition of lymph.

4. When there is what is commonly termed "a fluid or disorganized condition of the vitreous humour;" that is, when the cells of the hyaloid membrane exist. In such a case, were an incision made in the cornea of sufficient size to admit of the passage of the lens, through the same incision the whole of the vitreous humour would escape, and the eye sink

in the socket. Such an accident I have witnessed in the hands of a skilful operator conversant with diseases of the eye. It is also evident, that when the vitreous humour is in a fluid state, and an incision made in the cornea, that the slightest contraction of the muscles of the eye or eyelids would cause its escape.

5. When there is eversion or inversion of the ciliæ or palpebræ, either of which conditions would interfere with the closures of the wound in the cornea.

6. When the patient is extremely nervous, irritable, or timid, and deficient in self-command. In these circumstances, not only are the different steps of the operation rendered extremely difficult and embarrassing to the operator, and hazardous to the patient, but an involuntary contraction of the muscles of the eyeball, after the section of the cornea has been completed, has in many instances emptied the eyeball of its contents. To show the difficulties that may arise from this cause, I may mention the case in which I extracted a cystocercus from the eye of a girl eight years of age. The section of the cornea was made without difficulty, and in a perfect manner, but no inducement could make the girl again open the eyelids. To use force was out of the question. Indeed, the mere involuntary contraction of the muscles of the eyeball, forced out the animalcule, and along with it the lens, without my having even attempted to open the eyelids. Had any such attempt been made I have not the least doubt that the vitreous humour also would have been discharged, and all hope of vision irrecoverably lost; as it was, the iris partially protruded, and adhered to the cornea, diminishing the size and altering the form of the pupil. The sight is rendered still further imperfect from subsequent opacity of the capsule of the lens. This may, however, be in a great measure remediable by operation, should it at any future period be rendered expedient.

In all cases, therefore, of soft or fluid cataract, or when any of the above-mentioned objections to the operation of *extraction* are present, the needle must be employed.

But a most important question remains to be solved, viz. whether a hard cataract, when none of the obstacles alluded to are present, ought to be *extracted* or *displaced*. On each side of the question, we find ranged the names of the most distinguished in our profession, so that we

cannot settle the point by referring to authorities. It may be expedient, therefore, to compare the advantages and disadvantages attendant upon each mode of operating, and the relative success which has resulted in so far as that can be ascertained.

The operation of *extraction* has almost invariably been performed nearly in the same manner, viz. by making a semicircular incision through the cornea, by which the opaque lens is removed from the eye.

On the other hand, the operation by displacement is performed either by entering the needle through the cornea, or through the sclerotic, also by *depression*, that is, pushing the lens perpendicularly downwards, or by *reclination* as it is termed, by which the lens is imbedded in the vitreous humour, with its anterior surface turned upwards, and its upper edge backwards.

It is evident, that before we can compare the operations of *extraction* and *displacement*, it is necessary that we should determine in what mode the latter ought to be performed.

In the first place, it appears to me that the needle should be invariably entered through the sclerotic.

The following objections may be stated to the passing the needle through the cornea, or the operation of *keratonyxis*, as it is termed.

1st. If inflammation follow, it is most apt to occur in the wounded part, and may destroy the transparency of the cornea, which is essential to vision.

2d. From the edges of the wound in the cornea forming the fulcrum on which the needle is moved in its different motions, and from its not being a simple incised wound, it is apt not to close immediately, consequently the aqueous humour drains out, the iris is thereby brought in contact with the wound, to which it may adhere, and render the pupil permanently distorted.

3d. The margin of the iris impedes the motions of the needle; besides, from the pressure made upon this membrane, in the act of displacing the cataract, it has become paralyzed, in every instance in which I have seen this operation performed.

4th. The needle being entered through the cornea, it is almost impossible to displace the lens, except in the direction of the iris, and ciliary processes, by which disorganizing inflammation of the eye is

almost certain of being excited. The point of the needle is also apt to come in contact with and lacerate the retina.

5th. The needle can scarcely be made to avoid transfixing or splitting the lens, being entered almost at a right angle to that body, so that if the lens be of a firm or glutinous consistence, it will adhere tenaciously to the needle, and in the attempts to disengage it, either the vitreous humour will be broken up and poached, or the iris will be pressed between the lens and cornea in withdrawing the needle from the eye, and the operation be left not only unfinished, but the eye in a most dangerous condition.

6th. The hand of the operator intervenes between his eye and that of the patient; he cannot therefore distinctly follow the movements of the needle, or of the cataract, and particularly at the moment when, to *displace* the latter, it is necessary to raise the hand.

These objections appear to me sufficiently strong to forbid the introduction of the needle through the cornea in *displacement*, more especially as I am not aware of any advantage that can result of any importance.

The operation is not so objectionable for the purpose of breaking down a soft cataract, although by no means so advantageous as that through the sclerotic.

DEPRESSION.—In the operation of *depression*, the opaque lens is supposed to be pushed perpendicularly downwards, till its upper edge has passed below the margin of the pupil, so that it may no longer interrupt the admission of light into the interior of the eye.

On examining the relative diameter of this part of the eye into which the lens is supposed to be *depressed*, and that of the lens, it will at once be apparent that such an operation is impracticable. In fact, before the upper edge of the lens can be made to descend below the margin of the pupil, its lower edge must have come in contact with the coats of the eye, and if it be attempted still farther to depress the lens, its lower edge will glide towards the back part to the eye, and the upper be directed against the posterior part of the iris, the retina and choroid being at the same time ruffled and injured, or perhaps the lens may even be forced through the substance of these membranes. Indeed David says, that he has found, on dissection, the lens placed between the retina and choroid, and these two membranes torn in several places.

It is evident, therefore, that by *depression*, the lens will be imperfectly imbedded in the vitreous humour; part of it being situated in the posterior chamber of the aqueous humour, it will consequently be apt to reascend. It is also evident that injurious pressure will be made on the iris, retina, and choroid, and inflammation, or total destruction of the functions of the organ may be the consequence.

For these reasons, the operation of displacement by *depression* ought not to be attempted, and is always, and in all circumstances, unwarrantable.

We have now to decide whether, in a case of hard cataract, the operation of *reclination* or that of *extraction* is to be chosen.

To determine this point it will be necessary to consider the advantages and disadvantages attendant upon each mode of operating.

EXTRACTION.—In *Extraction*, the wound in the cornea must be sufficiently large to admit of the easy removal of the lens. In making this incision the iris is apt to bulge under the edge of the knife, from which position in many cases it cannot be extricated, so that we must either relinquish the operation for the time, cut through the iris, or enlarge the incision by scissors, after withdrawing the cataract knife. By any of these proceedings much injury is done to the organ, and violent inflammation is liable to follow.

If the cataract knife be not well tempered, and its point very sharp, or if the cornea be unusually hard, the point of the knife, instead of transfixing the cornea, bends towards the iris, so that the operation cannot be completed without a change of instruments, by which, also, the organ is apt to be injured, and the danger of subsequent inflammation increased.

The incision in the cornea being completed, if pressure be made on the eye, or if the muscles of the eyeball contract powerfully, the whole, or part of the vitreous humour, may be discharged. If the whole, the sight is irrecoverably lost—if a part, hyaloid membrane, in the cells of which the vitreous humour is contained, necessarily intervenes between the lips of the incision in the cornea, preventing or retarding their union. Attempts to replace the hyaloid membrane by the probe commonly call into action the muscles of the eyeball, by which a still greater portion is protruded.

I have seen the whole vitreous humour escape on the completion of the incision through the cornea, in consequence of undue pressure on the eyeball—of spasmodic contraction of its muscles, also from a disorganized state of the cells containing this humour. In each case, it was followed by total loss of the eyeball from the inflammation which followed. Such are the accidents which are apt to occur during the performance of *extraction* even by the best operators, some of which cannot be avoided by any degree of care or skill on the part of the surgeon.

Even when none of the above accidents occur during the performance of the operation, still, so severe an injury as the eye necessarily sustains, is usually followed by violent inflammation, which is indeed the most frequent cause of the failures in *extraction*. When the inflammation is severe, the incision in the cornea does not heal, the lips gape, and the iris protrudes. If it be subdued at this period, a large and unseemly cicatrix, and irregular or obliterated pupil is the result, with a greater or less injury to the sight. If the inflammation proceed, supuration and destruction of the organ is the consequence. In some instances, inflammation of the sclerotic and iris takes place, followed by effusion of lymph, and obliteration of the pupil. *Amaurosis* may also occur, either as the immediate effect of the injury inflicted during the operation, or of the subsequent inflammation. "It very rarely happens," says Dr. Mackenzie, "that this operation is not followed by such a degree of inflammation in one or other of the textures of the eye, as to require the abstraction of blood from the system. So well established is this observation, that some make it a general rule to bleed the patient in the arm in the course of the first twenty-four hours after the operation, whether pain is complained of or not."

In so hazardous a state is the eye placed by this operation, independent of the risks already mentioned, that "the patient must be put to bed with as little movement of the head and body as possible. A careful assistant or experienced nurse sitting confidently by the bed side for forty-eight hours, or even for several succeeding nights, or attentively to watch the patient when he wakes, taking care especially that he does not turn suddenly round upon the eye which has been cut, or put up his hand to rub the eye. If there is any particular reason to dread the

latter accident, it may be proper to muffle the patient's hands, and pin them down by his sides."

Such are the accidents which are apt to occur from the operation of *extraction* of the cataract. It is admitted, that, if the patient escape all these dangers, his sight will be as perfect as it is possible to be, after the removal of the lens.

RECLINATION—In the performance of *Reclination* through the sclerotic, the following parts must necessarily be wounded, viz., the conjunctiva, sclerotic, choroid and vitreous humour; but it is not contended by the advocates for *extraction*, that any permanent bad consequences can result from this part of the operation; nay, it is admitted that the injury inflicted is altogether trifling in comparison with that caused in the operation of *extraction*.

It is objected to the introduction of the needle through the sclerotic, that the long ciliary artery or the ciliary processes may be wounded, and blood thereby effused into the chambers of the aqueous humour, obstructing the view of the cataract and of the needle, and thereby preventing the completion of the operation. Such an accident is possible, but it may in almost every instance be avoided. It has never happened in my own practice, although I have passed the needle through the sclerotic at least three or four hundred times, and I have never seen it occur in the practice of others.

It is also said that the retina may be wounded, either in the introduction of the needle, or in the act of reclining the cataract. This accident may take place, but it must be occasioned solely by unskilfulness on the part of the operator, and not to the operation. The same remark is applicable to the objection that the lens may be placed in contact with the iris or ciliary processes, and acting as a source of irritation, induce iritis. In the operation of depression this accident must have been of frequent occurrence.

Perhaps the chief objection to the operations by the needle in cases of hard cataract is, that the patient is constantly exposed to a return of the disease by a reascension of the lens, and therefore that the cure is only palliative.

This objection is certainly applicable to the operation of *depression*, in which the lens, as I have stated, can be only imperfectly imbedded in the vitreous humour, and in cases in which the cells of the vitreous humour are disorganized. The lens also may perhaps return its ori-

ginal situation if the operator entangle his needle in the substance of the lens, and in his endeavours to disengage it breaks up entirely the hyaloid cells. But I have never yet seen the lens reascend after being fairly *reclined*, and deeply imbedded in the vitreous humour. Scarpa distinctly says, that he does not recollect a single case in the whole course of his practice, in which the lens returned to its original situation after being *reclined*.

Undoubtedly, a passage is made by the lens through the vitreous humour, but its reascension through that passage is prevented (to say nothing of the greater specific gravity of the lens than of the vitreous humour, to which I attach little importance), by the subsequent closure of the passage by adhesion, which we can scarcely doubt takes place, but which appears to have been overlooked by authors. Every other part of the system, when wounded, undergoes a reparative process, and I cannot conceive the hyaloid membrane to be an exception to so general a law; and in the accounts of the dissections of eyes which had been operated on by reclamation, there is no notice of any such previous passage through the vitreous humour.

I have had an opportunity of examining two eyes only which had been operated on by *reclination*, and they were both from the same patient.

The following were the appearances presented;—

Right Eye.—Pupil perfectly clear. The lens enveloped in its capsule was placed about midway between the iris and back part of the eye, and towards its outer side. It lay within about half a line of the retina, a portion of vitreous humour being interposed. It adhered firmly by its capsule to the hyaloid membrane, but had no attachment to the retina. There was no vestige of the course it had taken through the vitreous humour, the whole being equally firm and transparent. The hollow in which the lens was originally situated was partially obliterated, and the posterior chamber of the aqueous humour appeared larger than usual.

Left Eye.—The upper part of the pupil was partially obscured by a shred of opaque capsule, which adhered by a single point to the margin of the iris. The lens was in a similar situation to that of the right eye, not surrounded by its capsule, but reduced to about one-third of its natural size, and apparently in contact

with the retina. It was closely surrounded by the vitreous humour, in which it appeared indented, but not adherent to it. It was of a pearly white colour and firm consistence. As in the right eye the vitreous humour was uniformly transparent and equally firm, without the slightest trace of the passage through which the lens must have passed. The patient was sixty-nine years of age, and I had operated upon him for cataract about two years previous to his death. He could read with either eye with the assistance of convex glasses.

Velpeau (*Medicine Operatoire*, tom. i. p. 749,) mentions that he has examined the eyes of twelve individuals who had been operated upon for cataract by *Displacement*, and in every instance except one the cataracts had contracted adhesions with the retina and choroid, by means of the hyaloid membrane forming a sort of knot or cicatrix of about three lines in length.

We have thus the result both of experience and dissection in favour of the opinion that the reclined cataract does not reascend. There can be no doubt that when the cataract is simply depressed it will frequently return to its original place.

The objection to the operation of *Reclination*, which is considered by many to be of the greatest weight, is, that the lens remains a constant source of irritation, and that by its pressure and friction on the retina it is apt to induce chronic internal inflammation and amaurosis.

As the lens is embedded and fixed in the vitreous humour, and as no motion exists between the vitreous humour and retina, it is clear there can be no friction, and, besides, if there were motion between these parts, the surface of the lens is so perfectly smooth, that no injury would result. Again, allowing that the lens is in contact with the retina, which in the majority of cases I believe is not the case, the whole pressure it can exert will be proportioned to the difference in the specific gravity of the lens, and of the vitreous humour, but this difference is very trifling. The lens, if left to itself, is not heavy enough to sink to the bottom of the vitreous humour, but, at the same time, when once depressed, its difference in gravity is such as to prevent its being floated up to the surface again, even if it did not contract adhesions, or if the passage in the vitreous humour through which it had been depressed did not be-

come obliterated. (Specific gravity of aqueous humour, 1.0003; ditto of vitreous ditto, 1.0009; ditto of lens ditto, 1.0790.) But the best argument which can be adduced is the result of the operation. Scarpa, in speaking of internal ophthalmia followed by amaurosis, as taking place after the operation of *Reclination*, says, "This distressing accident has only happened to me in a single instance during my long practice." It cannot therefore be considered as arising from the pressure of the depressed lens, otherwise it would be of more frequent occurrence. I myself cannot say that I have witnessed any case of internal ophthalmia followed by amaurosis, which was distinctly traceable to the irritation arising from a reclined lens.

There is a very interesting case related by Scarpa, of Signor Lattuada, a young man twenty-five years of age, in whose right eye there is no iris, and apparently no hyaloid membrane. The lens inclosed in its capsule is free from all attachment, and is perceived moving in the cavities of the eye in various directions. When he inclines the head forward, it comes in contact with the cornea, when backward, it falls to the back part of the eye, with the same facility as it would do in a watery fluid. If he remains long in the horizontal position, as during sleep, and consequently with the lens resting on the bottom of the eye, he has never experienced the slightest uneasiness, and he has never been affected with pain or inflammation of the eyes. By means of a convex glass he can distinguish well minute objects. In the left eye, the derangement is less. There is a small strip of fringed-shaped iris at the temporal angle. The lens with its opaque capsule is suspended in its place by a short attachment, which it has preserved with the ciliary zone at the upper and temporal part,—a proof, it would appear, that in this eye the vitreous humour is not entirely disorganized and dissolved into water. There is no attachment whatever of the rest of the capsule or lens, and during the motion of the eyeball and head, it oscillates a little from before backwards. Surely the right eye of this individual ought to have suffered from internal ophthalmia and amaurosis, if either pressure or even friction of the lens on the retina be capable of inducing such consequences, admitting that original malformations do not always produce the same effects as when the results of disease.

One of the principal causes of the failure of the operations for the cure of cataract by Extraction is the violence of the inflammation which follows. So violent, indeed, is the inflammation in many cases, that the depleting measures required often are productive of irreparable injury to the general health of the patient. The argument employed by Mr. Guthrie for operating on both eyes at the same time is, that the patient, should inflammation occur, may be able to bear up for once under the active treatment that may be requisite, although he might not be able to do so a second time, were another operation performed. It is not my intention to enter at present on the consideration of the soundness of this argument. I adduce it simply to show the severity of the inflammation that frequently follows the operation of extraction.

On the other hand, the operation of reclination, if properly performed, is rarely productive of such inflammatory action. So rarely, indeed, that it is almost never necessary to open a vein to subdue it.

Although the observations which I have made on the comparative advantages of the operations of Extraction and Displacement lead to the opinion that the latter is the more successful; still, as mere reasoning on such subjects often leads to false conclusions, I have endeavoured to obtain as correct an account, as possible, of the actual results of these two modes of operating, in the practice of different surgeons, and these strongly confirm the opinion, that displacement is the preferable operation, as is shown in the following tabular views:—

BY EXTRACTION.

Operators.	Cases	Cured	Relieved	Failed
Graefe, Berlin	19	18	—	1
Rosas Vienna ..	26	22	1	3
David	240	207	—	33

Jules Cloquet ..	80	28	—	52
Fabini, Pesth...	94	71	—	23
Total	1307			397

Or 30 three tenths per cent. of failures, or about three in ten.

BY DISPLACEMENT.

Operators.	Cases	Cured	Relieved	Failed
Graefe	14	12	—	2
Hotel-dieu from				
1806—10 ...	43	24	4	15
Bowen	160	154	—	6
Lusardi	5034	4168	—	866
Dnpuytren	306	263	—	43
Jules Cloquet ..	166	97	—	69
Morland	6	3	—	3
Total	5729			1004

Or 17 five tenths per cent. of failures, or one and three-quarters in ten.

It is to be regretted that so few authors have given an account of the proportion of successful cases and failures, according to the mode of operating adopted. On looking at the above table, we must be at once struck by the great relative success of the operation by displacement.

In the tabular view are included a great number of cases operated on by depression. In as much, therefore, as the operation of reclinacion is preferable to depression, in the same degree ought the resulting success in such cases to be greater than that stated.

It is proper also to remark, that the operation of extraction is usually performed only in the most favourable cases, whereas that by displacement is had recourse to even the most unfavourable circumstances, and it is evident that the apparent success would have been still greater from displacement, had that operation been performed only in those cases in which the operation of extraction was advisable. To show that such is really the fact, I subjoin a statement of the cases of hard cataract, without any complication, and in eyes otherwise healthy, on which I have operated. Under the head of successful operation, I have placed all those persons who were able to read moderate sized print, with the aid of cataractous glasses. Under the head of relieved, I have placed those who, though unable to read, were able to guide themselves without assistance. All others I have classed as failures. Of 179 cases of hard cataract without any complication, there were operated on by

	Cured	Relieved	Failed
Extraction	64	33	14
Reclinacion	115	94	10

Proportion of failures by extraction 28 one-eighth per cent.

Proportion of failures by reclinacion 9½ per cent.

CAUSES OF FAILURE.

Extraction.

Suppuration of eyeball, 3; atrophy of eyeball, 5; opacit of cornea, 4; obliteration of pupil, 3; amaurosis, 3: total 18.

Displacement.

Suppuration of eyeball, 2; atrophy of eyeball, 3; obliteration of pupil, 4; amaurosis, 2: Total 11.

CAUSES OF PARTIAL FAILURE.

Extraction.

Opacit of cornea, 5; obliteration of pupil, 4; amaurosis, 5: Total 14.

Displacement.

Opacit of cornea, 1; obliteration of pupil, 5; amaurosis, 4: Total 10.

I have given in this table cases of hard cataract only, without any such complication as would preclude the operation of extraction, it being admitted that soft cataracts ought to be broken down by the needle, and that when the cataract is hard, but complicated with adhesions of the iris, obliteration of the pupil, diseases of the cornea, &c., the mode of operating, and the degree of success, will vary according to the peculiarities of each individual case. They could not, therefore, afford any means of comparison between the operations of extraction and reclinacion.

From what has been stated the following conclusions may be drawn:—

1. That the safest mode of operating when the cataract is soft, is by breaking it down, and thereby effecting its absorption.

2. That in all operations in which the needle is used, that instrument ought to be entered through the sclerotic, and not through the cornea.

3. That in cases of hard cataract, complicated with the various diseases of the eye, and its appendages, above-mentioned, the needle ought to be employed, the mode of operating being adapted to each individual case.

4. That hard cataract without such complications, may be effectually removed by the operations of extraction or displacement.

5. That the operations of depression is impracticable, and that attempts to perform it will be productive of the most injurious results.

6. That many of the accidents which may occur during the operation of extraction cannot be avoided by any degree of skill or dexterity, and, therefore, form valid objections to the operation.

7. That the accidents which may occur during the operation of reclination arise from faults on the part of the operator, for as soon as the needle is entered, he has complete command over the eye. They do not, therefore, form valid objections to the operation.

8. That the success resulting from the operation of reclination is very much greater than that from extraction.

9. That in cases of failure of the operation by reclination, the eye, in the majority of instances, is not left in so hopeless a condition as when the operation of extraction has failed.

10. That, in consequence of the comparatively rare occurrence of violent inflammation after reclination, there is infinitely less likelihood, than in the case of extraction, of such depleting measures being required as may prove ruinous to the general health of the patient.

58, Queen-street, Edinburgh.

THE ANATOMIST.

THE TIBIALIS POSTICA

sends off—

A. *Muscular.*

B. *Peronæal*, which sends off, 1st, the nutritia fibulæ; 2nd, the muscular; 3rd, the anterior peronæal; and 4th, the posterior peronæal.

C. *Nutritia tibiæ.*

D. *Internal plantar.*

E. *External plantar.*

THE TIBIALIS ANTICA

sends off the following branches—

A. *Muscular.*

B. *Recurrent.*

C. *Internal malleolar.*

D. *External malleolar.*

E. *Tarsal branch.*

F. *Metatarsal branches.*

G. *Arteria pollicis.*

H. *Arteria communicans.*

THE PLANTAR ARCH

is formed by the external plantar artery uniting with the arteria communicans of the anterior tibial; it sends off two sets of branches.

No. 16.

A. *Arteria perforantes.*

B. *Arteria digitales.*

THE PULMONARY ARTERY

divides into two branches.

A. *Right pulmonary.*

B. *Left pulmonary.*

VEINS.

The veins are not so uniform in their distribution as the arteries. Besides the numerous superficial veins which ramify on the skin, one or two are found to accompany each artery. In the extremities there are generally two to each artery, and in these situations they receive the name of *venæ comites*. When, however, an artery is of great size, as the femoral or the axillary, it is accompanied but by one vein, which receives the same name as the artery.

VEINS OF THE HEAD AND NECK.

The Parietal and Temporal veins unite behind the angle of the jaw, and here receive the *internal maxillary vein*; by their union is formed the

External jugular vein. This vessel descends obliquely backwards, and joins the subclavian vein. A little after its formation it receives the trunk of the *facial vein*, and in its course down the neck it receives several superficial veins.

Internal jugular vein commences at the termination of the lateral sinus, descends along the outer side of the common carotid artery, and joins the subclavian vein at the sternal extremity of the clavicle. It receives the laryngeal and some muscular veins.

VEINS OF THE SUPERIOR EXTREMITY.

The Cephalic vein is formed by the union of several veins from the back of the hand. It ascends along the radial side of the extremity, and terminates in the *axillary vein*.

The Basilic vein commences by a small vein from the little finger (*vena salvatella*), ascends along the inner side of the extremity, and terminates in the axillary vein, or joins one of the *venæ comites*, which accompany the brachial artery.

The Median vein commences at the fore-part of the wrist and hand, ascends along the anterior aspect of the forearm, and at the elbow terminates, by dividing into two branches. One of these joins the basilic vein, and is named the *median*

basilic; the other joins the cephalic vein, and is named *median cephalic*.

The *Axillary vein* formed by the union of the veins just described, and by the *brachial venæ comites*, ascends in front of the axillary artery, receiving the *thoracic veins*, and passes beneath the clavicle, where it terminates in the subclavian vein.

The *Subclavian vein* passes inwards over the anterior scalenus muscle, receives numerous veins from the neck and shoulder; also the *external jugular* and *vertebral veins*, and joins the internal jugular vein behind the sternal extremity of the clavicle.

Vena innominata, formed by the union of the internal jugular and subclavian veins, on the right side is very short and descends into the thorax; the left *vena innominata*, which is much longer, enters the thorax in a transverse direction in front of the trachea to join the right vein, and in its course receives the *thyroid veins* and veins from the anterior mediastinum. By the union of the *venæ innominatæ* is formed the

Vena cava superior, which descends in front of the right pulmonary vessels, enters the pericardium, and opens into the right auricle.

VENA AZYGOS,

commences on the first lumbar vertebra by one or two small veins, gains the posterior mediastinum, by passing through the aortic opening of the diaphragm, ascends along the right side of the bodies of the dorsal vertebrae, curves forwards over the root of the right lung, and terminates at the posterior aspect of the superior vena cava, as this vessel is entering the pericardium. In its course it receives the *intercostal veins* of each side, and the *œsophageal veins*.

VEINS OF THE INFERIOR EXTREMITY.

Internal saphena vein, commences at the inner part of the foot, ascends along the inner side of the leg and knee, behind the inner condyle, becomes more anterior upon the thigh, and reaching to within about two inches of Poupart's ligament, passes through the saphenic opening of the fascia lata, and joins the femoral vein.

External saphena vein, commences at the outer part of the foot, ascends along the back part of the leg and ham, and joins the popliteal vein.

Both these veins are superficial and in

their course receive several veins from the integuments.

Deep veins of the leg, two veins (*venæ comites*) accompany each artery in the leg, and terminate in the following—

Popliteal vein, this vessel accompanies the artery of the same name, and having received the external saphena vein, and the veins of the knee, terminates in the femoral vein.

Femoral vein accompanies the femoral artery, and having received the profunda vein, the internal saphena vein, and a few muscular veins, passes beneath the crural arch, and ends in the external iliac vein.

External iliac vein accompanies the external iliac artery.

Internal iliac vein is formed by the union of the veins which accompany the internal iliac artery and joins the external iliac vein at the sacro-iliac symphysis.

Common iliac vein, formed by the union of the internal and external iliac veins, joins its fellow at the right side of the body of the fourth lumbar vertebra to form the inferior vena cava.

Inferior vena cava ascends along the right side of the bodies of the lumbar vertebrae, behind the liver, and passes through the quadrilateral opening in the diaphragm and opens into the right auricle at its lower and back part. It receives the middle sacral, one and sometimes both spermatic veins, the emulgent and capsular veins, the *venæ cavæ hepaticæ*, and the phrenic veins.

VENA PORTÆ

commences on the back of the rectum by one of the *hæmorrhoidal veins*, ascends towards the meso-colon and unites with the *inferior mesenteric vein*; this trunk next unites with the *superior mesenteric vein*, and behind the pancreas it unites with the *great splenic vein* and receives veins from the stomach, duodenum and pancreas. The vena portæ thus formed ascends to the right side, inclosed in the capsule of Glisson, and reaches the transverse fissure of the liver where it divides into two branches; these enter the liver, ramify through its substance like an artery and its blood is returned to the inferior vena cava by the *venæ cavæ hepaticæ*, which are three or four in number and open into the cava as this vessel is entering its opening in the diaphragm.

THE DIGESTIVE APPARATUS.

THE MOUTH.

This cavity is bounded superiorly by the hard and soft palate, inferiorly by the tongue and the reflections of mucous membrane from it to the gums, and laterally by the cheeks. Its anterior opening, which forms the commencement of the digestive canal, corresponds to the lips; and posteriorly it communicates with the pharynx through the opening called isthmus faucium, the boundaries of which are, the soft palate and uvula superiorly, the tongue inferiorly, and the pillars of the palate and tonsils laterally. Within the mouth we observe the opening of the three salivary glands and follicles, and the teeth of either side. The parotid gland opens by a single orifice opposite the second last superior molar tooth; the sub-maxillary gland of either side, by a single orifice at the anterior part of the tongue, by the side of the reflection of mucous membrane called frenum linguæ, and the third salivary gland or sublingual by several small orifices (eight or ten) on either side of the tongue.

THE TEETH.

The number of teeth in the adult is thirty-two, sixteen in each jaw; and to distinguish them from the teeth of the child they are called *permanent*. They are divided into eight *incisors*, four *canine*, eight *bicuspidæ*, and twelve *multicuspidæ* or *molars*. The two last molars do not appear until late in life, and hence have been called the *wisdom* teeth. They are, however, sometimes wanting.

In the child the number of teeth is only twenty, and are called milk, deciduous, or temporary teeth. They are divided into eight *incisors*, four *canine*, and eight *molars*.

THE PHARYNX

Is a musculo-membranous bag of a conical shape, extending by its base from the posterior part of the mylo-hyoid ridge and base of the skull, to the posterior aspect of the cricoid cartilage, where it terminates in the œsophagus. It is connected by its posterior wall to the vertebræ by loose cellular tissue, and interiorly it corresponds to the mouth and larynx.

On laying open the cavity of the pharynx by a perpendicular incision along its posterior median line, the internal mucous lining of the bag will be

exposed, and the following openings, viz. superiorly, one on either side of the medial line, the openings of the posterior nares; more externally, one on either side the openings of the Eustachian tubes; inferior to these is the opening of the mouth into the pharynx, or the isthmus faucium; posterior and inferior to the tongue is the glottis, and lastly the opening of the pharynx into the œsophagus.

THE ŒSOPHAGUS

Extends from the termination of the pharynx to the stomach; it is placed, above, between the vertebræ and the trachea, inclines at the inferior part of that tube to the left side, and passes behind its left bifurcation to reach the posterior mediastinum. In the mediastinum it descends forwards, passes through the oval aperture of the diaphragm, and terminates in the stomach. The mucous membrane of the mouth, pharynx, and œsophagus is covered by epidermis.

THE STOMACH.

A large pyriform musculo-membranous bag, situate in the epigastric and left hypochondriac regions, communicating at one extremity with the œsophagus, and at the other with the duodenum.

Connexions.—Its large extremity, or *fundus*, to the spleen by the gastro-splenic omentum; its upper concave, small edge to the liver by the gastro-hepatic omentum; and its lower, convex large edge to the colon by the gastro-colic omentum. Its œsophagus, or cardiac orifice, situated between the fundus and lesser curve, connects it to the diaphragm, and its pyloric orifice to the duodenum. The superior-anterior surface of the stomach looks towards the diaphragm, ribs, and left lobe of the liver; the posterior-inferior surface towards the meso-colon.

The stomach is composed of three tunics, connected by cellular tissue, an external peritoneal coat, an internal mucous coat, and between both the muscular coat. The muscular fibres of the stomach observe three directions; the longitudinal are seen along the edges or curves, the oblique on the fundus and the circular are well developed at the centre of the organ, and at its pyloric orifice. The mucous coat presents minute piles (*villi*), it is thrown into wrinkles (*rugæ*, or folds (*plicæ*), which intersect each other, inclosing irregular quadrilateral spaces. Numerous mucous glands (glandulæ Brunneri) are found along the curves, and at the py-

lorus; in the fundus small glands exist, which have been supposed to secrete the gastric juice. At the pyloric orifice the mucous membrane is thrown into a circular fold, which forms an imperfect valve between the stomach and duodenum; and at the oesophageal opening the epidermic lining is observed to terminate in a fringed edge.

CHARING CROSS HOSPITAL.

A NEW RECOGNITION WANTED.

It will be fresh in the recollection of our readers, that the Medical Officers of the Charing Cross Hospital resorted to the most serious fraud in order to induce the Council of the College of Surgeons to grant them a recognition; and they had the baseness, in order to occupy the required number of beds, to collect individuals from the adjoining workhouses, to represent the required number of patients, bribing these paupers to participate in the conspiracy by giving them food and drink for a few days, during which Sir Astley Cooper and Sir Benjamin Brodie were delegated by the Council to examine the Hospital, and ascertain that the regulations of the College of Surgeons were duly complied with. When the gross imposition was detected, and when it was discovered that the hospital in place of containing 110 beds occupied by patients, had not in fact 70 patients, except on the "three glorious days," the College of Surgeons had the honesty openly to declare their abhorrence of the whole transaction, and immediately withdrew their recognition; and had it not been for a highly praise-worthy feeling, and

compassion for one of their body, who was deeply implicated in the whole transaction, he would have been dismissed from the Council.

Recollecting these almost unparalleled events, it will scarcely be credited, that the Director-General, with his accomplished staff, contemplate again to make an application, and that too before the 1st of October, to get the recognition, which was so ignominiously wrested from them by the Council of the College of Surgeons, once more within their iron grasp. With a view to obtain this new recognition, temporary inmates have been procured to fill up the number of beds directed by the College, and every nerve has been strained to raise a sum of money to provide them with food, so that the imputation of a three days comedy cannot be made.

Amongst the many ingenious devices for accomplishing their charitable purposes, none has been more profitable than subletting parts of the building for shops, and if a suitable tenant can only be found to pay handsomely for the "beautiful family residence," there can be little doubt but that the requisite number of patients will be engaged and supported for a limited period in order to obtain the recognition.

We have our own doubts whether there be any member of the Council who will have the hardihood to propose the recognition of an hospital, the whole history of which, as well as the imposition which was so lately exercised on their own body by its medical officers, is so discreditable; and although Mr. Howship, who is still a member of the Council, and a Surgeon of the Charing Cross Hospital, must feel deeply interested in obtaining a recognition, yet, we hesitate not to say, that he will feel the utmost delicacy, though he certainly may have *five hundred reasons*, in publicly coming forward

at the Council on this occasion. From the decided and active part which Mr. Lawrence has taken on this and many other occasions, in exposing the abuses and frauds of the Council of the College of Surgeons, we may confidently hope that the new intriguer from King's College will fail in his contemptible project. Although Mr. Lawrence's laudable proposal, which he had the manliness to bring before the College, was not acceded to on a former occasion, yet there can be no doubt, that should occasion require it, he will be warmly supported in any measure he may think it necessary to bring forward, touching the new recognition, by all the more respectable members of the Council; and we do fervently trust, that the net which was so artfully woven, and which entangled Sir Astley Cooper and Sir Benjamin Brodie, and which the Birmingham diplomatist is now manufacturing with such address, will be much too large in its meshes again to entangle the two surgical baronets.

Since the preceding remarks were written, an advertisement has appeared in the public prints announcing that a General and a Special Meeting of the Governors would take place, the former for the purpose of considering the affairs of the Hospital; and the latter to take into consideration certain negotiations which are pending between the JOINT STOCK COMPANY OF KING'S COLLEGE, and the Junta Committee of this Hospital. Our readers, no doubt, will be astonished at this information, when it is fresh in their recollection that the very men who are now anxious to effect a junction with the falling Medical School of King's College, made this very proceeding a pretext to the governors at large of the hospital, for removing out of their way, the two most efficient medical officers of the charity, Dr. Sigmond and Mr. Pettigrew. How

far these persons can reconcile their present barefaced proceedings with their former conduct, it is the duty of the governors at large to immediately investigate; and though they have, as usual, selected a time when the most influential governors are absent from town, or engaged in electioneering pursuits, yet their gross inconsistent conduct cannot fail to disgust the profession, and to excite its merited contempt.

ON THE TYPHUS FEVER, WHICH OCCURRED AT PHILADELPHIA IN THE SPRING AND SUMMER OF 1836;

Illustrated by Clinical Observations at the Philadelphia Hospital; showing the distinction between this form of disease and Dothineritis or the Typhoid Fever with alteration of the follicles of the small intestine.

By W. W. GERHARD, M.D.,
One of the Physicians of the Hospital.

During a residence of two or three years at Paris, I had studied with great care the pathology and treatment of the disease usually termed, in the French Hospitals, typhoid fever or typhoid affection. There is another designation for it, founded on its anatomical characters, and therefore more directly in accordance with modern medical nomenclature; it is dothineritis. This variety of fever, which is identical with the disease termed typhus mitior or nervous fever, is frequent at Paris, and is almost the only fever which can be said to be endemic there. Intermittent and remittent fevers are rarely seen, except amongst those individuals who had already contracted some form of these diseases in the malarious districts of France. Some slight fevers, attended with a whitish or yellow tongue and gastric symptoms, occasionally occur; they scarcely assume the form of a fixed disease, and usually disappear under a very simple treatment.

These fevers were the only ones known at Paris for some years past; but in 1813-14, there occurred a severe epidemic fever, characterized by extreme prostra-

tion and strongly marked cerebral symptoms. This epidemic was first noticed amongst the troops who returned from Napoleon's unsuccessful campaigns in Germany and the east of France; it afterwards spread amongst the inhabitants of Paris and other large cities, and was every where extremely fatal. No accurate description of this fever is on record, although it was witnessed by several of the most distinguished French physicians. Some of these, more especially Louis and Chomel, are inclined to consider it as identical with the prevailing dothineritis, but their opinion is probably erroneous, and the disease, as far as we know, should be classed amongst the forms of continued fever, distinguished by the terms typhus, typhus gravior, petechial or spotted fever, &c.

There are, however, complete histories of the typhoid fever or typhoid affection, or dothineritis, (all names belonging to the disease). It is one of the most frequent and the most severe acute affections observed at Paris, and has been studied with extreme accuracy, more especially by Louis and Chomel, who have both published admirable descriptions of it. The work of Dr. Louis is especially interesting, and is a model of its kind; he has analyzed the symptoms and pathological phenomena of the fever so accurately and fully, as to surpass any other description of individual diseases. The typhoid fever was placed by this work of Dr. Louis, in the same relation to other fevers that pneumonia holds in reference to the affections of the chest. They are both so well studied, and their symptoms are so well known, that they serve as types with which other less thoroughly understood affections may be compared.

It affords us, then, great advantages in the investigation of the history of fevers, to begin with the typhoid, as the best known of these affections. Assuming this disease as the basis of our investigations, one great point is gained, and much greater certainty can be given to our ulterior researches, if we compare the symptoms of any fever, which is little known and imperfectly described, with those of the typhoid fever, or dothineritis, as it is now frequently called from its anatomical lesion.

This inquiry was in accordance with a desire which I had long cherished of investigating the most common fevers in the middle states of America, where, from our geographical position, we witness the fevers observed at the northern, and occa-

sionally those of the southern states. The commercial relations of Philadelphia are so frequent with the whole southern coast of the United States, and the passage to the north so rapid in the summer and autumnal months, that we receive into our hospitals a considerable number of patients taken ill on the coast of North Carolina, Virginia, and even Alabama and Louisiana. There are, therefore, few places where such a study could be pursued to more advantage than at Philadelphia. During the last three years of a constant connexion with our largest hospitals, either as resident or attending physician, I have not lost sight of this object of study, and I have already published, in the American Journal, for the year 1835, some cases of the dothineritis as well as of the remittent and intermittent fevers.

Dothineritis is by no means a rare disease at Philadelphia, although less common than in Paris. In the essay alluded to, I established the identity of the anatomical characters and of the symptoms of the fever occurring at Philadelphia, with that observed at Paris. I also showed that the patients were chiefly those who had resided but a short time at Philadelphia, and that they were taken ill on ship-board, or some other circumstances causing an abrupt change of food and habits of life. They were also young persons, but few having passed the age of twenty-five years. Both these conditions of age and change of habit are observed to be essential to the development of typhoid fever at Paris.

Having once established the complete identity of a fever which is so common at Paris, and so well described, with a similar affection, not unfrequently met with at Philadelphia, I examined the pathological phenomena of our remittent and intermittent fevers of the severe malignant character so frequently observed along the southern coast, and sometimes occurring in those malarious parts of the country which are situated within a short distance of Philadelphia. In all these fevers, the glands of Peyer as well as the other intestinal follicles, were found perfectly healthy; the large intestine was occasionally but not constantly diseased, while the stomach, and to a still greater degree the liver and spleen were invariably found in a morbid condition. If the fever proved fatal in the course of the first fortnight, the liver and spleen were softened as well as enlarged; but if the disease assumed a more chronic form, the viscera were hardened as well as hyper-

trophied. The latter state was the first stage of these chronic lesions which are formed in the livers of patients long affected with remittents or intermittents, and which continue throughout the course of the ascites, which is so common a consequence of these diseases. I made numerous examinations of the bodies of patients who died of the same variety of malignant remittent and intermittent during the summer of 1835, and still more frequently in the epidemic of 1836, a year in which these diseases have been unusually fatal throughout the southern states. The results of these late examinations have confirmed those already obtained, and showed that the follicles of the small intestine are free from lesions, and that the anatomical character of the disease is to be looked for in the spleen, liver, and stomach.

The bilious and yellow fevers are probably referable to the same class as the malignant remittents, but in yellow fever the disorganization seems to be most extensive in the stomach, whence arises the black vomit, which forms a characteristic symptom of the disease. Bilious fever, or, in other words, the remittent fever attended with unusual alteration of the liver and a disordered secretion of bile, is common with us. Yellow fever is rare, and occurs in an epidemic form at such long intervals, that I have seen but few cases of it.

The typhus fever, which is so common throughout the British dominions, especially in Ireland, is not attended with ulceration or other lesion of the glands of Peyer. (I mean that this lesion, when it occurs, is merely accidental, or a complication not occurring in the ordinary course of the disease.) From the account of the lesions presented by most of the writers upon the subject, it would seem that there is no constant anatomical lesion, but that the lungs present traces of disease more than any other organ. My own observation of this variety of fever was limited to the examination of the fever patients under the care of the late Dr. Gregory of the Edinburgh Infirmary. This observation was not sufficiently long or accurate to enable me to do more than refer to those physicians who have enjoyed extended facilities for the study of this affection. The lesion of the glands of Peyer is now well known to the British physicians, but an error frequently committed by them is, that they regard this affection (dothinen-teritis) as a mere complication of their ordinary typhus, or a modified form of it.

At least I do not at this moment recollect any one who has clearly stated that the two diseases are always distinct, before the publication of a note in the *Dublin Journal*, by Dr. Lombard, of Geneva, (Sept. 1836.)

It is not possible to set this matter at rest, unless a series of accurate histories of typhus, with detailed symptoms and pathological lesions, should be published by British physicians. With the aid of a statement of this kind, such a comparison might be made as to set the points of difference between the ordinary British or Irish typhus and the dothinen-teritis of France in their true light. From the information we possess, we should conjecture that the two diseases are widely and entirely different in symptoms, anatomical characters, treatment, and mode of transmission. But the British typhus seems to us to be identical with the disease which forms the subject of the present memoir, and is apparently the same affection which is variously designated—typhus gravior, ship fever, jail fever, camp fever; sometimes petechial, or spotted fever. The term typhus minor of the older writers, seems nearly synonymous with that of typhoid fever, or dothinen-teritis, of the French physicians.

In America there have occurred several epidemics of fever, more or less similar in their nature to the British typhus. Some of these were confined to the New England States, where they were often known under the name of spotted fever, and are described by North, Hale, and others. Other epidemic diseases of a similar type extended to a larger district of country, and overran a considerable portion of the Middle States, causing extensive ravages both in town and country. It was of epidemics of this kind that many distinguished physicians of Philadelphia perished in different years, amongst them were the Professors of the University, Rush, Wister, and Dorsey. No distinct history of the typhus fevers which prevailed at Philadelphia, at different periods between the years of 1812 and 1820, is on record. I mean such an account of the disease as makes its diagnosis so clear that there can be no danger of confounding it with other analogous affections. The fever was well studied by the physicians who practised at that time, but the habit of analyzing symptoms had not been introduced, and their experience, however valuable to themselves, was in a great degree lost to their successors. These remarks are so true, that although an emi-

nent physician of Philadelphia pronounced the epidemic of 1836, to be the same as that of 1812 and succeeding years, another distinguished medical gentleman, who was not familiar by his own experience with the former disease, considered them as distinct affections, and that the one which first occurred was a low grade of pulmonary inflammation.

That the fevers were really identical, was proved by the opinion of Dr. Parrish, one of the most experienced physicians of Philadelphia, who practised very extensively amongst all classes of inhabitants in the winter of 1812-13, and was remarkably successful in his treatment of the prevailing fever. He saw some of the cases at the Philadelphia Hospital in 1836, before the disease had extended to the wealthier classes, and immediately recognized its true character.

For a period of at least ten years there has been no epidemic of this nature at Philadelphia. In the year 1827, a large number of Irish emigrants were ill of a typhoid fever, with ulceration of the small intestines, which was probably dothineritis, and during several successive years there were more or less extensive epidemics of remittent and intermittent fevers, occurring in the neighbourhood of the city, but not often extending into the central parts of the town. Occasionally, sporadic cases of fever of a comatose or typhoid character would occur, but these cases were nearly always either some form of malignant remittent, or else they occurred during the winter months, and were complicated with pneumonia. The inflammation of the lungs then appeared as the first stage in the disease, which afterwards assumed those cerebral symptoms of stupor and feebleness which have procured for it the designation of pneumonia typhoides. These cases I often witnessed while resident physician of the Almshouse Infirmary during the years 1828-30.

At Boston, in the year 1833, there was an epidemic dothineritis, of extreme gravity and unusually fatal. This fever was well studied by the late James Jackson, jun., and other physicians, and was proved by them to be identical in symptoms and pathological lesions with the typhoid fever of Paris. Some of the physicians of that city are inclined to regard epidemics as of this nature, but this opinion seems to us more than doubtful. Since the epidemic, the typhoid fever is there a common sporadic disease, rather more frequent apparently than at Philadelphia.

In the winter of 1835-6, there was an unusual number of cases of gangrene of the lungs at the Philadelphia Hospital, and but few of decided pneumonia. Several cases of dothineritis occurred in the autumn, but there were few afterwards. During the winter, a form of fever not commonly met with at the hospitals, was observed from time to time. It was characterized by pungent burning heat of the skin, dusky aspect of the countenance, subsultus, delirium, with great stupor and prostration; but there was no diarrhoea, and but few other symptoms referrible to the alimentary canal. It was the disease which afterwards appeared as an epidemic. At first it was not well understood by us, was sometimes confounded with bronchitis or pneumonia typhoides, from the complication of pulmonary disease with the symptoms of the fever. These cases recovered under the use of a mild stimulating and supporting treatment, with one exception, in which death ensued from the sloughing of the sacrum and gangrene of the lungs.

In the early part of the month of March, the admissions for the fever were more numerous. They attracted the greater attention from their occurring in groups of several from the same house, and almost all coming from a particular neighbourhood. Amongst the very first admitted were seven negroes, the entire population of a cellar in the lower part of the city. The symptoms varied but little in the seven cases, and upon an examination of two of the number who died, no lesion of sufficient importance to account for the symptoms could be detected.

As soon as these patients were admitted I resolved to note with care the pathological lesions presented by the bodies of most of those who should die of the fever, examine its symptoms, and ascertain the influence of therapeutic agents upon it. This research was commenced with a view to obtain more precise notions as to the character of an epidemic, which has probably more than once appeared in America, and seems to be endemic in Great Britain and Ireland. It was especially desirable to ascertain if there was a real fundamental difference between the form of disease which prevailed this year, and the dothineritis which is always to be met with in America, as a sporadic affection. My friend and colleague, Dr. Pennock, had charge of one-half the medical wards of the Philadelphia Hospital his observations were conducted at the same time with my own, but the autopsies and

the examination of doubtful cases were always made in the presence of both of us. Dr. Pennock noted a large number of cases, and has given me the privilege of adding his collection to my own. They are the more valuable from the familiar knowledge which he obtained of the dothineritis in the wards of La Pitié at Paris. Our inquiries were conducted so much in concert, and our opinions as to the symptoms and treatment of the fever were so often compared together, that this memoir is, in most respects, the expression of the results obtained by our joint labours.

A portion of the cases were treated by Dr. Pancoast; of these I have no notes excepting such as were obtained from the registers of the wards; they were chiefly admitted towards the close of the epidemic season, when we had already procured a large mass of materials.

These inquiries were greatly promoted by the zeal and industry of the resident physicians of the hospital, who were all much interested in the examination of the disease, and untiring in their efforts to relieve the suffering of patients, who always required much more than ordinary care. In the rotation of service the most arduous duty fell to the lot of Drs. Bush, Stillé, Patterson, Elmer, Frisby, and Johnson, of whom the two last mentioned were themselves attacked with fever.

Many of the observations are deficient in the history of the early symptoms, as the patients, at their entrance into the hospital, often did not retain intelligence enough to recollect the previous symptoms of their disease. The autopsies were always made with great care, more particularly the examination of the small intestines; but the weight of occupation, and the ennui of recording results which varied so little among themselves, caused us to neglect committing some of them to paper. We have, however, noted in detail, a very large number, showing the nature of the lesions; and we always took great care to remark the diseased or healthy state of the organs. We are quite sure that nothing of importance escaped us, and, above all, that the condition of the follicles of the small intestines was carefully ascertained. Our mass of facts is so considerable, that many important questions will be solved by them in relation to the history of this form of continued fever. They will clear up many questions relative to the disease; for although few cases are as complete as we could have desired, the information which

is wanting in one case may be gathered from others; none are deficient in all the particulars, or fail to give a tolerably exact statement of the symptoms at one period or other of the disease.

In our investigations, we availed ourselves of the opportunities we possessed to inquire into the pathological anatomy, the symptoms, the mode of communication, and the treatment of this fever, which had not been witnessed at Philadelphia for some years, even if it were the same disease as that of former epidemics. At each step of this progress, I shall compare the facts before us with those relating to the history of the typhoid fever, or dothineritis, and when the symptoms differ, it will be easy to draw the line of distinction between two diseases, differing in their treatment, symptoms, duration, and pathological lesions.

There is some confusion in the designations of these fevers, but it is not my intention to enter upon the discussion of their nomenclature. It is sufficient to state that in using the terms typhus, typhus fever, typhus gravior, spotted or petechial fever, I mean that disease which forms the subject of this memoir, and that by the terms typhus mitior, typhoid fever, or dothineritis, I mean the disease described by Louis, Chomel, &c., and attended with a lesion of the glands of Peyer.

The number of cases admitted with typhus, was 214. Of this number there were 120 men and 94 women. A few cases that were at the same time in the wards, and already under treatment for other diseases, are not included, although they were afterwards affected with the prevailing epidemic, but the names on the register present only the disease for which they had been admitted. The whole number of cases is, therefore, from 230 to 250. A large majority of the 214 patients were negroes or mulattoes, there were 147 people of colour, and 67 whites. The disease first appeared in the former class of patients, and always prevailed more extensively amongst them than the whites who were living in the same part of the town and exposed nearly to the same causes of disease.

The patients were taken with the fever in various parts of the city and neighbouring districts, but by much the greatest number came from that part of the town which extends from Lombard-street to a little below Shippen, and from Fifth to Eighth-streets; this small but crowded district became almost an infected suburb.

Within these limits the poorest and most intemperate of the inhabitants of Philadelphia reside. It is the St. Giles, or the Faubourg Saint Marcel of Philadelphia. The filthiest and most crowded alleys offered the greatest proportion of patients. Thus, Small-street and St. Mary's-street, with the numerous courts and alleys running from them, contained many more sick than other streets inhabited by a population nearly as poor and intemperate, but less crowded. The different streets were not infected at the same time, thus the earliest patients were taken ill in Shippen and in Small-streets, while St. Mary's-street, which furnished an immense number of patients, was comparatively free from infection until a month afterwards. The disease appeared very soon in the prison (now taken down) in Arch-street, but as the inmates of the prison came in great part from the infected district, it is possible that the disease may have been introduced by those who were admitted while labouring under it. Towards the close of the epidemic, patients were admitted in considerable numbers from some of the streets in the Northern Liberties, and throughout its whole course there were scattering cases from different parts of the city, and a few from the country, where there was no others ill in the house from which the patient had come. But few cases, however, occurred in the central parts of the town, where the inhabitants are generally in easy circumstances and comfortably fed and lodged.

Classes of persons affected.—The first patients were almost exclusively from the poorest and most intemperate class of people, chiefly day-labourers. Such was the case with most of the blacks, especially the men, who were almost without exception in the habit of drinking freely of ardent spirits. The women were without fixed occupations, or were servants out of place. As the disease extended to the different parts of the city, people of various occupations were affected, amongst them there was a respectable physician, who died of the fever. The extension of the disease to those in easy circumstances, was shown in the practice of several eminent physicians of Philadelphia; they had not seen a case until the fever had prevailed some months at the hospital, although they afterwards met with it in their private practice.

Mode of propagation of the disease.—The origin of the disease is as unknown as most epidemics; according to the general rule, it attacked those who were

sunk in poverty and intemperance, and huddled together in confined apartments. It also appeared at different and remote points, some miles distant from the focus of infection, without the possibility of tracing any direct communication with those already attacked. There was, thus, a general cause, which extended its influence throughout the vicinity of Philadelphia. But, besides the epidemic cause, from which the greater number of cases seemed to arise, the fever was evidently propagated in a considerable proportion of patients by direct contagion. Those who entered at an early period of the epidemic came in groups together, some from the prison, whole families from the same room or the same house. About that time, I made a careful inspection of the district as one of a committee of the Board of Health, and in some instances we found houses completely vacated, the tenants being either dead or at the hospitals. In other cases, the whole or a large portion of the inhabitants of a room were ill. It was rare to meet with a severe case without seeing others in the same house.

The evidence of contagion at the Philadelphia hospital was more direct and conclusive. Three of the principal nurses, and about a dozen assistant nurses, besides a number of patients ill with various diseases were taken with the fever. The principal nurses belonged, two to the wards for blacks, where there were the greatest number of fever patients, and the third to a ward for whites, where there were several cases. There was only one nurse of a ward in which many of the patients were collected, who escaped, but several of his assistants and patients were taken ill. Two of the resident physicians in attendance in the same ward, where the patients were most numerous, were also severely ill with the fever. On the other hand, no nurse from the part of the hospital where there were but few or no typhus cases, suffered, and the number of patients taken ill in the surgical or lunatic wards was very small, not exceeding six in number. The wards in which fever patients were placed did not contain more than a third or a fourth of the population of the hospital, yet the number of cases originating in them after the first introduction of the disease was at least four times as great as in all the other parts of the building. The Alms-house and house of employment, which are separated from the hospital by a space of at least forty feet at the nearest points,

furnished five or six cases, probably not more than the same number of poor in any other part of the neighbourhood would have done.

The proportion of attendants upon the sick who suffered was in exact relation to the number of fever patients in the ward; thus in the wards for blacks (both men and women), and in the men's medical, No. 1, scarcely an assistant escaped. In the other medical wards a few were taken ill, and in the surgical and lunatic wards, all the nurses escaped. The matter of the contagion, be it what it may, was generally mingled with the air, but sometimes seemed to be combined with the pungent hot sweat of the patients. In some cases the contagion was evidently direct from body to body. This was established by the evidence of a nurse and an assistant, both persons of intelligence, and, from their familiarity with the disease, quite free from fear. The nurse was shaving a man, who died in a few hours after his entrance, she inhaled his breath, which had a nauseous taste, and in an hour afterwards was taken with nausea, cephalalgia, and ringing of the ears. From that moment the attack of fever began, and assumed a severe character. The assistant was supporting another patient who died soon afterwards, he felt the pungent sweat upon his skin, and was taken immediately with the symptoms of typhus. Two other cases of assistant nurses also originated from similar contact, but as they were persons of less intelligence, I have refrained from relating their cases as they offer less undoubted testimony. The wards in which the fever patients were placed, were large and well ventilated. We were at first disinclined to believe that the disease would prove contagious, but as soon as the fact was clearly proved, measures were taken to remove the patients not yet affected from most of these wards, and, if it had continued for a longer period, an efficient local quarantine would have been adopted. Dead bodies either did not communicate the contagion, or its influences was easily counteracted by favourable circumstances. Both Dr. Pennock and myself, and several of the resident physicians were engaged nearly every day during the most intense prevalence of the disease in making long and laborious anatomical investigations, without suffering from the fever.

It is very clearly proved, that the typhoid fever, or dothinerteritis, is not contagious. Dr. Louis informed me that, in the course of his long experience of the

disease, he had never seen a single case originating in an hospital. I have seen but one. The contrast between the fevers, in this respect, is obvious.—*American Journal of the Med. Sciences*,

PATHOLOGY, PRACTICAL MEDICINE, AND THERAPEUTICS.

On the Indications for the Use of Chlorine and Muriatic Acid Vapours in Diseases of the Air-Passages and Lungs.

By Professor ALBERS, of Bonn.

[In the years 1829, 1830, and 1831, Professor Albers instituted a series of clinical experiments in the Medical Hospital at Bonn, on the effects of chlorine vapours in phthisis, chronic bronchitis, and chronic pneumonia; these experiments were repeated in his private practice, during the years 1832 and 1833, and derived much value from the care taken to establish the diagnosis in every case with sufficient accuracy, a point to which very little attention had been paid by preceding writers on the subject.]

The chlorine vapour was applied in the manner recommended by Murray; or, instead of exposing the patient to vapour strongly impregnated with chlorine, for the space of a few minutes at different times in the day, he was kept the whole day in a chamber filled with very weak chlorine vapour. The vapour was produced by boiling chloride of lime and then heating it in a large dish, or by sprinkling it with muriatic acid; sometimes it was generated by pouring sulphuric acid on culinary salt. The following cases exhibit the results of Dr. Albers' experience.

Case 1.—A woman, aged forty-seven, of consumptive habit, and born of parents who died of consumption, was admitted into the hospital in January, 1830. Her symptoms were, cough of twelve months standing, progressive emaciation, hectic, great dyspnoea, copious expectoration of tubercular matter streaked with blood, sharp rapid pulse, anorexia, and constipation. She had pectoriloquy and mucous rhonchus under both clavicles, absence of the respiratory murmur at some spots, and bronchial respiration at others; respiration normal in the lower part of the right side only. There could be no doubt of the existence of phthisis in this case.

As soon as the hæmoptysis had ceased

under the use of acetate of lead and nitre, the patient was exposed to the chlorine vapour for the space of fifteen minutes four times a day. On the third day, she complained of violent constriction of the chest, copious expectoration, and stitches in the side, and was obliged to omit the use of the vapour. Two days afterwards the experiment was again repeated, but had to be discontinued a second time from the same cause. The only effect observed, was a diminution in the frequency and hardness of the pulse. During the use of this remedy she had observed a mild nutritious diet. She died five months afterwards.

Case 2.—A man, aged twenty-six, was admitted into the Medical Clinic in February 1831. His symptoms were cough of two years standing, (said to have arisen after exposure to cold,) latterly increased, and accompanied by expectoration; fixed pain in a circumscribed spot between the fifth and sixth ribs on the right side, about three fingers' breadth from the sternum; occasional attacks of dyspnoea, ending in copious expectoration of clear viscid mucus mixed with firm globular masses streaked with blood; habit of body normal; slight emaciation. Over the spot already noticed, sonorous and sibilous rhonchi were alternately heard; on the left side, the respiratory murmur was nearly natural; on the right side, particularly at the upper part of the chest, it was feeble, and bronchophony was heard at the spot where sibilous rhonchus was present. The diagnosis here recorded was "ulceration of the bronchial tubes, with a healthy state of the parenchyma of the lungs." Under the use of cupping, blisters, and expectorants, the pain disappeared, and the respiratory murmur in the right side became clear, but the cough and expectoration continued, with a slight sibilous rhonchus. The patient remained for a few minutes, four times a day, in a chamber abundantly filled with chlorine vapour. On the first day, he had violent constriction of the chest at each inspiration; on the second he was somewhat easier, but on the sixth his breathing was so much oppressed that he thought he should be suffocated, and the expectoration stopped. He was afterwards cured by other means.

Case 3.—I. J., aged twenty-six, born of healthy parents, and without any sign of the scrofulous diathesis, except a few swollen glands in the neck, placed himself under the care of Dr. Albers in 1831. For the last six months he had laboured

under cough, at first dry, but afterwards attended with expectoration of greyish, fetid, tubercular matter; he had pectoriloquy under the left clavicle, and the usual signs of tubercles in the second stage, but no pain in any part of the chest. After having used the ordinary remedies for a fortnight, he was kept the whole day in a chamber filled with weak chlorine vapour. He suffered considerably at first from constriction of the chest, although there was no diminution of the cough or expectoration, but subsequently bore the vapour extremely well, and remained in it for twenty-three days without any remarkable inconvenience. During this period there was no diminution of his symptoms; the expectoration became more copious, and lost its fetid odour, and pectoriloquy became developed under the right clavicle also. Shortly afterwards, he was attacked with colliquative diarrhoea and died. Dissection exhibited tubercles in all stages, and ulceration of the intestines.

Case 4.—A man, aged forty-six, who had been two years under treatment in the medical clinic at Bonn, and who exhibited all the signs and symptoms of tubercular disease of the lungs in third stage, was exposed to the chlorine vapour in the manner already described. At first, the inspiration of the vapour was distressing, but afterwards agreed very well with the patient, and he continued to use it for the space of five weeks without any intermission. The expectoration became more fluid and less fetid, the hectic paroxysms less regular, the pulse less excited, and the nights were passed more easily; the local symptoms, however, continued unchanged, and the patient sunk two months afterwards under the usual colliquative diarrhoea.

Case 5.—A man, aged thirty-three, who had laboured for six months under cough with copious expectoration of thick yellowish matter, placed himself under the care of Dr. Albers. His symptoms were dyspnoea, increased by motion; emaciation, occasional pains in the chest, and cough, which was so violent at night and in the morning that the patient was afraid of being suffocated. The stethoscopic signs were bronchophony over the whole of the right side, bronchial respiration, and mucous rhonchus at various spots in the same side, and clear sound on percussion. His appetite and digestion were good, and he had no hereditary tendency to phthisis.—*Diagnosis:* Dilatation of the bronchial tubes.—The patient was exposed

to a very weak vapour of chlorine, which he bore tolerably well for the first day; but on the second, he suffered great distress of respiration, and on the third the expectoration stopped, and his symptoms became so violent that he was obliged to give up the remedy. After eight days, during which the patient was brought back to his former state, a second experiment was made, but was followed by the same result; the sense of constriction and suffocation was so great, that the man could not endure it, and the use of the vapour was wholly abandoned. The patient died some time afterwards, and on opening the body, the lungs were found healthy, and the bronchial tubes generally dilated.

Case 6.—A man, aged twenty-two, and previously healthy, was attacked in the winter of 1831, after hard labour, with violent pain in the right breast, increased during motion and inspiration, dyspnoea, and short cough, accompanied by scanty expectoration, at first of a dark brown, but afterwards of a bright red colour. He was bled three times, had forty leeches applied to the right side of the chest, and used several mixtures with more or less relief. After some days the cough increased, and he began to expectorate a fetid matter of a yellowish grey colour; his fever diminished, but the dyspnoea and sense of constriction in the chest remained, with occasional stitches in the side. Under these circumstances he was admitted into the medical hospital at Bonn, and presented the following train of symptoms:—Chest well formed, right subclavicular region somewhat less prominent than the left, and tender on pressure respiratory murmur distinct in the whole of the left lung anteriorly and posteriorly; on the right side, it was absent in the subclavicular region; over the remainder of the right side it could be heard distinctly. When the respiratory murmur was absent, mucous and cavernous rhonchi were heard, and pectoriloquy, circumscribed to a small spot. Decubitus on the back or the left side brought on violent paroxysms of coughing; the expectoration was greenish yellow, very fetid, and occasionally streaked with blood; the patient had regular attacks of hectic every afternoon, his pulse was always hard and frequent, his strength greatly diminished, and he appeared to be considerably emaciated.—*Diagnosis*: an ulcerating vomica in the upper lobe of the right lung. Under the use a mild

diet, the constriction of the chest and bloody expectoration disappeared, and it was then determined to expose the patient for a few minutes each day to the vapour of chlorine. The first two turns, the patient was unable to remain in it longer than a minute or two, in consequence of cough and sense of suffocation produced by it, but by degrees he began to bear it better, and at the end of three weeks was able to remain a quarter of an hour in the room six times a day. During this period, the fever diminished, the cough became less violent, the patient's appetite returned, and the night sweats disappeared; the expectoration however remained the same, except that it contained less mucus. The patient became now anxious to return home, and left the hospital. In 1835, Professor Albers heard from a physician in the patient's neighbourhood, that he had progressively improved after he left the hospital, and was able to serve in the Landwehr without any further inconvenience.

Case 7.—A girl, aged twenty, and born of healthy parents, was attacked, in November 1830, with febrile symptoms, accompanied by dyspnoea, flying pains in the whole of the left side of the chest, hard short cough, and bloody expectoration. Under the use of local and general depletion, the pains diminished in violence, but the cough became increased, and she continued to have copious expectoration of yellowish green matter, mixed with air bubbles, and streaked with blood. When seen by Dr. Albers, she seemed considerably emaciated, and exhibited indications of the scrofulous diathesis; but she had no fever, and her sleep and digestion were normal. Her pulse was hard, her cough violent night and morning, at other times less troublesome; expectoration copious, fetid and of a greenish yellow colour, sinking in water; decubitus on the right side always produced severe paroxysms of cough. The left mammary and subclavicular were tender on pressure; at this spot, a distinct bubbling sound was heard, and bronchophony was slightly audible in the morning, but distinctly in the evening after copious expectoration. The respiratory murmur could scarcely be heard over the whole of the upper part of the right lung; in the left lung, the respiration was puerile.—*Diagnosis*: Ulcerating vomica, with inflammation of the surrounding pulmonary tissue. As the patient exhibited a great tendency to hæmoptysis, she was bled, took nitre,

and used an antiphlogistic diet, until the expectoration no longer showed any streaks of blood. She was then exposed to the chlorine vapour, which, in the beginning, she could only bear for half a minute at a time, but subsequently was able to breathe it for an hour, three times a day, without inconvenience. Under this treatment the expectoration became diminished and lost its fœtid odour; the cough improved, and the mucous rhonchus disappeared, but the pectoriloquy remained. After using the chlorine vapour for six weeks, the quantity of expectorated matter was scarcely one-sixteenth of the original amount, she had hardly any cough, and the expectoration was quite free. She then went to the country and used a milk diet, and when examined again by Dr. Albers, in August, 1831, she was free from cough and expectoration, and capable of pursuing her ordinary employments. At the spot where pectoriloquy had formerly existed, there was still an indistinct bronchophony, and in the surrounding parts the respiratory murmur was very feeble. In other respects, the lung was quite natural.

The following are the conclusions deduced by Professor Albers from the results of his experience in numerous cases:

1. Chlorine acts as stimulant, but when the remedy gets into the blood, its effects are antiphlogistic. Its effects as a local stimulant are observable in every one of the foregoing cases. It produces a tickling sensation in the eyes, nostrils, and throat, and sense of roughness and constriction in the chest. If the throat of an individual who has been exposed for a long time to the vapour of chlorine be examined, it will generally be found of a deeper red than natural. These and other facts are sufficient to prove that chlorine vapour operates as a local stimulant. It is on this account more remarkable that chlorine when it gets into the blood, exercises an influence of directly an opposite nature. It diminishes the frequency of the pulse, calms excitement, and produces effects which may be termed antiphlogistic. This difference of effect, however, before and after the remedy gets into the blood, is not peculiar to chlorine; it is common to many remedies of an antiphlogistic character, and is observed in nitre, tartar emetic, and many of the neutral salts. When there is no hæmoptysis or violent local irritation present, chlorine inhalations may be used in diseases of the lungs and air passages; its stimulant

effect gradually diminishes, and after some time the mucous surfaces of the lung become less sensible to its exciting influence.

2. In tubercles of the lungs, in chronic catarrh, in chronic inflammation and ulceration of the bronchial mucous membrane, and in dilatation of the bronchi, chlorine vapour is of no service, and in most cases will not be borne, in consequence of the irritation it produces. On the other hand, it has a very salutary operation in pure ulceration of the lungs or vomica. This state, however, is not to be confounded with suppurating pneumonia, to which the use of chlorine vapour is not so applicable. How far patients labouring under disease of the lungs may be adapted for using this remedy cannot be determined; much will depend on general irritability and individual disposition, and the chlorine vapour should be always tried experimentally at first.

3. From the foregoing observations it appears, that chlorine vapour produces salutary effects in chronic ulcers of the lungs; this agrees with the results obtained in surgical practice from treating old ulcers with the solutions of chloride of soda and chloride of lime.

[The experience of Professor Albers coincides in some points with that of Dr. William Stokes, of Dublin. Dr. Stokes has always found chlorine inhalations prejudicial in phthisis, producing in all cases increase of bronchial irritation, dyspnoea, and arrest of the pulmonary secretion. In his trials of this remedy in gangrene of the lung, of which an interesting detail will be found in the fifth volume of the Dublin Hospital Reports, he has found it decidedly beneficial, correcting the fœtor of the breath and expectoration, and therefore calculated to obviate, not only the local, but also the constitutional symptoms connected with such a state of the lung.]—*British and Foreign Medical Review*.

THYMIC ASTHMA OF INFANTS.

Thymic asthma of children is more common than is generally supposed to be. Who has not seen infants come into the world with difficult respiration, and live only a few weeks or months, without being able to get the better of this affection? No pains were taken to ascertain the

cause of their death, life is so uncertain immediately after birth. The lost child was compared to a plant which could not take root.

Nevertheless, it was evident that the cause of dissolution was in the air passages, the disease bearing great resemblance to Millar's asthma, although its progress be slower, its attacks more frequent, and of shorter duration.

Dr. Marsh, of Dublin, having seen a child expire from suffocation, attributed its death to spasm of the glottis; but it was only a conjecture, which he did not attempt to verify by a post mortem examination. He did not think of the thymus, which only necessary to intra-uterine life, was to be effaced, or scarcely leave signs of its existence after birth. Dr. Marsh was mistaken.

Mr. Hood opened six children, victims of this spasm; found the glands of the thymus of an normal size.

The publication of these pathological cases attracted the attention of observers; researches were made in scientific books, and in the works of Reicha and Vedries, written a century back, it was said that the asthma of children often originated in *hypertrophy of the thymus*. Since then, Dr. Frank has shewn that infantine asthma is often caused by extraordinary swelling of bronchial glands, and of the thymus.

In 1810, Dr. Brera verified this assertion on a child, a few weeks old, suddenly suffocated. Had the body not been opened, its death would have been attributed to Millar's asthma, so great was the similarity; but for what we know respecting this disease, that may be considered satisfactory, we are indebted to Dr. Koop, who has collected a great number of cases in his own practice, as well as in that of four of his brother practitioners; of which he composed a memoir, and read it at the academy of Heidelberg.

The characteristic symptoms he pointed out, were:—1st. Periodical suspension of respiration, accompanied by acute scream and great anxiety. 2nd. The return of fits of suffocation when the child awakes, screams, and tries to swallow. 3rd. The tongue being put out, and passing the lips permanently. 4th. The *trismus*, which is joined to these three symptoms, and terminates in death. Such is the form of infantine asthma. Dr. Koop attributes the disease to the extreme development of the thymus, whose size weighs on the air passages, and the centre of the circulation.

Dr. Brera fully coincided with Dr. Koop, appreciated the value of these symptoms, and gives a full exposition of organic alterations; enumerates the remedies proposed by clinical practitioners, and says, that thymic asthma attacks children of three weeks, and more frequently those from four to ten months, till a year and a half old.

The noise of the inspiration is analogous to that of the inspirations in hooping cough; only it is more acute, more piercing. Children breathe five or six times, and the same noise is heard before they make an expiration, which is as noisy as in violent attacks of asthma; respiration is suspended, and if the child be not immediately suffocated, the acute cry is heard each time the little patient breathes till the respiration becomes free.

Accessory signs.—The other signs generally met with have nothing remarkable; they depend on difficulty of respiration, such as are seen in hysterics and asthma. Thus the body is thrown back; the face drawn, it is livid, then becomes pale; the nostrils are in motion, the eyes fixed, the hands cold, the thumbs drawn back, the excretions sometimes involuntary. The attack may last one, two, or three minutes; when it is over the child moans, and feels uncomfortable, but soon regains its usual temper, though it continues pale, is oppressed, and shows an inclination to sleep.

If you compare one of these young patients with children in good health, you will recognize it by its tongue being continually out of its mouth; and during the intermission of attacks, the motion of the heart is not distinctly felt. Any effort of respiration made by the child, either by screaming, laughing, swallowing rapidly, or even yawning, may bring on suffocation.

In the first instance, the fits occur every eight or ten days; they gradually become more frequent, and as many as twenty in four and twenty hours sometimes take place.

It is by no means uncommon to see the poor little patient perish as though it was struck by lightning; though infantine asthma mostly takes a chronic character, and terminates in epileptiform convulsions. The muscles, *lumbricales* of the hands, and the adductor of the thumbs, remain contracted. There is much to fear from the age of three weeks to twenty months; the symptoms preceding death are those of apoplexy, and asphyxia.

Where is the seat of the disease? The

nature of the symptoms of the disease, and the suddenness of death, could only tend to a supposition, before the scalpel was used, and made this discovery; all the phenomena of life emanate from the circulation of the blood, respiration, and innervation. The encephalus and its appendages, have a direct influence on the heart and lungs, which receive from them a similar impulse. These three organs perform their functions in mutual dependence, and form between them a compact union. If we examine the phenomenon of life, we shall find it proceeds from the encephalus to the heart by the nervous fluid; the blood impelled by the ventricles of the heart is the vehicle of life; and the lungs, by means of the air breathed, assist in reviving the blood. Thus do these three masterpieces act; they give a general impetus, and constitute life; each of these functions necessitate the action of the other, and cannot exist separately. If there be absence of air in the lungs, or absence of blood in the heart, or want of nervous fluid in the encephalus, death is the immediate consequence; the subject may pass, without warping, from health to death.

The practitioner might, therefore, foretell when he saw a child die suddenly, just as it awoke from sleep, or after laughing or gaping, that the primitive or consecutive cause of death, was in the alteration of the brain, heart, or lungs; and, in fact, the skin is livid, there are stases of blood in the brain and lungs; the heart is flabby and sometimes retains *le trou de Botai*; but the most constant and essential alteration is hypertrophy of the thymus; that is the root of the disease; the excessive development of this gland is both in length and breadth, and mostly in thickness. The lungs are repressed, pushed backwards, and applied against the arterial trunks, venous or nervous, with which they contract adherences, more or less extended to the neck and chest. It has been more than once observed, that the mass of thymus with edged borders embraced and strangled the organs.

The tissue of this gland is sometimes in a normal state, but more frequently hard, and red, without any appearance of inflammation, carnification, or any other degenerescence; if cut in two, a milky fluid escapes. Its weight varies from six or seven grains to an ounce.

Dr. Brera has seen the thymus two inches wide, extend from the thyroid gland, to the diaphragm, and in course strangle the trachea, the lungs, the heart, the ves-

sels, the nerves, &c. Another time, it was found adhering to the same gland, and covering the whole heart, so that the motion of this organ was very much restricted, indeed, nearly extinct. In a third case, the thymus was so lengthened, that it surrounded and strangled the jugular veins, the innominate and carotid arteries.

The prognostic is always alarming. There are no preventive means, and the disease left to itself, must terminate fatally. But our author thinks, that by assiduous care in the first instance, there may be hopes of arresting the disease. During the attack the child should be bent forward, and gently patted on the back, to facilitate the respiration; if the pulse be gone, efforts are made to restore circulation; the patient is placed horizontally, and cold water dashed on the face. In cerebral congestion, leeches are applied on the sides of the neck, and towards the superior intercostal spaces. After the fit, the spasms are relieved by small and gradual doses of laurel water, tincture of assafoetida, or musk, and cyanure of zinc.

When the child is strong, the seat of the disease, or the morbid condition of the thymus, is medicated by means of frequent local bleedings, energetic purgatives, either with laurel water, or hydrocyanate of morphia. With delicate children, bleeding and purgatives must be more scarce, and antispasmodics will be found preferable: for instance, the 20th part of a grain of musk, and acetate of morphia, three or four times a day. Regimen is the most to be depended on as a remedy for hypertrophy of the thymus, provided it be supported by derivatives and resolutes. Thus, benefit has been derived from stibiated pomatum, spread on the sternum; muriate of barytes, as a salve, is still better; and while either of these are applied, a blister should be put on one arm to day, and the next day on the other, without using cantharides. Internally, antimonials joined to mercurials, iodine, prepared charcoal, extract of hemlock and sunflowers, and preparation of gold.

The practitioner of Padova, relates three cures obtained in this manner; two in 1831, and the third this year. To justify the title given to this paper, it should be modified, and we ought to say, that thymic asthma was known, but reputed incurable, previously to Dr. Brera's publication.—*Continental and British Medical Review.*

NOTES OF LECTURES ON
PHYSIOLOGY.

THERAPEUTICS.

Revulsive remedies—Acupuncture— Opinions of Roche, Sanson, Cloquet, Dantu and Pelletan—Its abstraction of galvanism—Its connexion with animal magnetism—Its influence on the passions—Nothing really abstracted by acupuncture—Needles of steel and other metals—Wallace and Dupuytren on the stimulant effects of acupuncture—Not dependant on sensation—Collyria, gargles, and lotions in superficial inflammation—Caloric, electricity, and acupuncture in deep-seated inflammation—Their direct action—Indirect operation of epispastic remedies—Primary and secondary irritation—Irritation conveyed by sympathy—Nature of sympathy—Sympathetic flow of tears from irritation of the nostrils—Production of sneezing—Sympathetic contraction of the iris—Mechanism of setting the teeth on edge—Production of hæmorrhage of the gums—Production of coughing, salivation, and vomiting—Mechanism of respiration—Cause of hiccough—Laughter and convulsions from tickling—Influence of sympathy in health and disease—Cause of dyspepsia and gastritis—Operation of a stimulus in ophthalmia and orchitis—Beneficial effects of purgatives in inflammation—Caut of keeping the bowels open—The stools the least copious of all the excretions—Modern disease of diuretics—Dr. Pitcairn on diaphoretics—Greater effects of a day's sweating than a week's purging—Horse jockies in training—Vellication, urtication, sinapiams, and blisters—Counter-irritation—Unsupported dogma of Hippocrates—Improbable assumption of Darwin—Stimulant effects of

tonics in inflammation—Revulsive remedies are stimulant—Do good by the stimulus, and not by the discharge—Astringent medicines—All medicines astringent—Purging by astringents—Intestinal and urinary astringents—Stimulant and tonic medicines—Difference between them—Effect of stimulants and sedatives on the brain—State of the brain in phrenitis and apoplexy—Action of mercury and antimony—Vegetable and mineral tonics—Different way in which they should be prescribed.

What we have said of the action of heat, may be said with equal propriety of the action of electricity, and perhaps more decidedly still of that of acupuncture. The wonderful advantage derived from this remedy, in some case of inflammatory disease, has been described at one time (as by Roche and Sanson), to its withdrawing a portion of the nervous fluid from the part affected; at another (as by Cloquet, Dantu, Pelletan, and others), to its abstracting galvanism; which, according to certain physiologists, is the same thing as the "nervous fluid" of the former authors. The effects of acupuncture have sometimes been ascribed (as by the modern followers of Mesmer) to its exciting animal magnetism; and at other times (as by some of our British Journalists) to its operating upon the passions of the patient. Of these explanations, if such they may be called, the two first proceed upon the erroneous assumption, that something must necessarily be abstracted from an inflamed part, instead of added to it, in order to effect its cure. But, moreover, they fail in demonstrating that any abstraction whatever takes place in acupuncture. The evolution of a nervous fluid, distinct from galvanism, is altogether inconceivable; and the evolution of galvanism is found to happen only when the needles are of steel; whereas, the advantage of acu-

puncture is equally great when the needles are of any other metal. Galvanism, beside, is not evolved more freely from an inflamed, than from a healthy part. The third explanation, (that of animal magnetism,) is altogether untangible by persons of ordinary intelligence; and to the fourth (that which ascribes its efficacy to the passions) it may be objected, that there are some persons on whose minds the insertion of the needles makes little or no impression, and yet they are equally benefitted by the process. The explanation suggested by Wallace, and adopted by Dupuytren, is unquestionably the true one; that acupuncture operates, in inflammatory diseases, as a direct and strong stimulus. An exception has been taken to this solution;—that the advantage derived from the remedy, is more than commensurate with the sensation it excites. But this objection is not at all worthy of those who have advanced it, since it obviously confounds irritation with sensation; two functions which, however intimately connected, can never be made, in any degree, a measure of each other.

It appears, then, that collyria, gargles, and lotions (in cases of superficial inflammations), and caloric, electricity, and acupuncture (in cases of deep-seated inflammation) operate advantageously by communicating a stimulus to the affected vessels. Can we doubt, then, without great incon-istency, that when, instead of caloric, electricity, and acupuncture, epispastic remedies have been employed, they operate by effecting, indirectly, that which the remedies first spoken of effect directly? And if this be the case with respect to medicines applied to the neighbourhood of the part affected, it requires but very little extension of the same principle to persuade us that such is the case also with respect to all other remedies called revulsive; and that under their operation, it is always by sympathy with the parts primarily irritated, that capillary vessels, dilated by inflammation, become contracted.

It is quite unnecessary to enlarge here upon the nature of sympathy, or to investigate the means by which a primary irritation of one part, becomes a condarily a stimulus to another part. That such really is the case is indisputable, whether we can explain it or not; and the mere admission of the fact is quite enough for our present purpose. Thus, even in health, a primary irritation of the nostrils, frequently becomes a stimulus to the capillary arteries of the lachrymal gland, so

as to produce a flow of tears; and a similar primary irritation of the same organ (the nostrils), or even of the eye, may become a stimulus to the muscles of the soft palate and of the abdomen, so as to produce sneezing. A primary irritation of one part of the eye (the retina), always so far stimulates the muscular or erectile tissues of another part (the iris), as to occasion a contracted pupil; while a primary irritation of the ear, sometimes so far stimulates the capillary arteries of the gums, as to effect what is commonly called "setting the teeth on edge," or even to produce hæmorrhage. In like manner, a primary irritation of the external auditory canal, or (what is much more common) of the larynx, often becomes so great a stimulus to the muscles of the glottis and of the abdomen, as to excite coughing; and a similar primary irritation of the mouth or fauces, may so far stimulate the capillary arteries of the salivary glands, or the diaphragm, the abdominal muscles, and the muscular coat of the stomach, as to excite a flow of saliva on the one hand, or vomiting on the other. It is probable, also, that on a primary irritation of the lungs, depends the stimulus of those muscles by which natural respiration is effected; and while a primary irritation of the diaphragm may become a stimulus to those muscles by which the lower jaw is depressed, so as to produce yawning; a primary irritation of the stomach may, on the other hand, so far stimulate the diaphragm, as to occasion a hiccough. Lastly, a primary irritation of the arm-pits, or soles of the feet, is familiarly known so far to stimulate the muscles of the glottis, the respiratory muscles, and most of the voluntary muscles of the body, as frequently to give rise to uncontrollable laughter; and almost to general convulsions.

But if instances of sympathy like these are numerous in health (and many more might have been cited), they are much more numerous in disease. Of these it may be sufficient, in this place, to call to mind how often any primary irritation of the stomach and bowels, becomes a stimulus to the capillary arteries of the nostrils, eyes, ears, and other organs, so as to produce in them innumerable diseases; and how often an irritation of the liver, kidneys, or uterus, becomes, in the same way, a stimulus to the stomach, so as to produce dyspepsia or gastritis.

Whatever, then, may be the nature of sympathy, or the means by which it is conveyed, its existence is as certain as

that of any stimulus in nature; and it is surely more reasonable, after what has been said, to conceive, that when an emetic operates in suddenly removing ophthalmia or orchitis, it does so by communicating, through the stomach, a strong though indirect stimulus to the affected vessels; and not by abstracting any stimulus from them, or by counter-irritation, or by producing an evacuation or new determination of blood. In like manner, in the more numerous instances of inflammation in which purgatives are beneficial, we may, with justice, ascribe their effects to a similar cause; for purgatives are more generally useful than any other class of reputedly revulsive remedies, only because a greater number of organs sympathize with the bowels than with any other part of the body. The common cant of "keeping the bowels open," the propriety of which is so reiterated in almost every disease to which the body is liable, seems to me very inadequately to express the real object we should have in view, in the administration of purgative medicines; or the real nature of the service which they commonly afford us. To say nothing at present of counter-irritation, it is not easy to understand why nature should be habitually more tardy in her operations in the intestinal canal than elsewhere; or why it should be necessary for physicians to look so narrowly after the discharge of the stools (which are incomparably the least copious of the natural excretions of the body), while all the rest are allowed to shift for themselves. There will be but little doubt on reflection, I imagine, that the increased evacuation produced by purgative medicines, is, in general, rather an accident attending their operation, than the source of the benefit derived from them. Diuretic medicines are but rarely used in modern times, in the treatment of strictly inflammatory disorders; but with respect to diaphoretics, it is certain, as remarked by Dr. Pitcairn, that more may be done in the way of depletion, by doubling the quantity of halitus from the skin, for one day, than by doubling the stools for a fortnight. The truth of this is proved every day by horse-jockies, in the process of reducing their weight. But whether the advantage of these medicines, in the cure of inflammation, depends on the evacuation or new determination of blood which they produce, may, with great reason, be questioned. The greater quantity of fluid lost by perspiration in such cases, is in general compensated for by the more copious

potations in which the patient indulges, so that the blood really loses little by the increased discharge; and that little, so slowly, that no sensible relief can be presumed to be thus afforded to the oppressed capillary arteries. But the preternatural irritation of the whole surface of the body, which attends upon this inordinately increased secretion, cannot be regarded as inert, with respect to the numerous organs with which this surface so intimately sympathizes; and in the stimulus thus conveyed to the inflamed part, most probably consist all the advantage which is derived from diaphoretic medicines.

But whatever we may think of the action of internal revulsive remedies, in the cure of inflammation, the action of epispastics, in all their various forms, applied to the neighbourhood of the inflamed part, can hardly be disputed. It was long ago observed, as I before remarked, that the advantage resulting from these remedies, in inflammatory disorders, was often in no degree proportioned to the evacuations which they occasioned. The old remedies of vellication or urtication, for example, or a sinapism, although they produced no discharge at all, were often found to be equally effectual in relieving the inflammation of a deep-seated part, as a blister which drew off some ounces of fluid. It was with reference principally to this effect of epispastic remedies, that the axiom above alluded to was established; by which remedies since called revulsive were sometimes made to operate, by withdrawing a stimulus from the inflamed parts. But inflammation consists essentially in diminished irritation; and therefore it is absurd to look for its cure from remedies the effect of which is still further to diminish it. Besides, it is quite inconceivable how counter-irritation can have that effect; or how the production of an irritation in one part of the body, well adapted to convey a stimulus to other parts, can have the effect of abstracting a stimulus from them. The unsupported dogma of Hippocrates on this subject, explains nothing; and it was to reconcile the supposed action of counter-irritants, with the sympathetic irritations just mentioned, that Darwin and others thought proper to presume that as there was between some parts a direct, so there was between others an inverse sympathy; in other words, that as the irritation of some parts was calculated to communicate a stimulus elsewhere, so the irritation of other parts, on the contrary, was calcu-

lated to abstract one thence. But who can be satisfied to adopt so strained and compromising an assumption as this, and one, moreover, which is so utterly improbable, in order to explain facts which admit of so unforced and consistent an application without it. It appears unnecessary further to insist upon this explanation with respect to epispastic remedies, and equally unnecessary to prosecute the subject through the remaining classes of errhines and sialogogues; since with respect to these also, arguments will readily suggest themselves nearly the same as those which have been already adduced, in favour of the presumption, that the beneficial operation of all the previously mentioned classes of remedies, in inflammatory diseases, depends on the stimulus which they communicate to the inflamed vessels.

It would contribute to strengthen considerably the opinion I have here adopted of the action of the remedies called revulsive, in inflammation, to urge the highly efficacious employment, in some cases of this kind, of tonic medicines the action of all which, in such cases, is indisputably that of stimulants. As examples of this kind, might be cited the action of cinchona, iodine, the muriates of lime and baryta, iron and arsenic, and the action of mercury in some stages of the inflammation of almost every organ of the body. The extent, however, to which we have already pursued the subject, prevents our enlarging.

The question at issue is not one of mere speculation, but involves practical consequences of considerable importance. It is obvious that very different rules will be requisite in the administration of the remedies called revulsive, if their beneficial action be that of effecting an evacuation or new determination of blood, or of *withdrawing* a stimulus, from those which will be proper if their beneficial action be, as above assumed, that of indirectly *communicating* a stimulus. In no examination of these rules, however, we must decline entering at present, since we shall have abundantly fulfilled the object we proposed to ourselves, if we have succeeded in simplifying a subject which has always been involved in much obscurity, and have rendered at all probable the doctrines we have advocated. These doctrines are, that the operation of all remedies reputedly revulsive, is decidedly stimulant; and that the remark of the sagacious Stoll with respect to blisters, "non suppuratio, sed stimulus pro-

dest," is equally true of all the other remedies in question.

2. *Astringent Medicines.*—Astringents differ from evacuants, only in the stage in which their effects are displayed. All medicines must constrict at first, and alum and kino, which are very powerful astringents, produce purging if given largely. The resins, balsams, and turpentine, act on the mucous membrane of the urinary passages. Dr. Home is fond of uva ursi for this purpose. Kino (*ptero-carpus erinaceus* and *encalyptus resinifera*) and catechu (*acacia catechu*) act on the mucous membrane of the intestines. The acetate of lead is a very quick astringent, and is purgative in large doses. Besides those we have mentioned, the principal astringents of the British pharmacopæias are the sulphates of copper and zinc, the muriate of iron, the nitrate of silver, sulphuric and acetic acid, oak-bark (*quercus robur*), cinnamon-bark (*laurus cinnamomum*), great water dock (*rumex aquaticus*), galls (*quercus infectoria*), willow tree bark (*salix alba, fragilis, or caprea*), ash-tree bark (*ulmus campestris*), Venice turpentine, mahogany-bark (*swietenia mahogani*), horse chesnut-tree bark (*esculus hippocastanum*), rhatany-root (*krameria triandra*), gum arabic (*acacia vera*), logwood *hæmotoxicylon campechianum*, herb bennet (*geum urbanum*), agrimonia (*agrimonia eupatoria*), the red rose (*rosa gallica*), septfoil (*tormentilla erecta*), the purple willow-herb (*lythrum salicaria*), the pomegranate (*punica granatum*), red bark (*cincina rubra*, or *oblongifolia*), madder (*rubia tinctorum*), great bistort, or snake-weed (*polygonum bistorta*), and rhubarb.

3. *Stimulant and Tonic Medicines.*—Their mode of action is probably not essentially different from that of the first class—the evacuants. Stimulants and tonics increase the quantity of blood in the vessels of the grey matter of the brain, and they differ from each other only in the length of time their operation lasts, for stimulants act quickly, and are soon followed by reaction. In phrenitis there is too much blood in the grey matter of the brain; and the same effects are produced by all stimuli. In apoplexy there is too little blood in the grey matter, and the same effects are produced by all sedatives. Mercury acts as a tonic in ophthalmia, ptyalism, hepatitis, dropsy, dysentery, cholera, cynanche, in fact, in almost all inflammations. It is said to act by equalizing the circulation, but it must be by emptying the vessels, and stimulating

them to contract. Antimony also acts by evacuation. Vegetable tonics are given in large doses, at short intervals; mineral tonics are given in small doses at long intervals. The vegetable tonics are—colomba root (*menispermum palinatum*), quassia and simaruba bark (*quassia excelsa* and *simaruba*), augustura bark (*bonplandia trifoliata*), pale bark (*cinchona officinalis*), chamomile flowers (*authemis nobilis*), wormwood (*artemisia absinthium*), southernwood (*artemisia sanctonica*), tansy, the blessed thistle (*centaurea benedicta* or *criscus benedictus*), gentian root (*gentiana lutea*), buck-bean, the Carolina pink, and the smaller centaury (*chironia centaurium*). The mineral tonics are arsenic, iron, zinc, copper, silver, tin, bismuth, and the muriates of lime, soda, and baryta.

The officinal stimulants are white and black mustard seed, horse-radish, scurvy-grass (*cochlearia officinalis*), the cuckoo-flower, or meadow ladies' smock (*cardamine pratensis*), garlic, the onion, the (*allium porrum*), the resin of guaiac (*guaiacum officinale*), the balm of Gilead, mastiche (*pistacia lentiscus*) chian turpentine, balsam of Tolu (*Toluiifera balsamum*), copaiba, balsam of Peru (*myroxylon Peruvianum*) storax and benzoni (*styrax officinale* and *benzoni*), gum-resin euphorbia (*euphorbia officinarum*), common turpentine, Venice turpentine, Canadian turpentine, and Chian turpentine, gum-resin, olibanum (*juniperus lycia*), Winter's bark (*drymis aromatica*), guaiac, rue, orange and lemon peel (*citrus aurantium* and *medica*), canella-bark (*canella alba*), seneka root, cajepout oil, cloves, pimenta berries (*myrtus pimenta*), pellitory root, bark, the bay, sassafras, camphor, the nutmeg, cascarrilla bark (*croton clementheria*), contrayerva, black and long pepper (*piper nigrum* and *longum* cubebs (*piper cubeba*), savine, wake-robin, ginger, cardamoms (*amomum cardamonium*), and sweet flag (*acorus calamus*).

injury fever shall arise in the system, which is universal sympathy, commonly called symptomatic fever.

Convulsions often arise from considerable local injuries called irritation. Permanent contractions are also often the consequence of local injuries or irritation, as tetanus.

If another mode of action takes place in the part sympathized with, namely, the cure of the injury, then the inflammatory sympathetic fever will subside.

Sympathetic Hectic Fever.—If parts have not a power to effect a cure, the constitution sympathizes in another way: it is teased, as if conscious that the disease is incurable; and this teasing constitutes the greatest part of what has been called hectic fever. But if this incurable part is removed, the hectic fever will cease.

I have seen a wound in the knee keep a man awake several nights with pain and constant purging, and the patient becoming hectic; and by amputating the part he slept well the same night without opium, the purging immediately ceased, and costiveness ensued. A man had a wound in the elbow-joint, and was affected exactly in the same way, the pulse became slower and softer.

This universal sympathy, of whatever species, is greater when certain parts are diseased. The sympathetic fever will more readily take place from an injury done to the involuntary parts, as the stomach, intestines, testicles, &c., than if the same mischief had been done to the voluntary parts, as the muscles of the arm, for instance.

When vital parts are diseased, there is more sympathy among vital parts than among others.

Universal sympathy is greater if the injury received is further from the source of life, namely, the heart, than near it, provided it be a part of the same nature in both cases.

Sympathy is similar to sensation, action, motion, &c.; it can, and often does, cease instantaneously. Every sympathy ceases after the cause is gone, although its effects may remain, as tumefaction.

Some parts of the Body sympathize more than others.—The stomach appears to have this connexion with the body more than any other part. It would appear that the stomach was the seat of universal sympathy, sympathizing with every part of the body, and most parts of the body sympathizing with the stomach.

Every part of the body seems to have

LECTURES ON SURGERY

By JOHN HUNTER, F.R.S.

Sympathetic Inflammatory Fever.

In consequence of considerable local injuries, as a compound fracture, or operation of consequence having been performed, that accident or operation shall be followed by inflammation, suppuration, &c. In consequence of this local

some susceptibility of sympathy; but although there is universal sympathy between the stomach and whole body, yet the stomach sympathizes more readily with a complaint in the head than with one in the toe; more with the testicle than with many other parts. Also some parts of the body sympathize more readily with the stomach than many other parts, as the head, skin, &c. The skin sympathizing with the stomach is often very evident, from the effect some food has on the stomach, producing disease of the skin. A glass of cyder in some shall produce a flushing in the face immediately; and spirits, in the end, we know, produce inflammation and suppuration over the whole face, called pimples, especially on the nose. But whether the stomach loses part of this property I am not certain. It appears that other parts lose that susceptibility to sympathize with the stomach, as the skin, for that part does not seem to be so readily affected in the old as in the young.

The stomach sympathizes with the skin in many of its affections. Cold or wet feet will immediately affect the stomach. But the most striking instance is seen in the leech when its stomach is full of blood, by throwing salt on it, when, from sympathy of the stomach with the skin, it immediately rejects all the blood.

The intestines, especially the upper parts, have also sympathies over the whole body. Cases of worms show this perhaps more than any thing.

Observations on Sympathies of the different Principles with one another, producing similar and dissimilar Sympathies.—Continued sympathy is more commonly similar than the remote, as it is an extension of the same action, and commonly in a similar part which can act alike, as indeed most parts do in most of their common actions, although the peculiar actions of the part may be dissimilar. Thus, chancre on the scrotum, if it was to spread to the testicle, would produce the same mode of action in the testicle as in the scrotum, though it might at the same time produce effects peculiar to the testicle, as stoppage of the secretion, &c.

But the remote, local, or partial, is both similar and dissimilar, varying according to two circumstances: 1st, According to the nature of the part diseased and the nature of the sympathizer. 2nd, According to the species of properties in each part; as one property in the part diseased producing sympathy in another property in the sympathizer; disease in one part

producing increased natural discharge in another part, which makes sympathy very complicated.

Let us take sensation as an illustration; although we have no sympathetic sensation, it being wholly delusive, yet sensation is an absolute guide. We know that the sensations in the brain are not similar to any other sensations in the body, at least not similar to many of them; also the sensations of the stomach are unlike to many of the brain, if not to the whole of them; also that many of the sensations of the stomach are not similar to sensations of other parts; also that all sensations of the stomach are not the same; also that an action of one part shall produce sympathy of another, whose mode of action is not similar; we must see therefore at once why the two modes of action become not similar, and why the sympathy is not similar to the cause, producing by this means another cause of complication, and consequently a variety in the first principles of sensation and action respecting sympathy. Again, difference of properties may produce dissimilar sympathies between two different principles, as the principle of life and that of action. For as sensation in one part may produce sympathy in a part whose actions are dissimilar from that other part, the sympathy produced will be dissimilar, and this resulting from the difference in the properties of the principle of action.

Also when we consider that many parts have more modes of action than one, as the stomach, which has a variety of actions, and of course is capable of producing a variety of sympathies in other parts, or can sympathize in a variety of ways with other parts, so that any one of these peculiar actions in one shall produce an action or sympathy in that suitable to the first action of the disease, which of course will be similar to the action of the diseased parts; while another action in the same part, and from the same principle, shall produce another mode of sympathy in the sympathizer; when we consider all these, they will at first sight appear inexplicable; as an illustration, we may observe what a variety of sympathies are produced from one mode of irritation, as teething, or worms in the intestines.

This connexion of every part of the body with the others, by sympathy, becomes one of the extensive principles of action in the animal economy, indeed is the basis of most of the compound impressions, affections, and actions.

Similar Sympathy.—Sympathy must

be similar to the affection of the part first affected when between parts whose affections are wholly similar; similar in action when between parts whose actions are wholly similar.

Sympathy may be similar in disease when between parts endued with a variety of affections and actions, provided they are endued with the same affection or action, as irritation in one part producing irritation in another, which thus produces inflammation, as an injection into the urethra producing swelling and pain of the testicle.

Continued sympathy, I believe, in all cases is similar to the disease, at least the action is so, even though it may spread to a dissimilar part. If inflammation attacks the diaphragm, and extends to the liver from continuity, that inflammation of the liver will be similar to that of the diaphragm. The same also if the disease extends from the testicle to the scrotum, &c.

Dissimilar Sympathy.—Sympathy is dissimilar when the affections or actions of the part impressed are not similar to the actions or affections of the part which sympathizes; thus, sickness at the stomach cannot produce sickness anywhere else; or, secondly, where parts diseased are susceptible of a variety of affections or actions of which the sympathizer is not; or, thirdly, even in parts where both the part diseased and the sympathizer are susceptible of the same varieties of stimuli and modes of action, which varieties in themselves are similar to one another, yet the sympathizer shall not be the corresponding affection or action to that which is excited in the part diseased; for example, a medicine taken into the stomach shall produce flushing of the face or inflammation, though the stomach is liable to the same disease as that of the face, namely, inflammation. So that in this case the difference does not arise from the mode of action being different from that of the stomach, only that the face does not run on to the same degree of action as the stomach. In inflammation of the liver the pain in the shoulder is different from inflammation, though the shoulder and liver are equally susceptible of inflammation. So that many parts have a variety of actions in themselves which are similar to some actions in other parts; therefore sympathy shall or shall not be similar to the action of the diseased part, being according to the stimulus applied to such part, or mode of action of the diseased part joined with the mode of affec-

tion. Therefore simple stimulus, action, or affection shall not only be the cause either of similar or dissimilar action, but both, according to the variety of affections and different parts that sympathize. A stimulus in the testicle shall produce sickness in the stomach, which shall produce vomiting, which is an action; so that a double and different compound sympathy takes place from the same stimulus.

Of the simplest Sympathies.—In vegetables we evidently see actions taking place in consequences of actions having taken place in another part; but how far vegetables have a variety of properties and actions is not perfectly known; however, we can hardly doubt that they have a great many, for they produce a vast variety of effects, all these actions and effects arising from the principle of life. So that sympathies of vegetables may be complicated, and even dissimilar, but still more simple than the most simple animal. The succession of motions in a sensitive plant are no more than a succession of sympathies, or a succession of stimuli in consequence of those preceding. Here, then, we have exact similarity in the actions of the sympathizers with the part first acted on.

The most simple sympathy is perhaps to be found in vegetables, these being much more simple than the most simple animal. Vegetables have the same properties as animals without brain or stomach. Take away, therefore, the sympathies of the stomach with the body, and of the body with the stomach, and those between the brain and the body, reducing the sympathies of the animal to the simple properties of life, and an animal will be exactly similar to a vegetable; and this I know from experiments made on trees.

The motion of the sensitive plant I have said is produced by a succession of simple sympathies: something like this may be found in the more imperfect animals; but no animal can be so simple in all its sympathies, though it may in some. I shall at present suppose that every part of an animal is liable to be affected by the stimulus of agreeable or disagreeable sensations, and the more simple the animal the more likely it is to be under the same simple sympathy. A polypus is the most simple complete animal, and therefore must be most similar in its sympathies; but I can conceive a child in the womb to be still more so, being capable of one stimulus only, namely, want in the system; and perhaps it has no sympathy

even with his, as it has no demand on any part of its body for the supply. This simplicity of stimulus is found not only in the simple animals, but in some degree also in the more complicated. The similar sympathies may be compared to the unison in sounds.

A polypus, though so simple an animal, is susceptible of four different stimuli, disagreeable and agreeable, propagation of the species, and want of repletion. In the last the stomach becomes the original sympathizer, and produces action in the other parts, so that here is a sympathy as in plants, but not so simple, for the stomach first sympathizes with the whole body when it wants repletion, and afterwards by a reflex sympathy the body is called into action and its little arms are erected.

Difference of Sympathies in the Sympathizer arising from difference in the mode of Impression.—Difference of affection and action of the sympathizer from that of the part affected does not always arise from difference in the nature of the two parts, but often from difference in the nature of the stimulant, or mode of impression; for a stimulant of one kind shall produce a mode of impression of its own kind in the part, from which shall arise a peculiar sympathy, while a stimulus of another kind will produce an impression of another kind, which of course will produce a sympathy of another kind in the part that sympathizes. Thus, when the stomach is stimulated in a particular way, the head shall ache, which is often the case when something is taken which disagrees with the stomach; and if stimulated in another way, the headache shall be removed, namely, by exciting vomiting. There will be, therefore, a variety in the actions of the sympathizer, arising from varieties in the specific modes of action, created by different stimulants, which may also produce similar sympathy in dissimilar parts, for parts very dissimilar in their natural actions shall be put into similar actions by sympathy. When the stomach is stimulated in one way, an action shall be brought on in the muscles of respiration and of the belly for the expulsion of the irritating matter; or if stimulated in another way, sweating shall be brought on in the skin; or if stimulated in another way, universal debility takes place; a blow on the stomach may even kill.

Hence it appears, that a stimulus of one kind produces sympathy in one part of the body, while a stimulus of another

kind applied to the same part produces sympathy in another part, each mode of action in a particular part having other parts distinct from each other which sympathize with it.

I should suspect that specific inflammations are not able to give to the sympathizer their specific virtues, though they may be able to give them to others. In *continuous* sympathies the affection is similar, but not in the remote. A swelled testicle in venereal gonorrhœa does not partake of the specific nature of the original disease. In a cancerous breast, the glands in the axilla will often inflame and subside again, which they would not do if they were affected with cancer.

Sympathies of the body arising from affections of the mind.—The living principle of the body sympathizes with the mind. Strong affections of the mind will produce involuntary motions, even of those parts commonly at the command of the will. This must be by means of the nerves, for the body has no connexion with the brain but by the nerves. Fear will produce action of the involuntary parts, as purging, discharge of urine, &c.

I suspect that particular parts may sympathize more readily with the mind than others; therefore in such cases sympathies may be called local or remote, but they are, I believe, in most cases universal.

Sympathies of the Mind with the Living Principle.—The third principle, mind, is capable of sympathizing with the first, or actions depending on the living principle, for I should think that a state of the body often forms a state of the mind; however, it is not so readily affected by what does not produce sensation as by that which does. A man in pain not only feels pain as a sensation, but becomes depressed; or if the actions of life can produce sensation in any part, then the mind becomes affected, as when the whole body is in want of food the stomach sympathizes strongly with the whole, and the sympathy of the stomach causes a sympathizing mind. This is not sympathy immediately with the first principle, but sympathy with the sympathizer, or second, which, however, arose from the first. There are, however, instances where the mind sympathizes with the first, or life, for there are many instances where the mind is depressed without a sensible cause, called *hypocondriasis*, and also where the mind is light or easy without any sensible cause. I suspect that both these states arise from

the living principle being either diseased or at rest.

Sympathy of the mind with the voluntary parts is curious. If the voluntary parts are rendered useless, the will has no longer any power over them; it produces a state of mind which prevents the will putting the parts into action. Thus, when the tendo Achillis is divided, the person cannot put the muscles attached to that tendon into action by the will; but as soon as union takes place and grows strong, the mind allows the will to take possession of its action over the muscles.

Use of Sympathies.—Sympathies are designed for very important ends. They produce a communication between the three principles of the animal economy. The use of sympathy is often very evident. If their is an uncommon irritation in the lungs or throat, the muscles of respiration act with uncommon force, and the offending substance is thrown up. The irritation is frequently in the lungs, then it is transferred to the larynx, the muscles of respiration sympathize with the latter, and cough is excited either to get rid of the disease or of its consequence, which is increased and morbid secretion. In pregnancy the breasts become swollen, preparatory to their secreting milk in parturition. In labour the uterus is stimulated by the child, now become fit for expulsion, and the muscles of the abdomen sympathize with the uterus.

Sympathy in diseases, by becoming the symptom of disease, often leads us to the cause, especially when the cause is in a deep-seated part, as the pain in the knee when the hip-joint is affected.

We find that the sympathizer in some cases relieves the part irritated or under diseased action, as the testicle relieves the urethra; but there appears to be nothing gained by this, as the sympathy is the worse disease of the two.

By the sympathizer often relieving the part diseased, and sometimes even curing it, it becomes similar to a constitutional affection becoming a local one, as in the gout; and, as in the swelled testicle from gonorrhœa it often changes sides almost instantaneously, it is in this exactly similar to the gout.

Some sympathies are opposite in their action to the original action: pain in the liver is depressing, that in the shoulder rousing. Nature is incapable of sustaining the former, and sets up the rousing pain in the shoulder to continue life.

ADDRESS OF EARL STANHOPE, PRESIDENT OF THE MEDICO- BOTANICAL SOCIETY, AT THE ANNIVERSARY MEETING.

We have much pleasure in placing before our readers some extracts from the admirable address, whose title we have just indited, as it reflects great credit on the noble lord who delivered it, and who stands pre-eminent among the friends of Medical Science. The indefatigable zeal, and the ardent desire of the revered President of the Medico-Botanical Society, to promote its laudable objects, are rarely displayed by the high order to which he belongs, and deserve the warmest thanks of the Medical Profession. It would not become us to offer an observation on the high literary and scientific attainments of this distinguished nobleman, but we must take leave to applaud the deep interest he invariably evinces for the enlargement of therapeutical means for the alleviation of human suffering. He has cheerfully exerted his high political influence with the British and foreign courts, and obtained the great privilege for the Medico Botanical Society, of corresponding, free of expense, with all parts of the globe, and of receiving herbaria from every quarter; and so interested is he, on all occasions, in the prosperity of the society, that he gives an account annually of its proceedings, which embraces much varied and valuable information on medicines used in other countries, which are unknown to us, though highly efficacious. A few specimens from the address before us will confirm the validity of these statements, and we earnestly hope that we shall long enjoy the gratification of recording similar ones for the information and approval of our reader.—

"This society owes the station which it has now acquired amongst learned bodies, and the reputation which it enjoys, not to the individual who, during several years, has, through your favour, been its president, but to the assistance of those members of the medical profession with whom he has the happiness of being associated, as well as to the scientific eminence of its professors, and to the exemplary manner in which its other officers discharge their several duties. With the exception of the president, and of the treasurer, whose conduct is most honourable to himself, and most satisfactory to this society, all its officers, and nine of the

eleven other members of the council, belong to the medical profession, to which our pursuits cannot fail to be interesting, and will, I trust, be serviceable. In offering to all of them the humble tribute of my praise, I wish to take this opportunity of expressing our gratitude to our learned conservator, Dr. Farre, for the indefatigable labour which he has bestowed on the valuable herbaria of the society, and for the important advantages which have been derived from his laudable exertions.

“My learned and revered friend, the president of the Royal College of Physicians, has favoured this society with the communication of a letter which he received from Sir Robert Ker Porter, at Caracas, transmitting a translation of the official report, made to the governor of Venezuela by the medical board, on the subject of a plant that grows in the central and southern parts of Columbia, and is called by the natives *Cuichunchulli*. It is administered in cases of that deplorable disease the *Elephantiasis tuberculata*, or what may be more properly called the *Lepa tuberculata*, which happily is almost, if not entirely, unknown in Europe, but which is not unfrequent in some part of the new world, and has hitherto been considered as incurable. The medicinal properties of this plant reside in its root, which being reduced to powder is given in doses of half a drachm, and in some instances of two drachms and a half; and it is deeply to be regretted, that the extreme difficulty of procuring it, the insufficient quantity in which it has been found, and the high price which it bears, of £3 6s. per ounce, have in every case prevented a full and satisfactory trial of its efficacy. Experience has proved that it alleviates the symptoms of the disease, and the medical board consider it ‘very probable that it will effect a cure in some cases.’ But Dr. Arvelo expresses a contrary opinion, and the question cannot be decided until medical practitioners are furnished with an ample supply of this plant, which ought to be cultivated for that purpose. The government of Venezuela is willing to encourage, by pecuniary assistance, the procuring of the plant; but its rarity is such as to preclude the expectation of obtaining it in abundance, and its price would of course be enhanced by the demand. Its cultivation is therefore an object of so much importance, that I earnestly hope it will soon excite the attention of those who possess the opportunities of administering the remedy, and

particularly of Dr. Bancroft, of Jamaica, who is a corresponding member of this society, and who is the author of a paper on this subject, which was read in 1835, before the College of Physicians and Surgeons in that island, and which is by far the best and most complete that I have hitherto seen. It is stated by Fuenmayor, in a report to the Secretary of State for the Interior in Venezuela, that this remedy operated simultaneously as a cathartic, diaphoretic, diuretic, emetic, and sialogogues; but although it produces nausea and sometimes vomiting, it seems to me doubtful whether it can strictly be considered as an emetic. In another paper, which is also prefixed to the report of the Medical Board, it is observed, that in all the cases of which the writer had any knowledge, and in which the remedy had been employed, ‘more than two months elapsed generally before any sensible effects were visible.’ In the case, however, of a patient who had been ten years afflicted with the disease and had received no relief, considerable improvement took place in twelve days, and after having taken about thirteen drachms of this medicine, the supply of which was, as the Physician says, exhausted ‘at the most opportune moment.’ It is also observed, in the same paper, that in two or three cases the effects of the plant were ‘small or almost imperceptible,’ but that there was much alleviation in two other cases, in one of which a solution of corrosive sublimate was externally applied, and in which the trial cannot therefore be considered as satisfactory. Dr. Bancroft mentions also the case of one of his patients who received no benefit whatever, after taking, in about two months, five ounces of the plant. In the six other cases in which it was administered by him, in quantities of ten drachms to each, and in which he very judiciously abstained from employing any other medicines, he perceived no violent effects, but a slow improvement in five or six weeks, and the cure was, as he remarks, ‘scarcely begun,” when the quantity of the plant that had been allotted to each patient was consumed. Senor de Aroche has given details of the case of a patient who, in twenty-five days, took above four ounces of the plant, without any permanent benefit; but he notices only the operation of the medicine, and not the alteration, if any, which had occurred in the symptoms. The Medical Board of Venezuela states in its report, that few remedies ‘have offered better prospects of success at the com-

menhement of the trials; and although this does not appear to have been universally true, the improvement that was experienced in several cases, and amongst others in two at Cuenca, respecting which no medical statement has been received, is such as to render most desirable a further investigation. The Padre Velasco, a Jesuit, relates of his own personal knowledge, that a lay brother of the order was, in 1754, cured of Leprosy by the Indians, and in a short time restored to perfect health; but he gave no description of the plant which was employed, by which it could be recognized, and by which its identity could be shown with that which has been subsequently used, and his statement is thought by Dr. Bancroft to be exaggerated, and in some respects unfounded. A medical practitioner at Bogota supposes this plant to be the same as that which is administered as a purgative to children, and the similarity in the name which led to this conclusion may naturally have been the cause of error. Too much praise cannot be bestowed on a French gentleman, M. Marcucci, for the zeal and perseverance which induced him to encounter many difficulties and dangers in obtaining this plant, the botanical character of which has been very accurately defined by Dr. Bancroft. It was called by Mutis the *Viola parviflora*, and by Ventenat the *Viola Ionidium*; but Dr. Bancroft is of opinion that although it "most nearly resembled" the *Ionidium parviflorum*, it is however a new species, and it was named by him, as a just tribute of respect to M. Marcucci, the *Ionidium Marcucci*. Until the cultivation of this plant shall have afforded such a supply as would enable practitioners to form a just estimate of its efficacy in a disease which Dr. Bancroft, in a letter to my learned friend, Dr. Sigmund, describes as 'most intractable and grievous,' I would with all deference submit to their consideration, whether it might not be proper to try in such cases some medicine which would be compounded of drugs suitable to the climate, and which in its sensible operations would be similar to the *Cuichunchulli*.

"To my learned friend, Dr. Hancock, who collected, during his long residence in the new world, and has subsequently communicated to this society very valuable information, we are indebted for some papers of great importance; and, amongst others, for one on the medicinal properties and uses of a plant which is called, in British Guiana, *couru-matti*,

and by the tribes of the interior, *conopia*. Unlike the plant which I before mentioned, it is found in abundance; but though Dr. Hancock has fully described it, he thinks that it is liable to be confounded with others, and he observes that, as the natives are very accurate in discriminating their more useful plants, it is requisite to attend to the names which they have affixed to them, and which are of far more service than their botanical appellations. It appears to be of the natural order of *cannæ*, and it may be the same as that which is described by Rolander; but Mr. Parker, of Liverpool, who is well skilled in Botany, considers it to be the *Alpina exaltata* of Meyer; and it is allowed by the greatest authority, by M. de Candolle, that much uncertainty prevails throughout this natural family of plants. Dr. Martius, of Erlangen, for whom I entertain the highest respect, thinks that the plant which produces the larger cardamoms, is, according to Rleedo, a species of *alpinia*; and it seems to deserve the attentive consideration of botanists, whether there is any, and what, real distinctions between the genera *canna*, *costus*, *alpinia*, and *amomum*. The leaves and fruit of the *couru-matti* are medicinal, as well as the root, which is diaphoretic, diuretic, and, in large doses, emetic. From the two former of these qualities it is very useful in dropsies; and Dr. Gill, of Demerara, knew cases of that description which appeared to be desperate, but which had been cured by a strong decoction or infusion of the root, with an addition of gin. It is also of great service in the hooping cough, as was shown by the example of a family consisting of twenty-one children, all of whom, except one or two, were attacked with the disorder, but recovered in a week or ten days, after taking small doses of the root prepared in syrup, and, thrice a day, a strong infusion of the root which operated frequently as an emetic, and caused a free perspiration. It is employed, moreover, in rheumatism, dysentery, asthma, and fevers, as well as in cases of poisoned wounds, by laying on them some of the bruised root, and by administering, internally, its decoction. The leaves of this plant are sometimes used to envelop the whole body, and produce a profuse perspiration; and other leaves, especially those of the *arum arborescens*, and of a species of *sterculia*, are applied in that manner, and for the same purpose. M. De Candolle states, in mentioning the *aroidæ*, that in cases of general dropsy

at Demerara, the Indians cover the whole body with the fresh leaves of the dracontium *partusum*, which occasions a slight vesication, but are not more rubefacient than many others. Dr. Hancock has no doubt that the aroidæ might be used, externally, with similar advantages to those derived from them by the Indians; and he recommends a trial, in aid of internal remedies, of the leaves of the rumex *maximus*, and also of those which are more stimulant, as the arum *maculatum*. He informs us, that very dangerous dysenteries have been cured in South America by producing perspiration through the employment, in this manner, of the leaves of the great climbing arum, a mode of treatment which he believes to be the most certain, though circumstances may require a deviation from it; and he mentions, in another very interesting paper, on the Indian practice of medicine in Guiana, that by externally applying the aromatic leaves of the alpina *odorata*, by warm infusions of sudorific plants, and by vapour baths, the patient, after an hour or two, falls asleep, and in general is, when he awakes, free from pain and fever. Those leaves which are not of a stimulant nature may be supposed to operate through the absorption of their exhalations, but the subject is, both physiologically and therapeutically, highly deserving of attention, and leads to considerations of great practical importance. In order to simplify the inquiry, and to arrive at more certain results, I would propose that trials should be made in several disorders, and particularly in those above mentioned, of leaves of various qualities, aromatic, rubefacient, &c., but without the employment of warm infusions, vapour baths, or other agents."

Earl Stanhope next comments upon the value of popular remedies, and his observations are so correct that we shall quote them at full length.

"The practice of the Indians in curing diseases is not to be slighted as unscientific, for it is founded upon nature and experience, and has been proved to be eminently successful. Mr. Whitlaw, who had ample opportunities of observation, states, that pleurisy, and all acute inflammations, were cured by them without bleeding; that 'the patients were convalescent frequently in a few hours, and in general in a period not exceeding two days, that the same effects were produced upon the white population as upon the natives; and that 'scrofula, liver complaints, consumption, and cutaneous dis-

eases, were unknown among them.' Dropsies, which had defied the medical art, have been vanquished by their simple remedies; and Dr. Hancock has, in several instances, known the Indians to make 'sound cures of limbs which had been condemned to amputation by European practitioners.'" It is not the skill and science which may be displayed in an operation, or the success which may attend it, that are either the most advantageous to the patient, or the most honourable to the practitioner; it is, on the contrary, that superior talent, when it is possible to exert it, which, by judicious treatment and by due attention to the constitutional disease, renders the operation unnecessary. The amputation of a limb cannot justly be considered as its cure, but as the lesser of the two evils to which the patient is exposed, and requisite in some cases to the preservation of his life, or, according to the expression of an ancient physician, '*detractio amissio partis est non sanatio*;' and I need not observe that a solvent for the stone would be very far preferable to the dangerous and painful operation of lithotomy.

"The important advantages which may be derived from popular remedies were fully appreciated by Dr. Oslander, who composed a most instructive work upon this subject, and has collected, with great industry, many interesting facts. He states, as the result of his own experience in a variety of cases, that remedies which appeared insignificant had, however, proved effectual, when the strongest medicines and the skill of eminent physicians had failed of success. Such was also the opinion of Hoffmann, who, after a practice of many years, found that the remedies, which he describes as '*vernacula, parabiliora, et domestica omnibus nota*,' were far preferable, both in their power and in their utility, to chemical preparations, and accomplished a safer and more certain cure. Many medicines, which now are universally prized, were originally only popular remedies, some of which were discovered perhaps by accident, as was lately the use of cotton in cases of burns, and some of them may have been derived from an attentive examination of the habits of animals, guided as they are by unerring instinct. It is stated by my learned friend, Dr. Sigmond, in his excellent paper on the *secale cornutum*, which is considered by Mr. Mitchell, after long experience, to be a 'safe and efficacious medicine,' possessing 'all the properties which a practitioner could

desire,' that it was not tried in this country till 1824, although it was mentioned by Camerarius in 1688 as a common remedy in Germany. The constant employment of any popular remedy shows that it must, at least occasionally, have been successful, and that it is deserving of accurate and scientific trials, made with that caution which may have been neglected in popular practice. I am aware that empiricism on the one side, and credulity on the other, have given great vogue to some pretended nostrums and universal medicines, which seem to assume that all diseases have the same cause and are susceptible of the same cure; but these are not what are termed popular remedies, and the former are almost unknown where the latter are often employed. As an example of the medicinal effects produced by vegetables which appear to be insignificant, we are told by Rust, that a young woman, who, till the twenty-second year of her age, had been afflicted with St. Vitus' Dance, and had derived no relief from medicine, was completely cured by living, during ten weeks, entirely on spinach. As an example that vegetables may possess other medicinal qualities than those which are generally ascribed to them, I may mention that an infusion of the common tansy is used in Russia to cure the jaundice, although the late Professor Geiger, whose name I cannot pronounce without grief for his irreparable loss, and the utmost reverence for his inestimable services, says that its medicinal qualities are '*nervina, anthelmintica, diuretica*.' A warm infusion of sloe leaves, which are so often employed for the adulteration of tea, has been administered in cases of scrofula; a decoction of dried peach leaves for the stone; and yew leaves, reduced to powder, for Hydrophobia. These, like other popular remedies, demand our attention; and the veneration which all of us must feel for the authority of Linnæus ought to add weight, if it were possible, to his admonition: '*discant itaque juvenes medici minime spernere, sed ea annotare accurate, quæ apud vulgum audiant medicamenta decantari*.'

Every one will agree with the noble author that popular remedies are often efficacious, and that many of them are now introduced into our pharmacopœia, and that many valuable remedies may be yet obtained from the same source, both in this and foreign countries.

THE ANATOMIST.

SMALL INTESTINES

are divided into duodenum, jejunum, and ileum.

Duodenum, the shortest portion of the small intestines, forms a curve in the concavity of which is situated the head of the pancreas; it is divided into a superior transverse portion, a middle perpendicular portion, and an inferior transverse portion. The superior part is covered by peritoneum on both its surfaces, and on this account is more moveable than the perpendicular or inferior portions, which are only covered on their anterior surface by this membrane.

Besides the numerous mucous glands which open on its interior surface, the apertures of the pancreatic duct and of the common biliary duct enter at its perpendicular division. This intestine differs not only in these particulars from the rest of the small intestines, but also in being much larger, more dilatate, more fixed to its position, in having a greater number of valvulæ conniventes (or circular folds of the mucous membrane), and in its muscular fibres being much stronger.

The duodenum has also been called *ventriculus succenturiatus*.

Jejunum and Ileum form the longest part of the intestinal tube, being in general from 28 to 30 feet in length; the upper two-fifths are given to the jejunum, and the remainder to the ileum, but there is no anatomical foundation for this arbitrary boundary as the intestines run into each other insensibly; and from the duodenum the remainder of the small intestinal tube gradually diminishes in thickness, has fewer valvulæ conniventes and exhibits less vascularity, so much so that the termination of the ileum is much thinner and paler than the upper part of the jejunum, and it is in these situations only that the differences between both are marked and striking. The mucous membrane of the small intestine is studded with glands of two orders, viz the *glandulæ solitariae* or *Pyeri* and the *glandulæ agminatæ* or *Brunnerii*. The solitariae are disseminated like granules over the mucous membrane, and the agminatæ are placed in oval clusters. The fibres of the muscular coat of the small intestines take a circular and longitudinal direction, the latter being placed externally.

LARGE INTESTINE

divided into the cæcum, colon, and rectum, forms about one-fifth of the intestinal canal. It differs from the small intestine in its great size, in being sacculated, in having small processes along its entire course called *appendices epiploicæ*, in presenting three well defined longitudinal bands, in being thinner, and in having but few *valvulæ conniventes*. It is composed of an external serous coat, an internal mucous coat, and between both, a muscular coat. The fibres of the muscular coat take a circular direction, and some have contended that the longitudinal bands are also muscular, but in addition to their anatomical structure, the use these bands serve in throwing the intestine into a permanent sacculated condition renders it very probable they are of an aponeurotic nature.

Cæcum or *caput coli*, placed in the right iliac fossa and connected to the iliac and psoas muscles, is fixed in its situation by the peritoneum which only covers it anteriorly and somewhat laterally; it receives at its inner side the ileum which terminates in its cavity by a slit like opening, and which is guarded by two valves; these, in health, allow the transit of alimentary and excremental matter from the ileum to the colon, but not in the converse direction. The inferior valve or *ileo-cæcal* is the larger and placed obliquely; the superior or *ileo-colic* is smaller and rather horizontal; both are united at their extremities forming the *commissures*, from each of which proceeds a permanent fold of mucous membrane called *retinaculum*. The *appendix vermiformis* is a small diverticulum which proceeds from the posterior part of the cæcum, it is the size of a goose-quill in diameter and from three to five inches in length, its orifice of entrance into the cæcum is guarded by a small valve: the cæcum has no *valvulæ conniventes*, but is thrown into irregular sacculi by the three longitudinal bands.

The *colon* extends from the cæcum to the rectum and is divided into four portions, viz. the right or *ascending* colon, the middle or *transverse*, the left or *descending*, and the *sigmoid flexure*.

The *rectum* extends from the sigmoid flexure of the colon to the anus; its upper third is covered by peritoneum, its middle third is only covered by this membrane upon its anterior aspect and sides, and its inferior third has no peritoneal covering. In the male subject the antero-

inferior aspect of the rectum is connected to the inferior fundus of the bladder, the *vesiculæ seminales*, and the prostate gland, and in the female to the uterus and vagina. The rectum has no longitudinal bands and is not sacculated like the other parts of the large intestine.

SALIVARY GLANDS

are three in number, viz. the Parotid, the Sub-maxillary, and the Sublingual.

Parotid gland, the largest of the three, is bounded superiorly by the zygoma, posteriorly by the mastoid process and sternomastoid muscle, and advances on the side of the face partly resting upon the masseter muscle. It sends off deep processes, which fill the posterior part of the glenoid cavity, the fossa between the ear and perpendicular process of the lower jaw, and the intervals between the pterygoid, digastric, and styloid muscles; it often unites with the sub-maxillary gland. Its duct (*duct of Steno*) passes across the massiter muscle, pierces the buccinator muscle, and opens into the mouth opposite the second superior molar tooth.

A small gland (*soria parotidis*) occasionally is found between Steno's duct and the zygoma, the duct of which unites with that of the parotid gland.

Sub-maxillary gland, placed in the digastric space, and covered by the skin, platysma-moides muscle and superficial fascia, is of an oval figure and much smaller than the parotid. Its duct (*Whartonian*) turns round the posterior edge of the mylo-hyoid muscle, and runs forwards and inwards towards the *frænum lingue* at the side of which it opens into the mouth.

Sublingual gland, is placed between the mucous membrane of the mouth and the mylo-hyoid muscle, is the smallest of the salivary glands, and opens by several small ducts (*Rivianian*), which perforate the mucous membrane, reflected from the side of the tongue.

LIVER.

Situated in the right hypochondriac, the epigastric, and partly in the left hypochondriac regions, is the largest gland in the body. It presents an upper convex surface, a lower irregularly concave surface, a posterior thick margin attached to the diaphragm, and an anterior inferior margin which is free. The upper surface is unequally divided by the falciform ligament into a right and left lobe. The inferior surface presents the following fissures and depressions.

1. *Horizontal fissure* extends from a notch in the anterior thin edge of the liver backwards and upwards, defining the boundary between the right and left lobes of the organ; it is crossed at right angles by the transverse fissure, which thus divides it into an anterior and posterior portion, the former containing the obliterated remains the umbilical vein, the latter the obliterated ductus venosus.

2. *Transverse fissure* extends from the horizontal fissure into the right lobe of the liver, it contains the trunks of the right and left hepatic arteries, the trunk of the portal vein, the hepatic extremities of the biliary ducts, the hepatic plexus of nerves and absorbents.

3. *Fissure of the vena cava*, situated to the right of the horizontal fissure and behind the transverse fissure, forms the right boundary of the lobulus Spigelii.

4. Depression for the gall-bladder, situated to the right of the lobulus quadratus.

5. A broad notch in the posterior thick edge of the liver, which corresponds to the right crus of the diaphragm. Besides these there are superficial depressions for the colon, right kidney, and stomach.

Lobes of the liver.—1st, right lobe, the largest; 2nd, left lobe, separated from the right by the horizontal fissure; 3rd, lobulus Spigelii, bounded before by the transverse fissure, and placed between the œophagus and vena cava; 4th, lobulus caudatus extends from the lobulus Spigelii along the right lobe; it lies posterior to the transverse fissure, to the left by the horizontal fissure, to the right by the gall-bag, its anterior edge being free.

Vessels of the liver.—1st, the hepatic artery; 2nd, the vena porta, which ramifies through the liver like an artery; 3rd, the hepatic ducts which commence in the pori biliarii; 4th, the venæ cavæ hepaticæ which return the blood of the vena portæ and hepatic artery to the vena cava; 5th, the absorbents of the liver.

Ligaments of the liver.—Besides the liver being invested with a proper fibrous capsule, it is also covered by peritoneum, which forms four of its ligaments, viz. 1st and 2nd, a right and left lateral triangular form, and connecting the right and left lobes to the diaphragm; 3rd, a suspensory or falciform ligament, which connects its upper convex surface to the right rectus muscle, and to the diaphragm; and 4th, the coronary ligament which connects the superior thick border of the diaphragm. There is also a fifth ligament (*ligamentum teres*), the obliterated umbilical vein,

which extends obliquely from the umbilicus upwards and backwards to the anterior portion of the horizontal fissure.

Gall-bladder, pyriform in shape, and composed of an internal mucous coat, a proper fibrous coat, and a partial serous covering; is lodged in a depression on the under surface of the right lobe of the liver. Its large extremity, or *fundus*, is directed downwards and forwards, its upper extremity terminates in the *cystic duct*, about an inch and a half in length, which unites with the *hepatic duct*, formed by the union of the right and left ducts from the corresponding lobes of the liver. The common biliary duct thus formed by the cystic and hepatic ducts, is called the *ductus communis choledicus*, which is about three inches in length, and which conveys the bile to the duodenum.

PANCREAS,

A flattened oblong gland from five to six inches in length, similar in its formation to the salivary glands. It consists of a left caudal extremity, situated in the lower part of the left hypochondrium, a body which crosses, anterior to the left crus of the left diaphragm, the aorta and the vena portæ, to the right side; and a right extremity (*the head*) which is the largest part of the gland, and which is surrounded by the duodenum. Its duct of a whitish colour, extends along the centre of the gland from left to right, but lying near its posterior aspect; receiving the small ducts from the granules of the pancreas, it finally opens into the duodenum, close to the ductus communis choledicus, which it sometimes joins.

THE SPLEEN,

Connected to the large extremity of the stomach by blood-vessels and peritoneum, and situated between the stomach and ribs of the left side, is of a deep blue venous colour, and varies in weight from six to fifteen ounces, its figure being oval. It presents a convex surface, which corresponds to the ribs, and a concave surface towards the stomach, is enveloped by a proper fibrous membrane, and a peritoneal coat. Its interior is composed of *cells* separated by *septa*, with *white granules* intermixed. It has no excretory duct.

URINARY APPARATUS.

THE KIDNEYS.

Two glandular bodies of an oval form situated, behind the peritoneum, in each lumbar region, lying upon the diaphragm,

psaos magnus, and *quadratus lumborum* muscles, and enveloped in a thick layer of adipose tissue. The right kidney, which is rather lower than the left, is below the liver, above the cæcum and behind part of the duodenum and the ascending colon; the left being bounded above by the spleen, below by the sigmoid flexure of the colon, and anteriorly by the descending colon. The extremities and outer border of each kidney, are convex, whilst the inner margin presents a concave aspect called *the renal fissure*, and contains the trunks of its blood-vessels and its excretory duct, observing in general the following order, the veins anterior, the arteries behind, and inferior to both. Besides the adipose capsule which envelopes each kidney, it also has a proper fibrous coat which adheres closely to its outer surface, and sends prolongations into its interior, as far as the calyces.

Structure is of two kinds, viz. the *cortical* and the *tubular*. The cortical is highly vascular, of a brownish red colour, from a line and a half to two lines in thickness and consists of minute spherical granules, it is placed on the outer surface of the kidney and also sends prolongations inwards between the fasciculi of the tubular substance. The tubular substance consists of minute capillary tubes (*tubuli uriniferi*, *tubuli Belliniani*), arranged in conical fasciculi forming from ten to twelve bundles: the bases of the cones being directed towards the external cortical substance, the apices towards the inner concave edge of the gland.

Papillæ is the name given to the nipple-like apices of the conical fasciculi. Each papilla presents numerous minute tubes, the apertures of the tubes of which the cones are composed; these apertures are not so numerous as the tubes, several of which are united in one common orifice.

The Calyces are small membranous sacs which surround one or more papillæ.

The Infundibula are three funnel-shaped tubes formed by the union of the calyces.

The Pelvis is the membranous reservoir formed by the union of the three infundibula.

The Ureters extend from the termination of the pelvis of either kidney to the bladder. Each ureter, about eighteen inches long and of the diameter of a moderate sized quill, passes behind the peritoneum, lying anterior to the *psaos magnus* muscles and to the iliac vessels, and gaining the inferior and posterior part of

the bladder, passes obliquely between its coats and perforates its interior at the outer angle of its trigone.

THE URINARY BLADDER.

This musculo-membranous viscus when moderately distended is of an ovoid figure and occupies the lower region of the pelvis, behind the pubal symphysis, and anterior and superior to the rectum in the male, and the uterus and vagina in the female.

Ligaments of the bladder are divided into *true* and *false*. The true ligaments are four in number, viz. two anterior and two lateral. These, being nothing more than reflections of the vesical layer of the pelvis fascia, will be noticed when this structure is described. The false ligaments are five in number, viz. two posterior, two lateral, and one superior, and are formed by the reflections of the peritoneum.

The regions of the bladder are divided into six. 1st. *The superior region*, to which are attached the urachus and obliterated umbilical arteries. 2d. and 3d. *The lateral regions*, on which the vesical fascia of either side passes. 4th. *The anterior region*, the aspect of which looks towards the recti muscles, the pubes, and the triangular ligament of the urethra or the deep perineal fascia. 5th. *The posterior region*, the aspect of which looks towards the rectum in the male and the uretus in the female. 6th. *The inferior region* or *fundus* which rests on the vesiculæ seminales, the prostate gland, and the rectum in the male, and on the uterus and vagina in the female.

Coats of the bladder. Besides the partial peritoneal covering which invests all the posterior region and the posterior parts of the upper, lower, and lateral regions, there are also three *proper* coats, 1st. *The muscular*, flaccid externally, the fleshy fibres of which take three directions; the external running longitudinally, the anterior and superior fibres being stronger have been distinguished by the name of *ditrusor urinæ*, and those deep circular fibres immediately in connection with the mucous coat, which are best developed around the neck of the bladder. 2d. *The cellular coat*, and 3d. *The mucous*, which is exposed on opening the bladder. This coat is in general thrown

* To gain a view of the parts just described, a perpendicular section of the gland should be made from its convex to its concave margin.

rugæ by the projection of the muscular fibres.

The *trigone* or *vesical triangle* is the name given to a smooth space inclosed between the orifices of the ureters into the bladder and the vesical orifice of the urethra.

The *uoula* is a small duplicature of the mucous membrane on the under surface of the vesical orifice of the urethra, and corresponds to the third lobe of the prostate gland.

The urethra which terminates the urinary apparatus being in the male more connected with the reproductive organs, we shall defer its consideration until these organs are being described.

THE PERITONEUM,

The largest serous membrane in the body, lines the parietes of the abdomen, and invests almost all the abdominal viscera; like all serous membranes, then it is distinguished into two layers, a *parietal* and a *visceral*. The abdominal parietes being divided by a transverse incision, corresponding to the umbilicus, the uninterrupted continuity of the peritoneum, and the different productions it forms in its course may be thus demonstrated:—lining the inner surface of the upper section of the abdominal parietes, it ascends to the margin of the thorax, and lines the inferior surface of the diaphragm; from this muscle it is reflected on the spleen on the left side, on the stomach in the centre and on the liver on the right side, forming its ligaments (*vide ligaments of liver*). From the transverse fissure of the liver the two layers, where the laminae, which covered the convex and concave aspects of this organ, meet, it is conducted by the hepatic vessels to the lesser curvature of the stomach, thus forming the *gastro-hepatic omentum*, which is also called the *capsule of Glisson*, and between the two layers of which are contained the hepatic artery to the left, the ductus communis choledicus lying to the right, and vena porta, which lies behind and between both. At the lesser curve of the stomach the two laminae of the gastro-hepatic omentum separate and enclose this organ, passing from its left extremity to the spleen, thus forming the *gastro-splenic omentum*, and at the great curve of the stomach, and lower extremity of the spleen, the two laminae again meet and descend in front of the colon, and the small intestines, to the lower part of the abdomen; these two layers then turn upon themselves backwards, and ascend

to the transverse arch of the colon, where they separate to enclose this intestine, thus forming the *great omentum*. Having enclosed the colon, the descending layers again unite and form the transverse meso-colon, which passes backwards to the spine; having arrived at the spine, the two laminae again separate into a descending and an ascending layer; the descending layer passes into the lumbar regions where it is reflected upon the ascending and descending colon, forming the right and left lumbar meso-colon, and attaching itself to the left sides of the bodies of the lumbar vertebrae forms the *arteria lamina* of the root of the mesentery; from this fixed point it is continued around the jejunum and ileum, forming the peritoneal coat of these intestines, and returns again to the spine, forming the posterior lamina of the root of the mesentery. This descending layer of the transverse meso-colon having thus formed the mesentery, still pursues its course descending, and passes into either iliac region, and into the pelvis; on the right it attaches the cæcum to the right iliac fossa, thus forming the meso-cæcum, on the left side it attaches the sigmoid flexure of the colon to the left iliac fossa, forming the sigmoid meso-colon, and in the middle it connects the upper portion of the rectum to the upper and anterior part of the sacrum, forming the meso-rectum; still pursuing its course downwards, and covering the upper and anterior aspect of the middle third of the rectum, it is at length reflected on the posterior surface and sides of the bladder, to the superior region of this viscus, from which, and from the iliac fossa, it is reflected on the inner surface of the lower section of the abdominal parietes to the transverse incision, from the upper edge of which the description was commenced. Having thus traced the descending layer of the transverse meso-colon, the continuity of the ascending layer remains to be noticed;—ascending in front of the inferior and middle portions of the duodenum and of the pancreas, it is conducted to the liver by the vena cava on the right of Spiegelian lobes, of which gland it becomes continuous with the peritoneum, which has been reflected from the diaphragm on the posterior aspect of the liver.

Foramen of Winslow.—By this opening the cavity which is between the layers of the great omentum, communicates with the general peritoneal cavity of the abdomen. It is of an oval form, being bounded anteriorly by the gastro-hepatic

omentum, posteriorly by the ascending layer of the meso-colon, superiorly by the liver, and inferiorly by the duodenum.

Inguinal Pouches.—As the peritoneum is ascending on the lower part of the abdominal parietes, it is thrown into four pouches, two on either side, by the obliterated hypogastric artery. The *external* pouch, between the ilium and hypogastric artery, is the largest, and corresponds to the external abdominal and the femoral rings.

In the female the peritoneum passes from the rectum on the upper and back part of the vagina, from which it ascends on the uterus, forming on each side its broad ligaments, and is reflected from the anterior part of the uterus to the back of the bladder.

The London Medical

AND

Surgical Journal.

Saturday, July 29th, 1837.

CAPITAL OPERATIONS IN SURGERY.—COMMENTS ON HOSPITAL OPERATIONS.

As journalists we have always considered it as our bounden duty, when employed in collecting Hospital Reports, not to permit our pages to be influenced by any individual, or set of individuals, for the purpose of publishing only those cases which they may conceive give a lustre to their practical talents, and conceal those unfortunate results, a knowledge of which is of such importance to all those engaged in the practice of their profession, and in an especial manner to the student. Looking back to the last few months, had not some appalling though highly instructive, surgical, operations been detailed in this Journal, the profession might have been led to suppose that no operations were performed either at the *North London, St. George's,*

or *St. Thomas's* hospitals, which had not been completely *successful*. We are now led to make this observation, because it will be seen in our report of cases at the North London Hospital, that two unsuccessful operations had been performed some weeks ago at that charity, of which not the smallest notice was taken by that Journal which professes to give so impartial an account of our *London* *Pures*. We have always upheld that there is no rule in surgery more sound and better established, than that it is essential, before performing any important operation, not only that the patient should be deemed a fit subject for it, after the most rigid investigation, and that no operation, more especially one which endangers life, even when performed under the most favourable circumstances, should be undertaken without the patient previously undergoing a preparative treatment for a period more or less extended, according to his general health, or peculiarity of his temperament. Of all operations there is none for which it has ever been considered more necessary that the patient should undergo such preparation as that of Lithotomy; and the great success which has for a century been experienced by the Surgeons of St. Thomas's Hospital, has been chiefly attributed to the management of stone-patients by the nurses, in preparing them for, and attending to them after, operation. The distressing result of the operation for Lithotomy performed by Mr. Liston, which will be found in another page, we are inclined to attribute, not to his inexperience in performing the operation, for we are aware that great practice and dexterity are necessary, but to his not having subjected his patient to a course of preparation; the patient having been, in this instance, operated upon the second day after his admission, and after a long voyage; so that whatever advantages might,

in the opinion of some, have been derived from rest and a careful preparation, were unhappily omitted. The distressing result of the Taliacotian operation is still more remarkable, the patient's death having been occasioned by the bad state of his constitution at the time of the operation, he having gone through a succession of mercurial courses. Mr. Liston's non-success therefore in this case is not to be attributed to any want of preparation of the patient, but to the selection of a patient whose constitution rendered him the victim of an operation which is not usually considered to endanger life.

If our great Hospital Surgeons at St. Thomas's, St. George's, Guy's, and Bartholomew's, who, in their own opinion, are masters of the art, chose to pursue a line of practice at variance with the established rules of "sound chirurgical knowledge," to use their own phrase, we deem it a duty to humanity and science to comment upon it, and to warn others against a practice so often fatal to human life.

Our readers have fresh in their recollection the fatal cases at St. George's, St. Thomas's, the Westminster, and other hospitals, which have appeared from time to time in this Journal, and which warranted severe animadversion. It is not to be expected that every surgical operation can be successful; but every care should be taken, as far as human precaution admits, to prevent fatal results. Our British Surgeons have long been celebrated for their bold and successful operations; but they must not depend too much upon the knife, and too little upon constitutional treatment, and they should never forget the opinion of John Hunter, that operations are the disgrace of Surgery.

CHARING CROSS HOSPITAL.

In the last number of this Journal we laid before our readers a full account of the serious and most alarming imposition which was practised on Sir Astley Cooper and Sir Benjamin Brodie, by the medical officers of the Charing Cross Hospital, in order to obtain a recognition of the *charity* from the Council of the Royal College of Surgeons; and at the same time we referred with much pleasure to the honest and open avowal of the members of the Council, in which they declared their abhorrence of the whole transaction, and to the decided manner in which they publicly expressed their opinion, by immediately withdrawing the recognition which was thus surreptitiously obtained from them.

We again return to the important duty of calling the especial attention of the Council of Surgeons, of the Council of the King's College, and of the Governors of the Charing Cross Hospital, to the proceedings which have taken place during the past week at this notable asylum.

It is now well known to the public, that the office in the Charing Cross charity, designated by the imposing title of DIRECTOR, has been filled by Dr. Golding; and it is as equally notorious that this office of *Director*, in hands even less scrupulous, less economical, less high-minded, and having less self-interest to advance, is not only, as our esteemed (?) contemporary, the Gazette, forcibly expresses it, "*an absurdity*," but also a clog on the prosperity and advancement of any medical charity. Not only do we look upon this office of *Director* as being injurious to any medical institution, but as being particularly so at the Charing Cross Hospital, where this "*absurd office*" is filled by one of the physicians. Indeed it is almost difficult

to conceive how a medical officer, engaged in the scientific and practical pursuits of an arduous profession within the wards of an hospital, as Dr. Golding must be, could devote time to the petty investigations, and all the minor circumstances which such an office brings with it; either the one or the other must be grossly neglected, or both imperfectly performed.

The office of Director, when filled by a medical officer, also frequently brings its possessor into many disagreeable collisions with his colleagues; thus, judging from our own feelings, nothing must have given *greater pain* to Dr. Golding than the *active* part his office imposed on him to take, in getting out of his way the two most efficient officer, merely because these gentlemen expressed their candid and open opinions, that it would be highly advantageous to both institutions, particularly to the hospital, if a junction of *interests* could be effected between it and King's College. Yet with all these strange events before us, the office of Director is still in existence at this *charity*—still in active operation—still in the possession of Dr. Golding, physician to the hospital—and still, in all its pristine vigour, impeding the only possible chance there exists of redeeming its lost character, of wiping off the dark odium cast upon it by the Royal College of Surgeons, and of rendering it in the eyes of the public and the profession, what its well-intentioned donors expected it would be, a great means of relieving the poor afflicted with the additional misery of disease.

We have thus freely canvassed the *advantages* a charitable institution is likely to derive from the incumbrance of such an officer as that of a DIRECTOR, for the purpose of opening the minds of the governors of the Charing Cross hospital to the *real impediment* which stands in the way of the advancement of *their* institu-

tion, and the ends *they* had in view in giving *their* money to build and support it. Mr. Partridge, the junior, though not less able surgeon of this *charity*, seeing the inefficient state of the hospital under its present management, had the honesty and manliness, some days since, to endeavour to effect a junction between it and King's College. The object of Mr. Partridge in endeavouring to accomplish this junction was two-fold; first, by the union an increase of money would be obtained for the support of the hospital, and some chance afforded the medical officers of being able to keep up permanently the number of beds required by the College of Surgeons for a recognition; and, secondly, the medical classes of King's College, instead of exhibiting the meagre appearance they have done for the last three or four years, would be likely to get some *pay* pupils to their members.

Accordingly Mr. Partridge got a requisition signed by *thirty-nine* Governors, amongst whom were eleven noblemen, and two of Dr. Golding's *special committee*. This requisition was sent in on the fourteenth, and a meeting of the Governors was called, contrary to the laws of the hospital, in a *week* after its receipt, to take its contents into consideration. The calling of the meeting rested with the DIRECTOR and his SECRETARY; and with that extraordinary tact which is displayed on all "*special*" occasions, care was thus taken by calling the meeting so soon, that the principal persons who signed it, being absent from town, or engaged in the elections, could not attend, and thus for a time have the laudable intentions of Mr. Partridge been frustrated and his fondest hopes destroyed.

When next Mr. Partridge endeavours to effect an union between the hospital to which he is an ornament, and the King's College, he should bear in mind, that re-

quisitions have been in the hands of the AUTHORITIES of the CHARITY for months before a *convenient* time to call a meeting presented itself; and that he should first direct his attention to the law of the charity, if any exists, which specifies a definite time for calling a meeting after the receipt of a requisition, before he hopes to compete with the DIRECTOR and those *friends* and *benefactors* of the *hospital* who are always at home.

THE JOINT STOCK COMPANY IN GOWER STREET.

Our readers will startle at the fact, that the Council of the Gower-street College and the Governors of the North London Hospital, after deluding the public with professions of the great want of an hospital in the northern part of the metropolis, have now determined to christen the charity, the University Hospital; thus jobbing the public money to their own purposes, and lest this proceeding was not sufficiently outrageous, they have also determined to charge all pupils from other schools £12. a head more than their own students!! Such is the conduct of the mock liberals in Gower street. Their College being imperfect without an hospital, they first gull the public to build one for them, and as soon as it is established, they change the name, give it that of their own institution, and plunder all students whose means do not allow them to pay the exorbitant college fees of the liberals, in the shape of an increased hospital fee out of their pocket. They thus imagine they will gain pupils for their large fees of the College and the small ones of the hospital, by excluding all who enter to the various other medical schools whose fees are little more than one-half of the liberal university

college, and they close their doors, over which is the motto "*Patens omnibus scientia*," against all who cannot pay their excessive and increasing demands. This barefaced job is the work of a clique, it behoves Lord Brougham, Mr. Warburton, Mr. Hume, Mr. Tooke, and other patrons of the Diffusion of Knowledge, and shareholders in the company, to prevent this gross and shameful attempt at monopoly.

GENERATION OF THE ANIMAL KINGDOM.

GENERATION OF ANIMALS.

What a vast, sublime, and at the same time delightful field, is the study of the generative functions in this class of living beings, at the head of which stands the human species! What curious and varied phenomena, all tending to the same result! What an incalculable profusion of different reproductive processes nature employs for the propagation of the numerous species which she calls into life! And, nevertheless, what unity and what analogy of propagative actions among all the individuals of the same class, from the bramble heath on which we tread, to that proud being who is so eminently qualified to be prince of animals, and king of the universe.

Though the study of the generation of animals presents to the mind of the observer a host of subjects capable of vividly exciting the curiosity, it still furnishes a host of gifts of the deepest interest, whether we consider the advantages of the beings under our empire, whether to serve our comprehension and explication of the numerous phenomena of human generation, on the mechanism of which nature would appear, at first view, to have thrown an impenetrable veil.

A complete history of the generation of animals, and especially of the infinity of modifications in this mysterious process of perpetuating each species, would be an immense undertaking, to the elucidation of which the entire life of one man would be insufficient, and which is perhaps beyond the comprehension of his natural faculties. What an infinite number of organizations and different species among the millions of living beings which the

earth receives on her surface, which fly in the air, and which swim in the unfathomable ocean! What an immense number of others whose organization, and consequently whose mode of reproduction escapes the eye, even assisted by the most powerful microscopes!

How numerous the springs, says Buffon, the powers, the machines, and movements included in that small portion of matter which composes the body of an animal! What relations, harmony, and correspondence between the parts! How many combinations, arrangements, causes, effects, and principles, which concur to the same effect, and which we only know by the results, so difficult to be understood; and they have not ceased to be marvellous, but on account of our not reflecting upon them. But, however admirable this work may appear to us, it is not in the individual the great wonder exists; it is in the succession, renovation, and duration of the species, that nature appears altogether inconceivable. The number of the species of animals is much greater than of plants, which amounts, it is said, to 56,000. There is, perhaps, a greater number of insects, most of which escape our observation, than there is of the earth.

ANCIENT AND MODERN THEORIES OF HUMAN GENERATION.

The animation of the first of the human species presents a question of physiology full of interest, on which men of the greatest genius have commented, though they have completely failed to solve it. The continuation and reproduction of our species has also occupied the reflections and investigations of the greatest philosophers and physiologists of ancient and modern times, some of whom have proposed hypotheses and theories replete with the grossest absurdities and errors. These hypotheses are about two hundred and fifty in number, and a brief notice of those which were best received, may not be uninteresting to the modern physiologist as well as general reader.

Plato thought that the reproduction of man, as well as of almost all organized beings, was effected by spectres and images extracted from the creative Divinity, which, by a harmonic movement, were arranged in certain numbers into perfect order. It was in the unity of the number three, that this great philosopher made the essence of all generation to consist. That which engendered, or the father, formed the first number; the be-

ing in which the conception was effected, the second number, and that which resulted, the offspring, the third number.

The opinion of Plato was, that all generation emanated from the Divinity himself, who, by a perpetual course of miracles, maintains and renews the living world; and, consequently, that man is, in the phenomena of reproduction, but an instrument of the consummate wisdom and power which govern the universe; and, secondly, that generation can only be effected by a male who furnishes certain principles to a female, in whose womb the result, or new being, is developed; and that this law equally governs the whole of the animal or vegetable kingdoms. This tripartite harmony was considered an image of that mysterious power, the Trinity in Unity, which created and perpetuates all organised beings.

Pythagoras supposed that a vapour descended from the brain and nerves during coition, and formed the embryo, which developed according to the laws of harmony. (Diogenes Laer. L. viii. ix.) Impressed with this idea, the Scythians took blood from the veins behind the ears, to produce impotence and sterility—a practice recommended by Mr. Shandy to his brother Toby, when his ass was kicking violently on the recollection of the Widow Wadman.

Epicureus held that the perpetuation of man was effected by a mixture of the fluids of both sexes, which were mixed in the sexual organs of the female, animated, developed, and changed into a being resembling those who furnished them.

Lucretius and a great number of ancient physiologists admitted this doctrine. That great poet considered that there was a mixture of fluids, and that the most vigorous determined the sex, which is now the general opinion. His words are:—

*Et commiscendo, cum semen forte virile
Fœmina compulsit subita vi corripuitque.*

*Semper enim partus duplici de semine
constat.*

*Atque utrique simile est magis id quod-
cunque creatur.*

De Natura rerum, l. iv.

He explained the resemblance of infants to their parents in the following manner:—he thought that whichever parent furnished the most elaborated and abundant seminal fluid would impress the lineaments and form on the offspring—that the most vigorous parent who would possess most genital power, would determine the

sex and physical powers of the infant, and, consequently, that the offspring would most resemble this parent, both in mind and body. But if the father and mother possessed equal power, the infant would resemble both.

Hippocrates and a vast number of his successors, as well as all modern physiologists, admit this doctrine.

Hippocrates, Pythagoras, Democritus, Aristotle, Anaxagores, Alcmeon, Parmenides, Empedocles, Epicurus, Galen, Avicenna, Zacutus, Lusitanus, Decartes, Venette, Rousel, and Buffon, acknowledged the existence of a fecundating sperm in woman; while Zeno, the Stoics, Hippon, and Fallopius, with many other celebrated anatomists, denied it. It is important to observe in passing, that the mucous fluid which is generally, but not always, effused by the uterus and vagina, during copulation, is not seminal or prolific, nor does it contribute to the formation of a new being. It is furnished by the lacunæ and glands of the vagina and neck of the womb, and by the lining or mucous membrane of these organs, and the Fallopian or uterine tubes. This fluid may be more or less abundant; and according to Magendie and others, is not effused by some individuals, and by others only very sparingly. Moreover it does not occur at the most excited moment, which is during and immediately after the male emission.

Galen related the case of a hysterical woman, who, on the slightest excitement of the genitals, had a mucous evacuation, accompanied by voluptuousness, and this also happened during sleep. Sauvage mentions the case of a young girl, of the most rigid chastity, who suffered from abundant vaginal discharges, even at the feet of a decrepid and disgusting confessor. (T. iii. p. 277.) Loyer Villermay describes a similar occurrence at the access of hysteria. Such evacuations may also be induced by an excited imagination, by relaxation of the mucous membrane of the vagina, as in leucorrhœa or vaginal debility, and they may also occur in those who are sterile from diseases of the womb or ovaries; so that they cannot be considered seminal or prolific. The prolific fluid is supplied by a small vesicle or egg in the ovary, and is too trifling to be appreciated during coition, and scarcely even in the ovary on inspection after death. The ancient anatomists were therefore right, when they termed the ovaries *testes muliebres*—the organs which secrete the seed in woman, as the testi-

cles do in man. This fact is also attested by Divine authority;—"I will place an irreconcilable bar between the seed of the woman and the seed of the serpent."

Hippocrates, who was unacquainted with human anatomy, supposed that the spermatric fluid of man was furnished by all parts of the body, and especially by the brain, as the principles of generation formed a new being, a miniature of our entire organization. As to the opinion, that the spermatric fluid was formed by the brain, that it descended along the spine to the loins and sexual organs, it is decidedly erroneous; for when the testicles, which secrete it, are removed, there is no seminal secretion. It is a remarkable fact, that the organ of love is now placed in the cerebellum by the followers of Gall and Spurzheim. The father of physis also entertained the opinion of Lucretius, that the resemblance of infants to either parent depended on a greater or less quantity of seed furnished by either. He held that a male resulted from a mixture of both seeds equally hot and elaborated; while a female was produced when the father or mother supplied a weak fluid, on one which is suddenly secreted. He supposed that on the mixture of both seeds the new being was formed in the womb. That this mixture absorbed heat, and passed from a state of fluidity to a certain consistence. Acted on by continued heat and vitality, the germ or new being, evolved a vapour which formed a round pellicle which enveloped it, and that it always received a new principle of life from the mother.

This pellicle, or fine membrane, formed an entire covering of the body, which finally was the skin, gave out a vapour which was condensed, and formed another membrane, and this part condensed a vapour into a fluid, by which the embryo was surrounded. In fine, he held that one point of this sac attached itself to the womb, by a spongy vascular union, through which nutrition was derived and carried to the navel of the fœtus by means of the umbilical cord or navel-string. It will appear hereafter, that this view of human ovology, though promulgated more than three centuries before the Christian æra, does not differ essentially, as regards the connexion between the embryo and mother, though otherwise erroneous, from that of the latest writers on embryology.

Aristotle admitted the female ejaculation, but denied that it contributed to the new being, that the male alone furnished the principles, while the female supplied

the necessary materials for their development, and these he considered, with Hippocrates, resided in the menstrual fluid. He said that woman furnished the marble, man was the sculptor, and the embryo the statue. (*De Generat Animal.*)

Averrhoes, Avicenna, and many others, adopted this doctrine; but the greatest number embraced the doctrine of Hippocrates.

Galen held that the embryo was produced by the seed of man, and that the materials afforded by woman nourished it. Diogenes, Hippon, and the Stoics, concluded that the embryo was produced by the male seed alone, and that the mother only served for its development, as the earth does for the germination of grain.

Descartes supposed that the mixture of the two seeds produced a fermentation in which the embryo was formed; while Pascal and other chemists, held that the spermatic fluid of man was acid, and that of woman alkaline. (*De Formatione Fœtus.*)

Viussens maintained that both seeds contained spirits; and Van Helmont held that the female furnished seminal fluid, and the male a spirit or vital principle.

Maupertuis was of opinion that each seed contained an imperfect animal, or parts of an animal, which it finally resembled.

Empedocles had previously supposed with Aristotle, that the embryo existed in separate parts, in the seeds of both sexes, which, on being united, formed a regular order and a perfect whole. (*Delamethria. Inst. Boerhaave.*)

Harvey concluded, after innumerable experiments, that the germ was in the ovary in animals and plants; and was the first who maintained the doctrine, now universally admitted as correct—*Omnia ex ovo*. He supposed impregnation was effected by a kind of magnetic influence. (*Exercitationes de Generatione Animalium. Quibus accedunt quædam de Partu; de Membris ac humoribus Uteri et de Conceptione. 1651.*) J. Fabricius proposed the theory of the *Aura Seminalis*. (*De Formatione Ovi, &c. 1625.*)

De Graaf contended that all animals were produced from an egg, maintaining the opinion *omnia ex ovo*, that germs existed in the ovary in the form of small transparent vesicle or ovules. (*De Mulier. Organis, &c., 1677.*) This doctrine was also admitted by Steno, Van Horn, Swammerdam, Malpighi, Harvey, Vallisnieri, Ploucquet, and many other cele-

brated physiologists, and is now generally received.

The next hypothesis was proposed by Hamme, and advocated by Hartsoecker, Leuwenhoeck, Boerhaave, Keil, Cheyne, Geoffroi, Cardinal de Polignac, Lieutaud and a host of others, who maintained, that the germs existed in the seminal fluid of man, in the form of small living worms, which they called *animalcules*, that one drop of sperm contained millions of them, that projected into the cavity of the uterus during coition, one or more of them ascended into the uterine tube, arrived at the ovary, entered a vesicle, caused impregnation, and returned into the womb under the form of a small ovum or egg; and finally developed into an embryo. MM. Prevost and Dumas also maintain this doctrine in their recent work. They alledge that in a vast number of artificial fecundations, they never effected vivication when the animalcules were killed or destroyed. Spallanzani stated that he mixed three grains of the spermatic fluid of a frog with seventeen ounces of water, immersed the point of a fine needle in this fluid, and having applied it to the spawn of the female, caused impregnation. According to Pritchard's *Microscopic Researches*, 1834, a drop of fluid contains myriads of animalcules of different forms, which corroborates the former opinion. M. Raspail contends, that the animalcules are organic remains, or product of the decomposition of sperm. M. Virey regards them as bladders distended by a sort of pollen, which burst when they arrive in organs of the other sex.

The objections against this doctrine are, the hybrid productions; as the mule, procreated by different animals; the creations between the stallion and the ass, and the jackass and the mare; and the error in supposing that only one of many million animalcules would be vivified and the rest destroyed. This would be contrary to the wisdom of the author of nature. Nevertheless, it has been lately proposed by an anti-population American that a woman who wishes to prevent conception, should inject the vagina immediately after coition, to destroy the animalcules. This recommendation displays great ignorance, and still greater depravity; and it is as ineffectual as it is impracticable.

Vallisnieri supposed that man commenced his existence as a worm, which developed itself by degrees, as an insect metamorphoses itself. This hypothesis was also entertained by Bourguet, Wood-

ward, Lyonnet Rai, Schelhammer, Paitoni, Launai, Duverney, Schlichting, Ploucquet, Hamberger, Senac, &c., and even Linnæus and Buffon seemed inclined to adopt it. But Spallanzani has shown the falsity of this hypothesis by fecundating the ova or eggs of a frog without these spermatic worms.

The succeeding hypothesis was designated *epigenesis*, or the partial or successive formation of the fœtus, a system maintained by Aristotle and Galen, revived by Decartes, Harvey, Needham, Muller, &c. This was called essential power (*vis essentialis*) by Wolf, *niscus formativus* by Blumenbach, and plastic form by Cudworth, and is analogous to the attraction of parts and superstructure of organs proposed by Maupertuis, (*Venus Physique*, 1745.) Buffon almost revived this hypothesis. He held, that during the most vivid enjoyment a number of organic molecules was separated from every part of the bodies of both sexes, that they resembled the parts which supplied them, that when they arrived in the womb, they approached each other and united; but that those supplied by the eye, the nose, the heart, &c., of man, could only unite with those supplied by the same organs in woman. Every anatomist knows that there is no passage for such parts to the womb, and that this supposition is imaginary.

Bonnet, Spallanzani, and the Italian schools, maintained that the germs pre-existed and were created since the beginning of the world, and were successively transmitted through innumerable individuals. According to this doctrine, Eve, the mother of mankind, possessed all the germs of men born, and to be born on the face of the earth; and every species of animals and plants, must possess the same power. Such is the system of evolution. MM. Virey and Velpeau object to this theory, on the grounds of the infinite divisions of matter, that a grain of corn might reproduce until it covered the earth; and the latter concludes that the ovary secretes the germ, (*Traite Elementaire de l'art des Accouchemens*, &c. 1829,) which is now the generally received opinion.

Sthal considers that the soul had the power of creating and organizing the fœtus; and Van Helmont admitted a formative spirit, a seminal being in the womb; and of the same genus of spirits as his Archæus in the stomach; both authors attributed marks and deformities to mental emotions. According to these

authorities the sperm is a living fluid which transmits the soul and the moral and physical qualities of the father to the fœtus.

The ancients were of opinion that the ovaries in women were analogous to the testicles in man, and supplied a seminal fluid proper for reproduction. The opinion prevailed until the time of Steno, a Danish anatomist who first maintained that the vesicles in the ovary contained a liquid resembling that in the eggs of birds, were ova or eggs, which contained the design and lineaments of the embryo, which after having been fecundated by the seed of the male, swelled, burst, escaped into the uterine (Fallopian) tube, fell into the uterus, there to undergo all the development of which the new being was capable.

The experiments of Fabricius ab Aquapendente, on the eggs of pullets, those of Harvey on bitches, sheep, and deer, already described, confirmed the opinion, and left no doubt that viviparous animals were produced from an egg like oviparous. De Graafe, Malphigi, Haller, Bonnet, and Spallanzani, after an immense number of experiments, confirmed the opinion of the pre-existence of germs in the ovaries. They concluded that the fecundation of the germ takes place in the ovary, and that the development of the product of fecundation is a simple evolution and not an epigenesis as formerly supposed. Harvey was the first who maintained that an ovum, egg, or vesicle, dropped from the ovary after impregnation, and De Graafe subsequently proved this fact by precise experiments. Dumas and Prevost have lately confirmed it by recent experiments. Brissiere saw this egg or ovule partly in the interior of the uterine tube, whilst it still adhered to the ovary. This is the received opinion of all modern physiologists.

Generation—Procreation of the Germs.

—The mysterious function of reproduction is still involved in obscurity. The transmission of life by parents in the animal and vegetable kingdoms remains as incomprehensible as ever.

Fecundation is effected differently in different animated beings. We have already observed that the generation in animals, insects, fishes, reptiles, birds, and vegetables occurs from the existence of a germ or ovum, and hence the truth of the ancient axiom *omnia ex ovo*—all generation is from an egg.

A question has been discussed but not as yet satisfactorily determined, what is

the seat of generation in the human subject; is it in the womb, is it in the oviduct or uterine tube, or is it in the ovary?

Almost all the ancients believed that the germs of male and female came in contact in the womb and formed the new being. Dr. Blundell and many recent physiologists suppose there is an electrical, or galvanic, or magnetic influence which effects generation.

"Has galvanism or electricity any share in the consideration of the Great Designer? Time, the discoverer of truth, may perhaps solve this important question!" (The Principles and Practice of obstetrics, &c., by James Blundell, M.D., with notes and illustrations by Thomas Castle, M.D., 1834.) This was previously advanced in the French Encyclopædia, *Art. Generation*. The great majority of modern physiologists entertain the opinion that fecundation is effected in the ovary. Prevost and Dumas adopt the idea of Buffon, Maupertuis, Aristotle, and Hippocrates, that the cavity of the womb is the seat of fecundation. Dr. Blundell concludes that the rudiments (ovum) and fecundating fluid meet in the uterus. This is contrary to the received opinion; and would not account for tubal, ovarian, and extra-uterine, or abdominal pregnancies. He admits "that the secretions of our sex reach to the ovaries, that there can be no full formation of the fœtus without the mixture of the two substances (male and female.) And it is clear that in ovarian pregnancy such deep penetration must occur. Perhaps the overaction of the genitals and the conveyance of the semen too far, may be the exciting cause on which the extra-uterine pregnancy depends." I cannot assent to the last notion, for were it true, extra-uterine pregnancy would be of common and not of rare occurrence; and I agree with those who ascribe it to relaxation of the uterine tube after impregnation in the ovary. Moreover, conception has followed the slightest possible penetration within the labia externa, even when the penis was not more than half an inch in length after amputation. In support of this hypothesis, some alledge that in all their experiments, they never found the animalcules in the uterine tubes or ovaries, that they found them in the cavity of the womb, that ovules must be imbedded in mucus which is supplied by the tube while conveying the ovum to the uterus; that they never could artificially fecundate ovules taken directly from the ovary, though nothing was more easily done

on those which had passed into the womb.

In refutation of this conclusion it is only necessary to state, that Ruysch asserted that he found the spermatic fluid in the uterine tube of a young woman who was caught in the act of adultery by her husband, and stabbed to death; and Haller discovered the fluid in the tubes of sheep after having been slaughtered. This was probably a mucous fluid supplied by the lining membrane of the uterus and uterine tubes. Recent cases of semen being found in the cavity of the womb, are open to the same objection.

M. Velpéau well observes, in commenting on the preceding statements, that it does not follow, because the ova of a frog could not be impregnated unless enveloped in mucus, the same thing happens in women. It was not to be expected that the removal of an ovum with an instrument could be effected without such violence as would injure it and unfit it for impregnation. We must also bear in mind the existence of ovarian, tubal, and extra-uterine pregnancies which clearly prove that fecundation occurs in the ovary and not in the uterus. Mr. Stanley recorded a case of ovarian pregnancy (*Med. Trans.* vol. iv.) and Dr. Granville another, in which the fœtus was four months old. (*Phil. Trans.* 1820) M. Brissiere relates a case in which one half of the embryo was in the ovary and the other in the uterine tube. Others attest the development of the fœtus in the ovary, tube, and abdomen, among whom are Verheyen, Cyprianus, Saint Maurice, Courtial, Littre, Haller, &c. Every woman and every female of the mammiferæ is barren, if deprived of both ovaries, or when these are completely disorganized or when the tubes are impervious or ligatures applied to them before impregnation.

The experiments of Nuck, Haighton, and Blundell, afford the most conclusive evidence in support of the opinion, that fecundation occurs in the ovary. Nuck applied a ligature round the tube between the womb and the ovary, immediately after copulation, he killed the animal a few days afterwards and found the ovum arrested by the thread. Dr. Haighton tied and also divided the tube in rabbits, and invariably observed that no fecundation occurred in the ovary on the side on which he operated (*Phil. Trans.* vol. lxxxvii). Dr. Blundell's experiments are described in the *Medico-Chirurgical Transactions*, in his work on *Generation*,

and also in the edition of his *Obstetricy*, by Dr. Castle. He divided the uretus of a rabbit, so as to obliterate its cavity; and he also obliterated the upper part of the vagina. The animal recovered, and was subjected to the male, but no fecundation took place, though there was an attempt at it, for corpora lutea were developed, and a quantity of water found in the uterus! His experiments were numerous; and led him to the conclusion that the germs of the male and female rabbits, and perhaps of all other animals must come in contact to effect impregnation. From these experiments he infers that corpora lutea may form in rabbits independently of the full excitement of the genitals—that the mere absorption of the semen from the vagina by means of the lymphatics is sufficient for the purposes of formation. In one vaginal experiment, the access of the semen to the ovaries being interrupted, impregnation was not accomplished, though the animal admitted the male as many as fifty times, mostly at intervals of two or three days or more—a quantity of water was found in the uretus, as in other experiments. In this case the male fluid must have been frequently absorbed from the vagina.

The observations of Dr. Montgomery of Dublin, are directly opposed to the opinion that corpora lutea exist without impregnation (*Cyclopædia of Practical Medicine, Art. Pregnancy, Treatise on Pregnancy, 1837.*) The theories of generation now maintained, are three:—1. The transmission of spermatic fluid of the male through the uterus, uterine tube, or oviduct to the ovary, a vesicle, ovum, or egg of which is vivified and passes into the womb to be developed, until the expiration of the ninth month, when it is born and becomes an independent being; 2. The transmission of subtle vapour or effluvium from the male semen (*aura seminalis*) through the same parts to the ovary, the impregnated ovum passing into the uretus to be developed in the manner before stated; 3. The absorption of the seminal fluid of the male from the surface of the vagina.

The transmission of the spermatic fluid through the uterus, uterine tube, or oviduct to the ovary, a vesicle, ovum, or egg, is vivified or fecundated and passes into the womb to be developed until the ninth month or fortieth week, when it is born, and becomes an independent being. This is the most general opinion.

During the act of copulation the external and internal genital organs of both

sexes, which are all supplied by nerves from the same source, are excited and stimulated, the vagina closes tightly on the penis, the uterine orifice is in close contact with the orifice of the male urethra, the tube or oviduct becomes straightened and erected, and its loose or floating extremity (*corpus fimbriatum*) seizes on the ovary, and allows the male fluid after its injection into the cavity of the womb, to advance through the tube to the ovary, by a species of vital attraction or suction. The moment the spermatic fluid arrives at the ovary, which is seized by the extremity of the uterine tube, it acts on and vivifies one or more ova or ovules, and forms the new being, or beings.

The fecundated ovule is now the seat of a new vitality, it becomes swollen, reddish, and finally bursts its membrane, and detaches itself from the ovary. The fimbriated extremity of the uterine or Fallopian tube is still in contact with the ovary, and favors the passage of the newly formed being, the embryo, into the uterus to be developed until the expiration of the ninth month, by a series of the most extraordinary changes. When the extremity of the tube loses its hold of the ovary, which may happen according to some writers, from excessive voluptuousness, fear, &c.; the ovule on bursting its covering will fall into the abdomen, there develop itself as an extra-uterine pregnancy, and finally destroy the patient unless relieved by gastrotomy or the first part of the Cæsarian operation. It is, however, a fortunate circumstance that abdominal and tubal pregnancies are of rare occurrence. A case of this kind was successfully treated in London, 1836.

Almost all physiologists are of opinion that the uterus possesses a power of suction and imbibes the semen after its ejaculation or a vapour arising from it. Ruysch, Haller, Lewenhoeck, Hartsoeker, Hunter, and others discriminated the spermatic fluid of the male in the uterus; a fact which is denied by others, and cases are on record in which the orifice of the womb was permanently fixed external to the genital aperture, through which fecundation happened. Dr. Ashwell and Mr. Kingdon mentioned cases of this kind at the Medical Society of London a few years since.

The Fallopian tube is said to become erected during the orgasm of coition, to embrace the ovary, which embracement was observed in different animals after coition, by Haller, De Graafe, and Cruikshank; in women who died soon after

coition by Littre; and in a virgin, who died of hysteria, by Vallisneri. The peristaltic and anti-peristaltic motion of the tube, the conveyance of the semen to the ovary, and the reconveyance of the impregnated ovum to the womb, have been proved by ocular demonstration, by Becard, De Graafe, Prevost, and Dumas, and by the experiments of Nuck and Duverney, who arrested the impregnated ovum in the tube, by a ligature applied three days after coition; again by the tubular and abdominal pregnancy, in which the tube has allowed an ovule to escape (Lallemand). It is probable that the increased dilatation of the tube, after fecundation, is intended for the retention of the ovum for some time. How can we explain the fact, but that one tube only is concerned in conception? What was the object of nature, in forming two tubes, two ovaries, two testes, two seminal receptacles, if one organ in each sex be sufficient for the propagation of the species? Or are the double organs in each sex intended for the formation of the distinct sexes?

(To be continued.)

AN EXPERIMENTAL INQUIRY RESPECTING THE PROCESS OF REPARATION AFTER SIM- PLE FRACTURE OF BONES.

By MR. BRANSBY COOPER:

The immediate effects of fracture of bone, and the process employed by nature to repair the injury, have at all times excited the curiosity and engaged the attention of physiologists; but, probably, at no period has the subject engrossed so large a share of professional inquiry as it has done of late years.

Many most distinguished surgeons, both on the continent and in this country, have zealously entered into the investigation; and, as might have been expected, much valuable information has been the result. Sir Astley Cooper has largely contributed to the exceedingly deficient and disjointed materials, heretofore possessed; his additional knowledge of the subject having been derived from the examination of the spontaneous efforts of nature towards the reparation of a fractured bone, watched through the succes-

sive stages, as they occurred, in the progress of repeated experiments upon animals.

Nevertheless, it is fairly admitted, that there remains much to be done—that there are many points upon which physiologists are at issue; and that further experiments are required, to place the subject in a clearer light, and on the foundation of sound principles; as, still, too many are inclined to consider the phenomena, attending the accidents incident to bone, as entirely different from those, accompanying the action set up by nature in the reparation of the softer parts; whilst, on the contrary, by strict investigation, it will be found that the same laws obtain in both instances; modified, however, in the re-production of bone, by the deposition of a portion of earthy matter, essential to the physical character of that hard and solid structure.

A recent conversation held with Sir Astley Cooper, led me to repeat a series of experiments, which he himself had many years ago projected and performed, and from which the contribution contained in this paper has arisen; and as no one has thought more deeply, or experimented more extensively, on this subject, than Sir Astley Cooper, so did I find that no one was more anxious for its farther investigation, or more sanguine in the expectation of some new light being thrown upon the process by which nature repairs a solution of continuity in the osseous system.

It was at his recommendation, therefore, and with the advantage of suggestions derived from his experience, that I undertook the task of repeating his experiments; the results of which appear to me to possess some novelty, and are certainly such as I had not altogether anticipated. To minds easily satisfied, and to those who think that the present subject has been amply illustrated and explained, it may reasonably be suggested, that even to go over old ground is often profitable, and, perhaps, in the pursuit, something unexpected may present itself.

As the experiments, necessarily entered into with a view to the investigation of this interesting point, are, of course, numerous, it must not be expected that the subject is to be completed in one article. My object is, moreover, to give a faithful detail of the appearances exhibited, from day to day, in the limb of an animal subjected to experimental fracture, and to present an accurate delineation of the minute alterations which occur in the dif-

ferent structures in the neighbourhood of the fractured bone; deferring theoretical comments on the facts observed, until the completion of my experiments will authorize me to form a just deduction from the results, which I shall then be enabled to lay before the profession. Nevertheless, from the experiments already made, I feel that I shall be justified in detailing the views I have formed relative to the first efforts of nature towards the reparation, by those tissues immediately influenced by the injury.

I shall proceed, therefore, to the description of the appearances, as they presented themselves upon examination in the experiments, without intending to give the minute account of each dissection; as, in some instances, it would be found that the advance towards reparation of the succeeding experiment varied but little from that of the one immediately preceding;—this circumstance depending, apparently, upon the mode of producing the injury, as well as the age and constitutional powers of the particular animal. In the choice of the rabbits to be subjected to the experiments in question, care was taken to procure them as nearly as possible of the same age and size; and the thigh bone I considered the best adapted for the investigation of reparative power, in consequence of its being so perfectly surrounded and deeply imbedded in softer structures, which, it seemed to me, would be found to assist greatly in the process of restoration.

The fracture has been produced, in each experiment, in such a manner as to injure the soft parts as little as possible; and the dissection of each animal has been carefully performed about an hour after its death, with the intention that the position of the fractured extremities of the bones might be similarly influenced by the subsequent contraction of the muscles.

Mr. Cooper made eight experiments upon rabbits, from which he draws his conclusions:—

On taking a retrospective view of the various effects produced by fracture of a bone, as detailed in the foregoing experiments, it will be my object to recapitulate the appearances, in the order they presented themselves; by which means we may be enabled to discover the process which nature adopts for the reparation of injured parts, when the work of restoration is left to her alone. The first effect produced in the solution of continuity of bone—as, indeed, must inevitably occur in lesion of any vital parts—is,

extravasation of blood; and even this first effect involves a very important question, as to the purpose to which that blood is to be applied. The immediate effect of this extravasation is, to infiltrate the cellular membrane in the vicinity of the fractured extremities of the bone and of the surrounding muscles, with blood, which, by its coagulation, immediately produces two desirable results; first, in effecting a degree of stiffness in the injured limb, which prevents the tendency to motion; and, secondly, in restraining a further hæmorrhage, by plugging up the torn blood-vessels, both of the bone and of the softer structures. The firmness of the coagulum filling up the cancelli of the two fractured ends of the bone is the principal feature to be observed, and I believe I may say, the first step towards reparation, after the infliction of the injury. So soon as the coagulum has effected this important object of staying hæmorrhage, its fluid parts begin to be absorbed, and the tumefaction of the limb to diminish; while the firmer parts of the blood still produce the beneficial effect of giving solidity to the limb. Little change beyond this is to be observed forty-eight hours after the accident, the coagulum only being found firmer than on the examination made at the end of the first four-and-twenty hours. On the third day, the surrounding tissues begin to be inflamed, from the irritating influence of the coagulated blood; as evinced by the disposition of coagulable lymph, by which the muscles become connected to each other, and their power of contraction diminished, leading to a further means of preventing motion in the fractured ends of the bone. At this period, also, it is to be observed that the coagula, closing the cancelli of the two ends of the bone, are firmly united to the medullary membrane, as well as to the surrounding deposited lymph; and must, in some degree, therefore, assist in maintaining a state of rest. The inflammation induced in the surrounding soft parts still continuing, leads to the effusion of more adhesive matter: at the same time, the erychymosis becomes less, and paler in colour, and the general surrounding tissues more distinct. From this period, the effused adventitious matter begins sensibly to thicken, and to acquire increased firmness; from a gelatinous effusion, forming a distinct tumour around the fracture, of sufficient solidity to limit still further the motion of the parts, and completely to prevent the muscles being irritated by the irregular ends of the

bones. If at this period—namely, between the fourth and sixth days—the callus be examined, it will be found intimately intermixing with the surrounding muscles, at the points opposite to the fractured ends of the bone; and, internally, it is also connected with periosteum and coagula filling the cancelli, thus isolating the fractured bone from the surrounding structures. After this, all the appearance of ecchymosis entirely ceases; and the only portion of the original coagulated blood which now remains, is that plugging up the ends of the bone, the fibrin of which appears to have become organized; and therefore it may be said, that the original extravasated blood in part assists in the reparation.

The progressive steps towards union, up to this point, are liable to interruption, either from the want of constitutional power in the animal, or the extent of injury done in producing the fracture; so that some of the experiments required to be repeated. About the sixth day, further consolidation ensues; the surrounding muscles appear distinct from the callus, excepting at the points opposite to the ends of the bone. The diffused matter has now both the appearance, firmness, and elasticity of cartilage; and, by its contraction, which occurs simultaneously with its increased density, tends to bring the hitherto separated fractured ends of the bone parallel, although they overlap each other, through the influence of the muscles. At the points where the bones come in contact, the periosteum is absorbed; but in all the other parts, this membrane is inseparably connected with the surrounding mass, much thickened, and easily detached from the bone, so as to give the appearance of the bone having been deprived of its periosteal covering; but the fact is, that it has only become blended with the effused callus. The portions of bone, where denuded, are softened, granular, and seem to be endowed with a higher degree of vascularity, than healthy bone, probably from the absorption of its earthy constituents. Here it is where the first traces of earthy depositions seem to commence; so that it would appear that the surrounding structures so far assist in the reparation of a fractured bone, as to induce approximation, limit motion, and diminish the irritability and contraction of muscle; while the osseous system itself deposits the earthy matter essential to hardness, the grand characteristic bone. This view, however, is to be considered as somewhat

speculative, as it requires further experiments to prove its validity; at any rate, it is shown that all the soft parts participate in the injury, and perform a very important office in the completion of a cure: this is rendered more obvious, by the consideration of the inefficiency of the bones of the cranium, neck of the femur, and some other bones, not surrounded by cellular and muscular systems, to work their own reparation. It is nevertheless certain, that so early as the seventh day, in some instances, and the eighth and ninth day in others, earthy matter is secreted in the dense cartilaginous mass in the immediate neighbourhood of the fractured bones. Small specks of the same deposit are observed, at this period, in the fibrin which closes the opening of the broken extremities, and, at a more advanced time, completely shuts up these canals with a firm septum of bone. If sections of the cartilage be made in the mass surrounding the ends of the bone, and placed on glass and dried, the white earthy matter is rendered clearly visible, deposited in minute specks in this more transparent substance.

*NORTH LONDON HOSPITAL.

TALIOCTOTIAN OPERATION—DEATH.

A man whose lower lip had been destroyed by ulceration, and who suffered much inconvenience by the escape of saliva, presented himself at this hospital, and Mr. Liston had no hesitation in recommending an operation for his relief, and to which the unfortunate sufferer was induced to submit. The callous edges were removed, a portion of skin was raised from the submental region of such a shape as to fit the excavation, and thus was formed a very respectable looking lip.

Although the operation was executed with that rapidity so desirable, and so highly appreciated at this hospital, the wound was attacked with erysipelas, and the sixth day, notwithstanding the most judicious treatment and repeated consultations on this interesting case, the patient expired.

CASE OF LITHOTRITY—DEATH.

A countryman, about 60 years of age, was admitted into this hospital under the care of Mr. Liston, on Saturday the 28th of June last, and it having been ascertained that there was a stone in the blad-

der, on the Monday following the operation of lithotomy was performed by Mr. Liston. The percursor was introduced in the usual manner, but made a sudden jerk on entering the bladder. Two stones of moderate size were discovered, and broken down, but no portions were extracted. On the fourth day, Friday, the patient expired. The body was examined *privately*, and the diseased parts having been removed by Mr. Liston, to his private abode, the cause of death has not yet been publicly announced to the students of the hospital, which is to be the more regretted, as it has given rise to many surmises on this most interesting and important case.

METROPOLITAN FREE HOSPITAL.

NOTES OF CASES UNDER THE CARE OF
DR. RYAN.

Hemiplegia of the left side in an aged subject—Administration of Strychnia—Recovery.

G. R., aged 77 years, was admitted March 20th, 1837, under the care of Dr. Ryan. He is a broken-down constitution, labouring under paralysis of the left side of the body. He states that he frequently bled from the nose previous to his attack of palsy; and he possesses sensation with partial motion in the diseased parts. He was ordered Cathartic pills, and a twelfth of a grain of strychnia in a pill night and morning. Antimonial ointment to the neck. He continued these remedies until June 1st, when he declared himself greatly improved; and he can now walk tolerably well.

Epilepsy relieved by Strychnia.

G. E., aged 48 years, of a bilious temperament, a carver and gilder, was admitted Nov. 21, 1836. He states that he never had a tranquil mind, and was always low-spirited. He is a native of Wales, and cannot account for the cause of his complaint. Hair black, countenance sallow, habit spare. About three months ago he was surprised at finding that he could not cover the holes of a flute, and soon afterwards he was suddenly seized with a fit, which speedily caused his face to turn towards his right shoulder, the ceiling of his apartment seemed to turn round, and then he became insensible. He has never experienced any creeping

sensation or aura epileptica. He had a fit every fortnight before he applied at the hospital, and was told by a practitioner that he would most probably go out of his mind.

He was ordered aperient pills, and a twelfth of a grain of strychnia morning and evening.

He continued his medicines until May last, when he considered himself well. He lately had a fit, in consequence of drinking too freely of ale.

July 25, 1837, the general health is now good, and the fits have entirely ceased. Ordered to continued his medicines and live temperately.

The strychnia has failed in other cases.

Ovarian Dropsy—Failure of Hydriodate of Potass and Hydragogues—Rapid Cure by Diaphoretics.

C. P., aged 28 years, the mother of two children, has been in bad health for some months, and subject to menorrhagia. In August, 1836, presented the usual symptoms of ovarian dropsy of the right side. She was ordered the Pulv. Jal. C. with calomel digitalis, and squill, which operated freely, as a hydragogue, but not as a diuretic. She also took the hydriodate of potass in full doses. These medicines were used freely during the winter and spring months, with other diuretics, but ineffectually. In May she was ordered diaphoretics, the acetate of ammonia, with antimony and flannel next the skin, when she began to perspire profusely, and is now (July) free from her disease. She was also ordered tonics during her treatment, as well as full diet.

Warts on the labia externa et interna of an Infant—Purulent discharge.

A. S., aged two years, a scrofulous habit, labours under purulent discharge from the labia, and an immense number of warts on these parts as well as the nymphæ. She was ordered a weak solution of the dydriodate of potass, with opium, and also hydr. c. creta cum rheo. m. n., which rapidly effected a cure.

Thymic asthma—Spasmodic croup, or asthma—Laryngismus stridulus—Cure by iodine

A child aged two years, laboured under spasmodic cough and croupal respiration, which at times threatened suffocation. He was attacked daily with spasmodic cough and convulsion, and his face became so livid as to frighten his parents.

The general health was good, and there was no swelling of the throat.

He was ordered two grains of hydiodate of potas., in two ounces of distilled water, a tea-spoonful to be given twice a day, sweetened; and an ointment composed of a scruple of the hydiodate, and an ounce of adeps, to be rubbed over the throat, in the proportion of a scruple night and morning. At the end of a fortnight he was perfectly free from his complaint.

It is worthy of remark that the late Dr. Ley had not mentioned that he ever used the iodated preparations in his numerous cases of this disease.

Syphilitic ulceration of the soft palate, of four years duration.

E. A., aged 24 years, married, of a bilio-nervous temperament, contracted syphilis from her husband four years and a half since, for which she was treated by an educated surgeon. For the last four years she has suffered severely from an ulcer in the throat, for which she was ordered mercury and fumigations, in Bartholomew's hospital. She is now, June, 1837, in very bad health, and considers her disease incurable. Her throat has been affected during the last four years.

Her general health was attended to, and she was ordered a gargle of the iodate of mercury, to be used three or four times a day. She is now, July 15, nearly well.

Poisoning of an infant with Colchicum exhibited to the mother—Recovery—Observations.

An infant aged six months, was seized with violent vomiting and diarrhoea, followed by coma, in consequence of its mother having taken eight doses of colchicum, for rheumatism, &c. combined with an aperient. Mr. Churchill, of Strutton-ground, Westminster, requested Dr. Ryan to see this case. The colchicum had acted on the breast milk. Treatment—Aromatic spirit of ammonia, brandy and arrow-root, warm bath, which effected recovery.

Observations.—This case proves the obstetric aphorism, that medicine taken by a wet-nurse, affects the breast-milk, and through it the infant. It also shews the necessity of combining aperients with colchicum, so as not to allow it to accumulate in the system. In this case the elder patient had no alvine dejection for three days, and the medicine had accumulated in the system.

TO CORRESPONDENTS.

Crito.—The three surgical pures in an early number. The portraits which the quarterly wag has depicted, are not only amusing but highly instructive.

Nemo.—Pressure of business has prevented it, but his want will be supplied, perhaps, next week.

Inquirer.—The rent of the beautiful residence at Charing cross may be heard of by a personal application, or by letter, not paid, to Mr. George Robins.

Westminster.—No change has yet been agreed upon by the shareholders of the Westminster Medical College. The hospital fee will certainly be diminished, and will not exceed that of the Middlesex.

Chirurgus.—We know of no particular advantage in removing a portion of the prostate gland, though it be enlarged, in the operation of lithotomy.

Medicus.—The Metropolitan University will not be in operation for several months. Its regulations are not published.

Erasmus.—The naufragium is too ominous.

Censor.—The negotiations between King's College and the Charing Cross staff are at an end. No junction—*divide et impera* is the motto. The Birmingham statesman encounters an older politician.

J. S.—The Physicians' Vademecum is just published.

Boheraate.—Professor Davis did attend her Royal Highness the Duchess of Kent at the birth of her most gracious Majesty.

Heraclitus.—Our laughing friend is too severe on the batch of the faculty at the levee. It was all pure loyalty and dutiful affection towards our beloved and most gracious Sovereign. Two and twenty Esculapians were, certainly, a most formidable array at one interview, without all the inadmissibles, who were hooked on the deputations.

An Irish Reformer.—An improved Medical Charities Bill will pass next Session, and the just rights of all British subjects will be properly protected. The Dublin College of Physicians like its benighted prototype in Pall Mall East, will, of course, allow the Surgeons to obtain all the loaves and fishes.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

NOTES OF LECTURES ON
PHYSIOLOGY.

BY DR. FLETCHER.

*Delivered in the Argyle Square School
of Medicine, Edinburgh.*

No. XXXIV.

THERAPEUTICS.

Sedative, antispasmodic, and narcotic medicines—Similar in their actions to astringents—Difference between sedatives, antispasmodics, and narcotics—Prussic acid—Mercurial erythism—Animal, vegetable, and mineral antispasmodics—Antacid and anthelmintic medicines—Antacids in scrofula—Antalkalies in scurvy—Mechanical, chemical, purgative, and specific anthelmintics—Action of lime-water on worms—Cowhage and filings of tin—Form of medicines—Lozenges—Pills—Proper weight of both—Three-grain pills—The bread-pills of the pharmacopœia—Conserves—Proportion of sugar they contain—Confections—Infusions—Decoctions—Maceration and boiling—Respective advantages and disadvantages of each—Emulsions—Mixtures—Powders suspended by mucilage—Different kinds of mucilage—Gum-arabic, gum-tragacanth and starch—Inspissated juices—Extracts—Different modes of preparing them—Proper mode of preparing a water-bath—Barry's mode of evaporating extracts in vacuo—Tinctures—Spirits—Distillation—Plasters—Ointments—Cerates—Use of oil, lard, and wax—Combination of medicine—Their virtues increased by it—Simplicity in prescribing carried too far—Huxham's prescriptions—Formulæ with four hundred ingredients—Alexandrian pharmacopœia—The British pharmacopœias—Surgery—Moxa—Introduction into Europe, France, and England by Bucholz, Putet, and Wallace—Difference between its action and that of the cautery—Sometimes combined with acupuncture, by means of a white-

No. 18.

hot needle—Electricity—Diseases for which it is employed—Sparks and shocks—Galvanism—Difference between it and electricity—Diseases in which it is resorted to—Galvanism in asthma—Wilson Philip on galvanizing in apoplexy—His mode of galvanizing the chest—Acupuncture—No bad effects from piercing blood-vessels—The needle passed into the heart and brain—Diseases for which acupuncture is recommended—Different theories of its efficacy—True solution by Dapuytren—Practice of the Japanese—Acupuncture with ivory needles—Blood-letting—Venesection, arteriotomy, cupping, scarifying, and leeching—Advantages of studying physiology—Its agreement with revelation.

4. *Sedatives, Antispasmodic, and Narcotic Medicines.*—The mode of action of these medicines is probably not essentially different from that of the second class—astringents. There are peculiarities in each of the three orders into which we have divided this class; and they are administered with different objects. Sedatives, for instance, act chiefly on the heart; antispasmodics on the muscles; and narcotics and sensation and thought. The chief of the sedatives are, digitalis, prussic acid, and tartar emetic. Mercurial erythism belongs to this division. Of the second order, the principal vegetable substances are, valerian (*valeriana sylvestris*), saffron, and the fetid gums, assafoetida, galbanum, opopanax, ammoniacum, and sagapenum. The animal antispasmodics are musk and castor. The other antispasmodics are petroleum, oil of amber, burnt feathers, and the oil of turpentine and cajuput. The officinal narcotics are opium, poppy-heads (*papaver somniferum*), petals of the red-poppy (*papaver rhœas*), monk's-hood or wolf's-bane (*aconitum napellus*), hellebore, stavesacre (*delphinium staphisagra*), cocculus indicus (*menispermum coccu-*

2 N

lus), poison-oak (*rhus toxicodendron*), bitter almonds (*amygdalus communis*), peach leaves, cherry-laurel leaves (*prunus laurocerasus*), hemlock (*conium maculatum*), the lettuces (*lactuca virosa* and *sativa*), nux vomica (*strychnos nux vomica*), deadly nightshade (*atropa belladonna*), thorn-apple (*datura stramonium*), henbane (*hyoscyamus niger*), tobacco, great mullein (*verbascum thapsus*), hedge-hyssop, camphor, and meadow-saffron (*colchicum autumnale*).

5. *Antacid and Anthelmintic Medicines*.—Antacids are given in scrofula, while antalkalies are given in scurvy. The chief antacids are the alkalies potash, soda, and ammonia; and the earths lime and magnesia, with the carbonates of them all. The antalkalies are the sulphuric, nitric, muriatic, acetic, citric, and tartaric acids; the orange, the lemon, sorrel (*oxalis acetosella* and *rumex acetosa*), tamarinds (*tamarinds Indica*), plums or prunes, the hips of the wild-briar (*rosa canina*), the mulberry (*morus niger*), the lettuce, and all fresh vegetables. The action of the anthelmintics is in general either simply chemical or mechanical. They are divided into four orders:—1. *Mechanica*. 2. *Chemica*. 3. *Purgatives*. 4. *Propria*. Lime-water is the only chemical anthelmintic. It dissolves the mucus in which the worms have their habitat. Cowhage, or cow-itch (*dolichos pruriens*), and filings of tin, belong to the mechanical anthelmintics. The last order—that of proper anthelmintics—comprehend those substances which poison the worms; such as bitters, polypodium, filix mas, and gin.

With respect to the form of medicines we may observe, that a trochiscus, or lozenge, weighs about ten grains, and a pill about five. The pill of the ammonuret of copper weighs but three grains, and is the only one ordered by the pharmacopœia to be prepared with crumb of bread. A conserve is any medicine mixed with sugar. Conserve of red roses contains about one-fourth petals, and three-fourths sugar. A confection is more complicated, the consistence of the medicinal substance being diminished by means of dried fruits, figs, tamarinds, &c. An infusion is made by maceration, and a decoction by boiling. The former is better, for boiling is likely to destroy the aroma, and the extractive principle is often changed by the heat, becoming oxidized, insoluble, and consequently inert. Hence the infusion of bark, or of senna, is better than a decoction; but the latter has the

advantage of saving time. An emulsion is oil suspended in albumen, or an alkaline solution. A powder may be suspended in a mixture, by means of mucilage. Mucilage of gum-arabic is made with one-third part gum; mucilage of gum tragacanth is made with one-tenth part gum, which is not dissolved but suspended; mucilage of starch is made with only one-sixteenth part of starch, for the latter swells up and the solution becomes very thick. Mucilage of gum-arabic is used for drinking, the other two mucilages for suspending powders. An inspissated juice, is got by pressing out the juice from the recent plant, and then evaporating it to the proper consistence. An extract is obtained by boiling the medicinal substance with eight parts of water, and then evaporating the decoction in various ways. If a water-bath be used for this purpose, the water should be saturated with salt, in order that it may bear a high temperature. Barry has a method of evaporating in vacuo. A tincture is prepared by maceration; a spirit by distillation. Plasters are generally made by litharge and oil. Ointments are substances rubbed up with lard; if wax be added, by melting the whole together, it is a cerate. Muriate of lime, and of baryta, are always kept in solution, from their tendency to deliquesce.

The virtues of medicines are increased by combination; and we have probably simplified too far in prescribing. Fluxham had four hundred ingredients in some of his formulæ. This was going to the other extreme, for it must have been impossible to tell *à priori* what the effect of such medicines would be. In the pharmacopœia of Nicolais, of Alexandria, there were two thousand six hundred and sixty-eight preparations, each containing, on an average, twelve ingredients. In our three pharmacopœias there are only thirty, and most of them contain only three ingredients.

III. *Surgery*.—This department of therapeutics comprehends the various operations which are performed on the different organs of the body. We shall notice a few.

1. *Moxa*.—This operation was introduced into Europe by Bucholz; into France by Putet; and into England by Wallace. It acts more slowly than the cautery; does not constrict the vessels so much, and allows them to expel their blood. Acupuncture is sometimes combined with the application of the moxa. The needle is hid in the roll of cotton, and, when while hot, is pushed forward

into the flesh. It is a very ferocious remedy, but is said to be very efficacious.

2. *Electricity*.—It is of little importance whether we draw sparks from the patient, or give them to him; for it is the change of electrical condition that cures the disease. It is resorted to in amenorrhœa, chlorosis, paralysis, diseases of the joints, rheumatism, &c.

3. *Acupuncture*.—The stimulus of galvanism is stronger than that of electricity. It is used in the same diseases, and in dyspepsia, asthma, paralysis of the œsophagus, &c. If asthma were produced by spasm, galvanism would aggravate instead of relieving it. Wilson Philip recommends that, in apoplexy, galvanic shocks should be passed through the chest; thus keeping the organic system going till the remedies adopted have time to restore the stimulus of the brain; for if this were not done the patient would die in the mean time. In galvanizing the chest, Wilson Philip applies one plate to the nape of the neck, and the other to the epigastrium, so that the galvanic current may pass in the direction of the spine, the phrenic nerve, and the par vagum.

4. *Acupuncture*.—No bad effects result from driving the needle through vessels; for the parts close after it is withdrawn. It has even been passed into the heart and brain. It is used in rheumatism, palsy, gout, deep-seated inflammations, and all functional diseases. It probably acts, as Dupuytren suggests, by applying an immediate stimulus. The Japanese have long employed it, with the object of drawing off the peccant airs, to which they think all diseases are referrible. They practice on images with needles, in order to hit on the three hundred and fifty parts, into which they believe the needle may be driven with impunity. Cloquet and others maintain that the needles are beneficial from drawing off nervous energy; but inflammation being diminished action, would indicate a deficiency instead of a redundancy of this nervous energy. Others attribute the good effects of acupuncture to galvanism; and the needles do exhibit galvanic phenomena; but they do the same when plunged into healthy parts, as when the parts are diseased; and needles of ivory will do as well for acupuncture as those of steel. Duncan says they do not act by imparting a stimulus, for very little sensation is excited; but there may be irritation without sensation. Some say acupuncture acts through the medium of

the passions; as animal magnetism probably does.

5. *Bloodletting*.—This may be accomplished in five different ways. 1. Venesection. 2. Arteriotomy. 3. Cupping. 4. Scarifying. 5. Leeching. Leeches are objected to in erysipelas, paralysis, and dropsy, from the fear of producing gangrene. Blisters are objected to in the same cases, for the same reason. Leeches should be avoided in parts to which pressure cannot be applied, or which are destitute of fat, as the subsequent hæmorrhage may be troublesome. Monro recommends the twisted suture to stop leech-bites. Arteriotomy is not general bleeding; for it takes away blood going to the part affected. In venesection, it does not matter whether the vein opened be near the part affected or not, provided it be of equal size; although if it be taken near the part, it may perhaps diminish congestion, by removing the resisting column of blood.

The objections which have been urged to the study of physiology are unfair and untenable, while, on the other hand, the inducements to engage in it are great and numerous. Is it not, in the first place, a tribute that we owe to the great Author of Nature, who has made all his works so admirable, and has endowed us with faculties for admiring them,—is it not a tribute that we owe him to admire these works, and thus to rise “through nature up to nature’s God.” Were our faculties given to us in vain, or rather that we should employ them in praise of his power, wisdom, and goodness? And how can we praise what we do not appreciate? We may use like parrots, the words of praise, just as a man ignorant of painting or sculpture may repeat what he has heard others say in praise of the author of a picture or a statue; but we cannot be actuated by the soul which should inspire these words, unless we know and feel how infinite are the merits of those works; for this knowledge and feeling alone can true admiration be founded. The blindest savage may be instructed to mumble lip-service to the Creator of the universe; but it is the man of intelligence alone, whose mouth can speak his praises from the fulness of heart. We may say, “How manifold are thy works, O Lord!” but it is almost scornful to say so, if we have taken no pains to know these works. We may add, “In wisdom hast thou made them all!” but the addition is mere mockery, if we have neglected to search for the evidences of that wisdom. A

wilfully ignorant man may be superstitious, but he can hardly be religious. He may fancy that he reverences his Creator, but he cannot reverence him as a thinking and a rational being, and as one liable to give an account of the talents entrusted to his keeping if he be content, at the same time, to remain indifferent to his works. And which of his works is so well adapted to inspire admiration of their Omnipotent Author, as the structure and actions of animals in general and of man in particular? It is on the evidences which physiology affords, of the wisdom, the power, and the goodness of God, that the Greatest men of every age have principally relied for inculcating a belief in the existence and attributes of a Deity; and can we, without reproach, neglect to avail ourselves of this assistance to the faith inspired by Holy Writ, of this means of illustrating and corroborating the sublime truths of Scripture?

Most unwilling should I be to lend myself, in the remotest manner, to any attempt to make what is called natural religion a substitute for revealed religion. Natural theology may tend to make a man more so; but natural theology can never make a religious man an irreligious one; for it can never teach him the immortality of the soul, and his moral responsibility. To attempt, therefore, to make the writings of any class of philosophers a substitute for the Bible is an attempt to annihilate all the noblest and best aspirations of man. But I am totally ignorant of the existence, in any class of persons, of a desire to effect this substitution; and I cannot help thinking that some well-meaning people have lately displayed rather more jealousy than is calculated to benefit their cause, of any interference by lay teachers with the business of religion. The same God who gave us the Bible as the mandate of his will, gave us likewise the objects of nature as the testimonials of his wisdom, power, and goodness; and I am at a loss to perceive by what train of fair reasoning, any who insists on the latter as bearing evidence of the highest attributes of the Creator, can be construed into an opposer of the former, as inculcating the same sublime truths of revelation. Why should facts which might be rendered mutually illustrative of each other, and be made to act allies, strengthening and receiving strength, be adduced only in opposition, or supposed to be so adduced? Can it be believed that the writings of a Boyle, or a Swammerdam, of Roger, of

Kirby, or of Bell,—men whose attainments in science make us proud of the species to which we belong,—can it be believed that their writings have tended, in the slightest degree, to shak the religious faith of a single individual? Has not the fervour of the piety which they everywhere breathe, tended rather to rouse thousands from their withering and fatal apathy? The pestilential precepts of infidelity have emanated, not indeed exclusively, but principally from benighted visionaries, blind to the beautiful harmony of nature; and from fools (base, illiterate, and cowardly) who have dared to “rush in where angels fear to tread”!

DR. FLETCHER'S POPULAR LECTURES.

During the early part of last year, (says “Chambers's Journal”) popular lectures on the physiological structure of the human body, were delivered to miscellaneous audiences in Edinburgh, by the late Dr. Fletcher, one of the most eminent physiologists of the Scottish metropolis. As these lectures were proposed to be delivered both to ladies and gentlemen, it was believed by many, those who allow that nothing new can be done, that they would not be successful. But the reverse of this was the case, and the public are left to lament that the unexpected death of the lecturer has prevented the renewal of these most agreeable and instructive exhibitions. We attended several of the lectures, and were much delighted with the ingenious views of the accomplished speaker. He illustrated his discourses with coloured drawings and wax models, and in such a manner that the most fastidious of his hearers could take no offence. The following observations on this point are from his introductory lecture, which has since been published.

“With respect to the indelicate and repulsive nature of physiological studies, the time is fortunately past, although not long past, when it was necessary to refute the calumnious charge. In teaching this science as a branch of medical education, I have never withheld from my hearers any fact with which it was incumbent on them, as medical men, to be acquainted, nor refrained from any illustration which I considered calculated either to arrest the attention, or to make an impression on the memory. But I shall never forget that, while in this place, I am not in a theatre of medicine, nor am I addressing those whose business it is to know *everything* relating to the physiological department of that profession. The privilege of selec-

tion is here allowed me, and I must very much fail in my object if I shall have occasion to see a single cheek for a moment suffused, or a single eye cast down or averted from anything that I shall utter or exhibit within these walls. There is no manner of necessity for using one word that can injure, in the slightest degree, "the fine enamel" of the purest mind, or for displaying one object which the most sensitive may not contemplate without offence; and heaven forbid that I should wantonly seek occasion for doing either! I can also make every allowance even for the natural weaknesses of the uninitiated, and as many such persons would perhaps shudder at the exhibition of any actual part taken from the human frame, I shall scrupulously abstain from introducing such parts. The organs of the lower animals, assisted occasionally by casts or delineations of the corresponding parts in man, will for the most part be quite sufficient for explaining any function of the human economy. The goddess of purity, and the god of prejudice (if there happen to be such personages), may look every day, with equal boldness, on my walls and tables."

We remember one lecture in particular, the subject of which was the construction of the lungs, the larynx, and the organs of voice. Dr Fletcher's observations on this subject tended to show that much injury is done to health by keeping silent; and he caused a laugh among the audience when he mentioned that one main reason why women generally live longer than men, is that they *speak* more. In other words, they exercise to a greater degree one of the most important functions in the system. This, he said, was the physical cause, although there were others of a moral nature. He therefore argued that speaking, and more especially singing, when indulged to a moderate extent, were of great benefit to health.

The American physician, Dr. Rush, coincides in opinion with Dr. Fletcher, as to the utility of singing, not only as an accomplishment, but as corrective of a tendency to pulmonic complaints. "Vocal music," he says, "should never be neglected in the education of a young lady. The exercise of the organs of the chest by singing, contributes much to defend them from those diseases to which the climate and other causes expose them. The Germans are seldom afflicted with consumption, nor have I ever known but one instance of spitting of blood among them. This, I believe, is in part oc-

casioned by the strength which their lungs acquire by exercising them in vocal music", for this constitutes an essential branch of their education. The music master of our academy has furnished me with an observation, which is still more in favour of this opinion. He informs me that he has known several instances of persons who were strongly disposed to consumption who were restored to health by the exercise of their lungs in singing.

LECTURES ON SURGERY.

BY JOHN HUNTER, F.R.S.

Delirium—Dreams.

A simple sensation in the mind of a local disease in the body which does not correspond with the seat of the disease itself has, I believe, been always referred to the principle of sympathy. Thus, sensation of pain in the shoulder from disease in the liver has been always supposed to arise from the shoulder sympathizing with the liver. The sensation of the glans penis from a disease or irritation in the bladder has been referred to the same cause. But I believe it is a delusion in the mind; for the nerves of the part are not the seat of the disease, and irritation could not communicate to the mind the sensation of pain in the part affected excepting they (the nerves) take on the same action, which they must do when they produce the sensation of pain of that part. But if the nerves of the part which is the seat of sensation in such cases do not act at all, it cannot be called sympathy.

That there is such a delusive principle in the animal economy we see every day, and that it not only exists between mind and body, so as to lead us astray from the real subject, but between the mind and other bodies with which it has no immediate connexion, not even by the common senses. But we must allow that certain sensations can form a peculiar state of mind, called a sympathizing mind, for we are capable of transferring the sensation of another person to ourselves, which is like a dream. A delusion in the mind is an object appearing to be where it is not.

Delirium.—It will be very difficult to prove whether delirium is a disease of the brain or nerves; it appears equally easy to prove that it is from one as from the other.

A delirium is a dream arising from disease, whether the dream is in the brain itself or in the body; only it is worthy of

consideration, as dreams arise from sleep, and as a delirium is a diseased dream arising from what may be called diseased sleep, whether it may not be first necessary to give a short definition of sleep

Perfect sleep is a cessation of susceptibility of sensation, and of course of all its actions; the consequence of which is a cessation of consciousness in the animal of its own existence; and also, of course, of the consciousness of the relation it bears to itself and every other thing. But whether this cessation of the susceptibility of impression arises from the brain not then having power to receive impressions of the actions of nerves, or whether the nerves are not then capable of acting or conveying their action to the brain in the state of sleep, is not so easily determined.

Dreams are actions of the mind in sleep; therefore may be independent of any immediate information or impression, but are always independent of the relative connexion between body and mind, or consciousness of the existence of that relationship between the two. For the connexion between the two enables the mind to distinguish perfectly what is sensation and what is only thought, without which all would be a dream. In a delirium, as in sleep, we find the susceptibility of external impression lessened. Whilst sensation is continued sleep is kept off; delirium may be also lessened by arousing the mind from that particular state by external impressions; so far delirium appears similar to dreams, but it widely differs in other respects. In natural sleep the more the brain puts on that peculiar state the less we have of dreaming; but the more the other state is put on the greater the delirium. Dreams often do arise from sensations of the body being conveyed to the brain, it being in an imperfect sleep; but the consciousness of the connexion between our own body and our mind being conveyed to the brain, it being in an imperfect sleep; but the consciousness of the connexion between our own body and our own mind being cut off by the state of sleep, the sensation may or may not be referred to our own body: it may be referred to some other body. In some cases it is not referred to the part of the body where the impression is made; and the same thing happens in delirium, where the connexion is cut off; these not distinguishing between real sensation and thought, what the mind thinks about appears to be real.

But even where the mind is in full pos-

session of the consciousness of its connexion and relationship with the body, we have in some cases this delusion, as the appearance of the turning round of the objects about us whilst they are really fixed, and that in consequence of our having turned about quickly; giddiness from going to a height, or from riding backwards in a coach. Delusion is also an effect of intoxication and disease. Whilst awake and in health, impressions produce sensations, which are conveyed to the brain, and from these the mind reasons: but suppose the mind to have lost, or as it were forgot, its former connexion with our body, then the above false reference takes place.

A gentleman came into this country in 17—; his memory was imperfect, and a particular kind of delirium began whenever he was going to sleep, but afterwards continued whilst wide awake; and for a week before his death he was not quiet from this delirium a moment, but whilst his impressions were forced on by external objects. His delirium was of this kind; he was constantly talking of former circumstances of his life, but referring them to the present moment and to some other person. There was a revival of past ideas in his mind, but from a want of connexion between his mind and his body, he was not enabled, by his present impressions, to infer how little relationship they bore to the present time, or to those persons to whom he referred them: at the same time, it really appeared more a want of connexion between the mind and the body than the mind itself being hurt, for he determined rightly what should be done in those circumstances which he supposed present, and would express his sentiments in really elegant language. That it depended more on want of connexion than on disease of the body, appeared, from his being sensible of impressions, and referring them to the part where they took place, but supposing that to be in any other body than his own. Thus, he would tell his nurse or the bystanders that they were hungry or thirsty; but upon offering food or drink, it appeared plainly by his eagerness that the idea had arisen from a sensation of hunger in his own stomach. He would show great signs of distress or anxiety, which he would say was because his nurse wanted to go to the close stool, but was restrained by his presence; and this from his sensations also. He had a violent cough, in which he would sympathize with some bystander, proceeding in his

story after the cough, no otherwise disturbed than by sympathizing with the person whom he thought so unfortunate as to have it. The objects about him were more to him than his own sensations.

A gentleman who was fond of his bottle referred all his own weaknesses and feelings, as he became intoxicated, to those around him; and upon his going home would insist upon undressing all his family and putting them to bed, declaring that they were too drunk to do it themselves; and this happened not only once, but whenever he was intoxicated. I myself once experienced what I have since thought must have proceeded from this want of connexion between the mind and the body. I was reading a remarkable case, and reasoning with myself upon it, when I found the letters and words made an impression on the retina, but that I was incapable of affixing a meaning to them: this I thought might proceed from want of sleep; but that was not the case: I tried repeatedly, but without effect, and at last I went to bed, from which I did not move for three weeks, a violent affection of the head following this extraordinary circumstance. It may not be amiss to say, that the case I was reading was that of the late Mr. Foote, who was not able to command his attention to more than one action or circumstance at a time: thus, if he took his snuff-box out of his pocket and held it in his hand, it was all very well, until he attempted another action, such as taking a pinch of snuff out of it, and then the box fell immediately out of his hand; in fact, he was going back into a state of second childhood, for a child is not capable of commanding his attention to more than one circumstance or action at a time; give him a stick to hold, and call his attention to another object, and the stick will be dropped; for it is by habit we become capable of attending to several actions at a time. If a person is blindfolded and put into a coach, he will think he is riding forwards though really moving backwards. An impression from any part, either healthy or diseased, may be conveyed, yet there may be no consciousness of the mind from which part of the body it was conveyed, the mind having full possession of the impression, and a perfect idea of it, but having nothing to direct it right in its reference of it. It must refer it somewhere, and is more likely to refer it to another than to itself.

A gentleman, a medical man, dreamed

he had given a patient too strong an injection for gonorrhœa, and that it had produced a total stoppage of urine: he awoke, and found an erection of the penis, and that he could not void a drop of urine. Here was an impression without the consciousness, and he referred the impression to another person.

A gentleman, upwards of ninety years old, suddenly lost his senses, and in consequence of this there was a reference of all the ails which he might be supposed to feel to his wife, who had been dead some time, but who he now thought to be alive, and ordering the utmost silence to be preserved, lest by noise her illness should be increased. The new-born child has probably sensation without this consciousness. The contrary takes place when a person refers the sensations of others to himself, or when the idea of sensation is supposed to be sensation itself, as happens in those who are affected by animal magnetism. I was asked to go to be magnetized, but at first refused, because the spasm on my vital parts was very likely to be brought on by a state of mind anxious about any event. Thus, at my country box I have bees, which I am very fond of, and I once was anxious about their swarming lest it should not happen before I set off for town; this brought it on. The cats tease me very much by destroying my tame pheasants, partridges, &c., and rooting up my plants. I saw a large cat sitting at the root of a tree, and was going into the house for a gun, when I became anxious lest she should get away before my return; this likewise brought on the spasm; other states, where my mind is much more affected, will not bring it on. Now I feared lest my anxiety for the event should bring on the spasm, and that should be imputed to animal magnetism. But considering that if any person was affected by it it must be by the imagination being worked up by attention to the part expected to be affected, and thinking I could counteract this, I went; and accordingly, when I went, I was convinced by the apparatus that everything was calculated to affect the imagination. When the magnetizer began his operations, and informed me that I should feel it first at the roots of my nails of that hand nearest the apparatus, I fixed my attention on my great toe, where I was wishing to have a fit of the gout; and I am confident that I can fix my attention to any part until I have a sensation in that part. Whenever I found myself attending to his tricks, I

fell to work with my great toe, working it about, &c., by which means I prevented it having any effect on me.

OF LOCAL AND CONSTITUTIONAL DISEASES.

It may be difficult in all cases of local diseases to distinguish between one truly local and one arising from the constitution; that is, one arising entirely in the part diseased, and one arising entirely from the constitution. For as one can and often does affect the other, which may be called mixed, it becomes the more uncertain where the disease originated.

Diseases may be called constitutional, local, and mixed. Diseases may be originally constitutional and originally local; that is, diseases may take place in the same person from constitutional or local causes, and be totally independent of each other; but they may affect one another.

The first, or constitutional, is either a universal action of some kind, as fever, or where there is a universal susceptibility for an action, but the action is local. Therefore they are divisible into two kinds, 1st. universally constitutional, and 2d. constitutionally local.

Universally constitutional is when there is universal action of some kind, as fever, where every part of the body is under some diseased action, which will be according to the nature of the influence which produced the fever, as inflammatory fever, putrid fever, &c.

Those arising from external influence will in some degree reduce all constitutions to some one mode of action; and whatever difference there is between one and the other must only arise from a peculiarity in constitution.

If an inflammation is produced in any part by violence, it will always be as the constitution is. If a man has a fever, a cut will partake of the disease, and the inflammation will be erysipelatous, or so on, according to the fever. But if the fever is of specific kind, superadded to the nature of the constitution, as small-pox fever, a cut will not partake of the specific quality of that fever, but will be exclusive of the specific quality. Nor will a cut on any part of a pocky patient be venereal.

Constitutional diseases are of various classes, which are known by their effects. A constitutional disease is a universal diseased action, as fever, every part taking on more or less of the diseased disposition. Such diseases, I apprehend, have no disposition for local action, though it is commonly supposed they

have, as where fever produces abscess. This I hardly believe, though an abscess may form in the time of that fever, and is caused by it, or is an effect of that fever; but it is not an act of the constitution, according to our third division, therefore does not relieve the constitution of that fever. What I shall call an act of the constitution relieves the constitution, as gout falling on a part; but in abscess from fever it is only that this part has been so disturbed in the time of the fever that it has gone into inflammation and suppuration.

The second of the universal is the constitutionally local, that is, when there is universal susceptibility of body to produce peculiar local complaints, but not the action, till disturbed: requiring an immediate cause, which may at the time be either universally disturbing, as fever, or in the part only, as an accident. Thus the whole constitution may be affected with a gouty disposition, but the disease becomes local and is cured. We see constitutional or universal diseased affection excite local, as fever exciting scrofula, not as a termination of that fever, but because the part affected was partaker of the universal affection, and being disturbed by that universal affection or action, it took on the mode of action it was most susceptible of. It would do the same thing on being locally disturbed; therefore, as to its diseased action, it is the same whether it is disturbed as part of a whole, or only by itself. The scrofula goes no further than a susceptibility for diseased action, until it is brought into action by the local injury or constitutional fever.

Perhaps there is no term so vague or undetermined in the mind as the term constitutional. Universal action of every kind may be called constitutional, even when arising from some local cause, which I have called one of the mixed; or one capable of producing local effects, which we have also called one of the mixed. But a true constitutional disease is one arising, as it were, spontaneously in the constitution, partaking of the nature of the constitution itself.

Local disease I would consider in two lights: 1st. When it is a natural local action, being a kind of violence on a part, there being no constitutional local affection. In this case the disease takes on no specific quality of the constitution, either from the constitution having none, or the disease not being affected by it, being such as either arises from itself in a

part from a local cause, and may take place in any constitution, or may be produced by accident or violence where the constitution was never affected. 2nd. Which will more properly come under the head of mixed, where the local affection either affects or is affected by the constitution.

The mixed may be said to partake of the first and second, and is often the consequence of either, namely, original constitutional producing local, or original local producing constitutional; therefore they are often of two kinds, and such as may be called secondary actions either of the constitution or part, as universal sympathy with local disease, yet not what generally comes under the idea of common sympathy, as sympathy of part with part. Of the mixed, the first kind is where original constitution produces local; the second where it influences local already produced. Therefore this kind is divisible into two species.

It may be difficult to say certainly when a constitutional disease really produces local; but it may be set down generally that there will be a distance as to the time of appearance of the two diseases. The first of these two species is of various kinds, perhaps belongs more to specific diseases than to common, and is where the constitution from its nature produces a local one, and is necessarily relieved by it, by what I have called an act of the constitution. Of this kind are smallpox, measles, fevers producing critical abscesses, erysipelatous fevers, gout, &c., and on this is founded the doctrine of revulsion.

Local diseases produced by an act of the constitution may be illustrated, I think, by the growth of plants. A plant or tree appears to have a disposition and power of producing either only a top shoot, or a number of shoots, called branches, which are according to the nature of the plant. If the top is cut off, then a new branch sprouts, and it serves as a top; so that the disposition is taken up by some other part most susceptible of action. The same thing happens in those plants which grow by branches. So that the removal of a part in action gives the disposition of action to parts not before disposed to act, but next in order of susceptibility.

The second of the mixed is where original local produces constitutional, and which may alter the constitutional disease already existing, or cure it. This may be of three kinds.

1st. The immediate; 2nd. Less determined as to time; 3d. The remote. Of the first there appear to be two; of the second but one, though it may appear in different forms; of the third probably only one.

Of the immediate we shall reckon that which is called symptomatic fever. Delirium I shall reckon the second, though it is not always the second as to time. The third, or remote, is hectic, to which may be added symptoms of dissolution, which last stage may be the consequence of either of them, or of any other disease.

The first of these is generally called symptomatic fever, but I choose rather to call it sympathetic inflammatory fever. It is sympathy of the constitution with the first stages of local diseases, which is the action of alarm on the constitution, rousing up its powers to produce action.

The second, or delirium, appears to arise from an affection of the brain or sensorium, producing sympathy of action of the brain with the nerves of the part; not sensation, as headache, but an action producing ideas without uniting sensation, which is therefore delusive.

The remote, namely, the hectic, is a sympathy of the constitution with local disease, but sympathy of another kind; it is sympathy with the operation of an incurable disease, where the constitution is conscious of inability of the part to perform a cure, by which means the constitution is at last, as it were, worn out, producing dissolution if not removed.

Dissolution is the last stage and consequence of all, whether local or constitutional.

Diseases are common or specific.—All diseases are either common or specific, but it is more than probable that most diseases have some specific qualities. A common disease is such as will attack every constitution, and perhaps every animal, and rather appears to be an increased action, as common inflammation, common inflammatory fever, &c.

Many diseases may be reckoned specific in their mode of action, though not in their cause. An ague is a specific action, but its causes are various. Gout is as specific action, but its causes various. Cancer is a specific action, though its immediate causes are various; but it is capable itself of becoming a true specific cause, by forming a poison. The cause of scrofula varies, though its action is specific. The remote cause of all is a greater susceptibility of such actions.

A specific is a peculiar mode of action, differing from every other mode of action. A true specific disease is one that probably cannot arise but from one cause, and which probably belongs only to morbid poisons; for although gout, scrofula, ague, &c. may be ranked among the specific, yet they can and do arise from a thousand causes.

There seems a specific susceptibility for those diseases in those that have them. But in poisons there must be a specific cause, which may be attended at the same time with specific susceptibility of such, as some have a greater tendency to small pox than others.

Specific diseases are such as we cannot increase, for they always act with the full force of the readiness in which the constitution is at the time. If the constitution can be made more susceptible of action, the action will be increased.

Every specific disease has two modes of action—namely, the common and the specific,—joined to it. There are specific inflammations, specific suppurations; or, in other words, there are inflammations and suppurations with specific properties, or which have specific properties superadded; thus, in smallpox there is common inflammation, with the specific qualities superadded. Specific diseases may be either universal or local; universal, as fevers of particular kinds; local, as scrofula; others are mixed, as agues, rheumatism; and these admit of a cure from a variety of medicines.

A circumstance worthy of notice takes place with respect to local specific diseases: parts appear susceptible of them as to take on their action so readily, that were it not for another very curious circumstance we might soon expect them to spread over the whole body; but the favourable circumstance I refer to is where the disease is spreading very fast, affecting parts which the disease has not yet touched, whilst in the centre this diseased action no longer takes place. Those parts which have already suffered this action appear to have lost their susceptibility of it, whilst the surrounding parts are contaminated by sympathy with those parts already affected: this property belongs to many, as erysipelas, herpes, &c. I have seen the same thing take place in ulcerated bubo, spreading over the whole belly and thigh, but healing in the centre. Another circumstance is to be added to what I have mentioned as hindering the disease from extending over the whole body, which is, that the constitution itself

alters or loses that peculiar susceptibility before such an event takes place.

Different parts differ very much in their power of resisting diseases, as well as in the power of curing themselves, or getting rid of the diseased action and putting on a curative one: this seems to be according to the strength of the circulation in the part; where this is less the power is less; thus, there is greater power of resistance in a muscle than in a tendon. But in specific diseases I should suppose there is little difference in this respect, in consequence of a difference in structure, although we know that specific diseases affect some parts more than others, as the smallpox affects the skin; the measles, the skin and surface of the lungs; whooping-cough and hydrophobia, the throat; &c.

LECTURES ON OBSTETRICY,

AND

DISEASES OF WOMEN AND CHILDREN.

DELIVERED BY DR. RYAN.

Generation—Ovology.

The same orgasm that affects the ovary and tube is said to render the womb vascular, and slightly congested (Harvey, Ruysch, Hunter, and others). Its internal surface, thus irritated, secretes the albuminous concretion, called decidua, by Hunter, and epichorion by Chaussier. These effects are purely sympathetic, because they exist in extra-uterine pregnancies; they are more perfect, however, when produced by the presence of the ovule.

The volume, form, and direction of the uterus are changed; its parietes are enormously thickened; its weight, at the completion of the term of gestation, is two or three pounds, and compared with that of a woman who has not been a mother (two ounces), and with that of a virgin half an ounce), we find it multiplied by nearly twelve and twenty-four. Its fibres are muscular (Lobstein); but not invariably so, as attested by Dr. Malins and myself, in a case we published (London Medical and Surgical Journal, January, 1831, vol. vi.)

The opening through which it escapes becomes cicatrized, and is called the corpus luteum; it is described by Fallopius, Malpighi, De Graafe, and Røederer; and

its development is not the effect of the male semen, but is a peculiar function of the ovary; it is an indispensable preliminary necessary for conception; it has been found in women who had not conceived, by Røderer, and in virgins by Haighton, Vallisnieri, Santorini, Bertrandi, Sir E. Home Brugnone, and Cruikshank; in mules, by Brugnone; and in animals whose Fallopian tubes were tied before coition, by Haighton. The male semen is said to be carried by absorption, or by a peristaltic motion of the womb and tubes (Galen, Fallopius, Morgagni, Hunter, Magendie, Richerand, Blumenbach, and Ruysch); and Haller found the sperm in the Fallopian tubes of women and animals, who were killed immediately after coition. Dr. Haighton tied the Fallopian tubes of rabbits and incised them; the animals lost all desire, were barren, and yet the copora lutea were said to have formed.

The transmission of a subtle vapour, effluvium from the male semen (*aura seminalis*) through the womb, one of its tubes, to the ovary, which impregnates an ovum, egg, or vesicle, which passes through the tube into the womb and is there developed, is a disputed theory.

The illustrious Harvey made a vast number of dissections of hinds after copulation, and never discovered the male fluid in the womb; hence arose the doctrine, that a vapour arose from it—*aura seminalis*—which passed through the womb and tube to the ovary, one of whose ova or vesicles it impregnated; and that the ovule was conveyed through the tube into the womb to be nourished.

In support of this theory it is urged that impregnation has happened though the hymen was perfect, and closed up the orifice of the vagina, except at the upper part, when no penetration of the male, further than between the external labia, took place. There are many cases of this kind on record; and a most remarkable one was lately described by Dr. Kennedy, of Dublin: I have also been consulted in similar examples. The penis does not enter the orifice of the womb, which is not much larger, in the unimpregnated state, than that of the male urethra. I have known several instances in which the application of the male fluid between the external labia caused impregnation; a fact also attested by Dr. Blundell in his lectures in the *Lancet*. "I know three cases in which the male organ was not suffered to enter the vagina at all, and where, nevertheless, I suppose, from

the mere deposition of the semen upon the labia, impregnation took place. I have known women astonished to find themselves pregnant, being persuaded that impregnation was impossible, until, to their sorrow, the unwelcome truth was unfolded. In a word, from several facts of this kind, too delicate for a fuller disclosure, I am satisfied that very small quantities of the semen introduced into the lower part of the vagina, where there is an aptitude to become pregnant, will give rise to the new structure." (Principles and Practice of Obstetrics, &c. 1834.) I have also recorded cases of imperfect penetration and prolific connexions, when the penis was so destroyed by disease that it was no more than half an inch in length.

I have been confidently assured by a gentleman of veracity, that he impregnated a woman although he barely penetrated the vagina; his paramour consulted me, perfectly unconscious of what had happened, for she was inebriated at the time, and she most positively denied, when I stated she was pregnant, that it was possible, as she never knew man. My opinion was, however, unaltered, and I advised her to consult other obstetricians as to her condition. Several eminent obstetricians told her she was not pregnant; she called on me again and again, and every time the womb was more developed, and at last she felt the motion of the foetus. Her paramour at length made the above confession; she recollected the circumstance of their having been together, and of his having induced her to drink too freely; and at the end of the ninth month, I delivered her of a healthy full-grown infant. Her case attests a fact I have stated in my work on Medical Jurisprudence,—that a healthy woman may be impregnated unconsciously, during inebriation, narcotism, catalepsy, and profound sleep. I have also known cases in which the greater part of the penis was destroyed by disease, or amputated close to the pubis, and yet persons so mutilated have continued to propagate. In such cases, there can be but very imperfect penetration, but the expulsive power of the ejaculatory muscles of the penis remains in its natural condition. These, and similar cases, prove that perfect or deep penetration is not necessary for procreation, and they also favour the third theory of absorption of the semen from the vagina.

These cases also show that it is not necessary that the male semen should be in-

jected into the womb. Dr. Blundell supposes that, when there is a deposition on the vulva, generation depends on the admixture of the male fluid with the secretions of the female: "for dilution does not destroy the fecundating power. If a glass of a certain height were filled with water, should sugar be thrown into the bottom of it, this, on solution, might soon be perceived in the upper part of the fluid, especially if agitation occurred; so the fecundating secretion may, by admixture, have penetrated to the inmost recesses of the genitals, more especially if the secretion of the genital surface be copious." He goes on to observe, that children are sometimes not procreated for want of sufficient penetrative power in the male organ, which I very much question, for the reasons just stated. He alludes to the experiments of Spallanzani, who found that three grains of the semen of a frog, dissolved in two pints of water, were sufficient to give it a fecundating power; even that small quantity taken upon the point of a fine needle, from which Dr. Blundell infers, "if the female genitals be apt for conception, the requisite quantity of the male material is small," p. 67.

In reviewing Dr. Blundell's opinions, I am bound by the many facts I have adduced in this lecture, to observe that they are, in my opinion, liable to many unanswerable objections. Repeated consultations enable me to state, that a complete emission of the male fluid at the interval of twenty-four or forty-eight hours will rarely, if ever, cause impregnation; nor do I comprehend the possibility of the germ or ovarian fluid passing into the womb to mix with the spermatic fluid of the male; and, therefore, the requisite quantity of the male material for impregnation, is not so small as is above supposed. Neither can I perceive any analogy between the mixture of sugar and water and the spermatic and ovarian fluids; nor do I believe that children are sometimes not procreated for want of sufficient penetrative power in the male organ. The orifice of the uterus is generally within two inches or two inches and a half of the external genital aperture, though it may be more distant, or be elevated under certain circumstances, and the slightest penetration when the semen is elaborate, is sufficient for impregnation.

Lastly, it is to be recollected that the conclusions of Spallanzani refer to frogs, and not to human species, and therefore it does not follow that such extreme dilu-

tion, as in the former cases, can ever happen in the latter, though there is generally some dilution of the male fluid. If this were the fact, the male material would be always prolific; but this is not the case, unless it has remained in the seminal receptacles for some days, as observed by Harvey and others. Many proofs of this fact have fallen under my own consideration.

The mucus of the seminal receptacles, the prostatic fluid and urethral mucus dilute the male fluid, as well as the vaginal and uterine mucus in most cases during the seminal emission; but this last dilution does not always happen.

The case mentioned by Mr. Hunter, in which his patient injected semen into the vagina and caused impregnation, appears to me open to objection; and I should think there was a more legitimate cause for the procreation.

On a careful review of all the theories of human generation, we can only arrive at the conclusion, that a union of the sexes is necessary, that both should be in good or tolerably good health, and that the function ought only to be performed when dictated by nature.

It would occupy too much time in a course of lectures, were I to introduce the history of comparative and human ovology, or the development of the impregnated ovum from conception to the period of delivery, which I have already done in my work on Obstetricy, and in my Lectures on Midwifery and Diseases of Women and Children, published in the London Medical and Surgical Journal, 1836, and to which I must refer the reader. I shall now content myself with describing the influence of the maternal imagination on the fœtus in the womb; the hygiology of women during pregnancy, parturition, the puerperal state, and lactation or suckling; and conclude the physiology of generation with an account of the function of parturition, the assistance required during that process, and offer a few hints for the physical education or management of the new-born infant.

Fœtus in the Womb.—All obstetric writers agree that the circulation between the mother and the infant is interrupted, and also that there is not a direct nervous connexion between them. Nerves have never been discovered in the placenta or its continuation, the navel cord, which passes into the infantine abdomen. The mind of the mother, therefore, cannot have a direct influence upon the fœtus, no

more than the circulation of her blood. Mental and corporeal excitement may derange the function of the brain, nervous system, heart, and digestive apparatus; but such derangements have only an indirect effect upon the fetus in utero. It therefore follows that the imagination of the mother cannot mark or deform the offspring, for if it could, no infant would be perfect; because there never perhaps was a pregnant woman who was not frightened, or who was free from longings during her condition; and yet how few deformed or disfigured infants are born. The imagination is excited in every case of pregnancy, there is a constant cause, but very rarely an effect. This is bad philosophy; for every obstetrician engaged in practice has repeatedly known pregnant women who had ungratified longings, who had been frightened by dismal objects, or had met with dreadful accidents or misfortunes, and yet their infants were perfect. We see this fact illustrated every day in this metropolis. Nevertheless, the belief is general among the middle and lower classes, and even among some medical practitioners, that the frights, longings, and imaginations of the mother can mark and deform the offspring; but this opinion is contrary to nature, reason, common observation, and medical science. I have known hundreds of instances in which women feared that their infants would be marked, but I never met with one case in which such anticipation was confirmed. The belief in this error is, however, of great antiquity. I have given a full refutation of the incredible fables reported as illustrations, in my work on Midwifery.

All these monstrous facts occurred in the sixteenth and seventeenth centuries, which were remarkable for superstition, ignorance, and credulity. A most singular illustration of the credulity of that era is afforded by a writer named Gofr. (Hegentii Itinerarum, &c., 1330.) This traveller states that he saw a tablet in the church at Leusdown (Lausdunum), about five miles from the Hague, with an inscription to the following effect:—that a certain illustrious countess, whose name and family he gives, in the fortieth year of her age, brought forth, at one birth, in the year 1276, three hundred and sixty-five infants! all of whom were baptized by Guido the suffragan, who called the males "John," and the females "Elizabeth," all of whom, with their mother, died on the same day, and were buried together in the above temple. This hap-

pened on account of a poor woman who carried twins in her arms, which the countess declared were not the offspring of one man, and this so incensed the mother that she prayed that her insulter might have, at one birth, the same number of children as there were days in the year. No rational individual can credit this story, though it is attested with much plausibility.

HUMAN OVOLOGY:

Physiologists hold that the ovum, or germ, is an organic production of the ovary, which is developed by the semen. In oviparous animals the yolk only is formed in the ovary, and a whitish tunic or shell in the oviduct. A tunic is formed in mammiferous animals in the uterus. Baer has ascertained the rudiments of the ovum along time before fecundation, in the vesicles of the ovary in the middle of a mass of granulations, in the form of a cone whose base is fixed to the wall of the vesicle, and its apex turned inwards. The ovum or ovule is from one-eighth to one-fourth of a line in length, is spherical, hollow, composed of two membranes and a liquid. When it escapes from the ruptured vesicle and penetrates into the oviduct, it draws with it the granulated membrane, which forms a kind of disc. Baer considers the mammiferous ovum or ovule and oviparous analogous. Velpeau considers the ovule, before incubation, as composed—1. Of a substance destined for the formation of the embryo, *embryotrophe*; 2. Of an organ from which springs the formative force fixed for the commencement of life, *blastoderme, membrana germinativa, or prolifera*; 3. Of an envelope composed of two bodies which protect it, at the same time that it establishes the reciprocal action with the exterior world, and the two first organs of incubation, *membrane of the shell*. These three parts are named, *nutritive, living, and protective*, they exist in the ovules of all organised beings. Sometimes there is an external envelope which covers the nidus or progeny.

The vitellum, yolk, or yellow substance in animals is the immediate product of the ovary. This yellow substance is albuminous and oily. The ovary furnishes an excessively small portion of *embryotrophe*, in proportion to the living part which afterwards takes the nutritive materials of the oviduct and womb. An albuminous fluid also exists between the chorion and amnios.

The external surfaces of the embryo-

trophe form its external coverings, which are the limits of the organised surface. Different membranes unite to form one envelope, and this is covered externally with a coagulum. The envelope of the embryotrophe has no vessels, but is perspirable to exterior substances—*cuticula ovi*. In plants it is called external perisperm (Theviranus), *secundæ exterioræ* (Malpighi), *testa* (Gartner), *shell* (Tidemann.) The *cuticula ovi* is formed in oviparous animals by coagulation of the surface of the embryotrophe, and this is the membrane of the shell (*membrana testuca*.) It is formed in the ovary, and is coeval with the embryotrophe. When this last is double the membrane is multiplied. It forms the membrane of the yellow substance, *cuticula ovi* on the exterior surface of the yellow part by the condensation of this last. It is without vessels, and without communication either with the yellow part or the internal surface of the ovary. It is only by the absorption of fluids, arrested by the ovary, that the yellow substance can augment. This last, and its membranes, are called *globus vitellarius* by M. Velpeau. When this is recovered in the oviduct of the secondary embryotrophe, it forms on the surface of this an exterior membrane, or that of the shell. In the egg of the pullet it is rough on its external surface; flocci lodge in the inequalities of the shell, and compose two layers united, except at the larger end where their separation forms a sac of air.

The ovule of the mammiferæ has been described as a simple vesicle filled with fluid (Kuhlemann, Graafe, Prevost, Dumas, Meygrier, &c.) Baer has shewn that there are two distinct membranes, as Cruickshank observed in the rabbit. The exterior is finer, more transparent than the internal, and is covered with inequalities which become villousities at a later period. This is called *exochorion*. The chorion is enveloped by the Hunterian membrane (*decidua, caduca*), and it covers the amnios, the umbilical vesicle and allantois, and is composed of two layers connected by a layer of vessels described by Wrisberg, Krummacher, Dutrochet and Emmert. These two membranes are distinct until the second or third month of uterogetation when they become confluent. M. Velpeau denominates them *endochorion* and *exochorion*. The *exochorion* is external, and connects the ovum with the exterior; the *endochorion* supplies the umbilical cord, and runs with it to the abdomen. The *exochorion* has

no vessel, but at a later period the *endochorion* supplies these to form the placenta. The *endochorion* which accompanies the vessels has the same relation to the *exochorion* as the external vascular layer to the membrane of the shell, only here the vessels do not penetrate this last. The villousities on the external surface of the *exochorion* are analogous to the flocci of the membrane of the shell, which lodge themselves in the anfractuositities of the shell. Finally, the *exochorion* is transparent, whitish, firm, tenacious as the membrane of the shell, without the shell. But it is not separated by a yellow or white membrane, or a yellow membrane covered by a white one.

The *exochorion* is the first part formed in the ovum or ovule. This is analogous to what takes place in the membrane of the shell. The embryotrophe secreted by the ovary commences to limit itself by the condensation of its surface. So in the ova of insects, a yellow substance without a white one constitutes the embryotrophe, so that the membrane of the shell is immediately applied on the embryotrophe and the blastoderme; and the ova of mammiferous animals is disposed in an analogous manner. The external membrane of the mammiferous ovum or ovule in the ovary has inequalities, which alternately form the villousities (Maygrier.) Baer has not discovered any external membranes. If we conclude from this, that the external membrane is formed first, and always remains external, we shall infer how it is constituted by the *exochorion*. For the *endochorion* springs from the embryo itself with its umbilical vessels, and cannot exist independently of both. This is the reason that twins have usually one *caduca* or *decidua* in common, but distinct chorions. When the chorion is common to both, it may have been formed by two chorions, at first distinct, or two embryos may be developed in one chorion.

The living or formative part of the ovum is the membrane of the germ (*membrana germinativa sive prolifera blastoderma*) or blastoderm, which is seen between the embryotrophe and the external membrane. When the embryotrophe is simple, it is found on the internal surface of the membrane of the shell, when it is double (yellow and white) it is on the internal face of the membrane of the yellow substance. In plants it is called the internal membrane of the grain (*chorion*) Malpighi, (*nuclearium*) Tidemann, (*endopleura*) Decandolle.

The blastoderm of viviparous animals is formed by a secretion of a granulated mass on the surface of the yellow part. Its base, is a granulated disc, *discus proligerus*, which is situated immediately under the membrane of the yellow substance, is transparent, and is seen like a navel, cicatricula, and a granulated cone, *cumulus proligerus*, which projects from the yellow substance. The globes or granulations of these two parts, or of the *stratum proligerum* are intimately connected with each other, and form a part of the yellow substance. There is also a vesicle, *vesicula proligeræ*, found in the egg of the pullet, by Purtrinius, and in all oviparous animals by Baer, which exists at the formation of the ovum, occupies the centre of the yellow or yolk, turns towards the *stratum proligerum*, and disappears towards the maturity of the animal. When this last descends from the oviduct, it perhaps ruptures and effuses its liquid. It is from this liquid, from a portion of the yellow substance, and from the stratum which then disappears, that the blastoderm is formed in the shape of a disc, composed of granulations which continually increase, envelope the yellow part, and tend to form a vesicle at the same time that it forms the embryo. Baer has discovered within the exochorion of mammifera, and separated from it by a small space, an opaque globe of granulations containing a small cavity, in fact, a vesicle with thick walls. He has found it in the ova of bitches. Baer regards it as the membrane of the yellow substance, within which the blastoderm is formed. Velpeau thinks it the blastoderm itself. This last in oviparous animals does not assume a vesicular form at first, but on account of the considerable volume of the yolk. In mammiferous animals the yellow part is excessively small, and the blastoderm is vesicular. The cumulus proligerus indicates the point of the blastoderm, or where life and the formative force is concentrated and excited, or where, at a later period, the embryo is formed.

There is a great and close analogy between the reproduction of plants and animals. In each there is a nidus. The sacs of the germs of the infusoria, of the polypi and acephala, bear a close analogy to the pericarp. In leeches and the mollusca, the ova are placed at the extremity of the oviduct, enveloped by a mucosity secreted by the collateral organs. The number and arrangement of the ova vary. These organs secrete a fluid which be-

comes indurated, and forms a sac which surrounds one or many ova. The ova of fishes are also enveloped in an albuminous fluid, and this becomes solidified in some species. In frogs there is also a secretion of albumen, which re-unites the ova to another.

In mammiferous animals there is a membrane, the decidua of Hunter, and epichorion of Chaussier. Fabricius ab Aquapendente was the first who examined the ovum, and, anatomically, he was succeeded by Faber, but both fell into much error. The illustrious Harvey, the pupil of the former, examined the ova in warm blooded animals, and was the first to establish accurate facts. He confined himself chiefly to the investigation of generation, and said little on the anatomy of the ovum. Hoboken followed, and described the afterbirth, or placenta of the human subject and of the cow. Drelincourt gave an account of the amnios and chorion; and Ruysch maintained the vascularity of the latter. Robault contended, in 1716, that the placenta was formed by thickening of the chorion, that its spongy tissue was composed of capillary veins from the umbilical vessels, and denied that there were anastomoses between these and the womb. In 1734 Dr. Simson, of St. Andrew's, attempted to prove that the placenta is formed by the chorion; and in 1754 Albinus held that it is formed of blood-vessels, cellular membrane, and membranous investments from the chorion. Noortwyth in 1743, Roederer in 1750—58, added further elucidation to the anatomy of the ovum; and Haller soon after examined all that had been written on the subject, offered his own observations, and gave the best account of ovology. He described four investments of the embryo, the membrana ovi exterior (decidua of Hunter), the chorion (decidua reflexa), the membrana media (chorion of Albinus), the allantois of Needham, Diemerbroeck, Bidloo, Horder, and Hoboken, (chorion of Hunter) and lastly, the amnios, containing a fluid in which the embryo floated. Dr. Hunter was the next writer and was supposed to have given a correct account of ovology. He held that the decidua consisted of two membranes at one period of uterogestation—that the chorion formed the next or third membrane from the second to the fifth month, and from this period to the end of pregnancy the second, and that the placenta composed of two layers, maternal and fetal portions, which did not communicate with each other.

According to Velpeau, whose observations are more extensive than those of any author in existence, there are new views on this subject. He says that the uterus is excited by conception, not inflamed, as stated by Breschet; that it becomes covered with an opaque, yellowish, reddish matter, which has the form of the uterine cavity, from which it is easily detached. Its external or uterine surface is spongy and tomentose, whilst its internal one is smooth and polished. It has vessels which may be injected through those of the uterus, but are soft and easily broken. It is thinnest at the neck of the womb, and also less vascular. This membrane was found by Lallemand and Boudelocque in extra-uterine foetations. Durochet denied its vascularity. It is formed about fourteen days after fecundation, and acquires its greatest development about the commencement of the second month, but it diminishes after the sixth week, when the villousities are shorter and less numerous. M. Velpeau contends that the matter which forms the decidua is gelatinous and mucous, differs from the products of inflammation, is inorganic, and hence he terms it anhiste, or tissueless membrane.

The ovule, according to this celebrated professor, after its descent through a tube towards the uterus, does not sink into the soft matter of the decidua, as maintained by Breschet, but depresses this membrane, glides between it and the womb, becomes attached to the latter organ, but not to the decidua; that as it grows it consequently pushes this membrane forward, and forms the decidua reflexa, or ovuline decidua of Lee and Owen. The invagination commences about the third week, and is very apparent at the sixth. The reflected portion is nourished by the vessels which penetrate at the point of reflexion. The decidua is therefore a nidus for the ovum, is the means by which the uterus acts on the embryo in the early weeks of gestation, and dies when the communication is established by the placenta. It is analogous to the pericarp and nidus of oviparous animals. It is no part of the ovum, and therefore is not analogous to the membrane of the shell, as said by Cuvier.

M. Breschet differs from the former and maintains that the ovum is too small to push down the decidua, but becomes attached to it or imbedded in it; that the uterine and reflected decidua are interposed between the uterine mucous membrane and the placenta in a very attenuated form. The villousities of the ovule

become adherent to the ovule; and as the growth of the ovule advances, these diminish over the general surface, become restricted to a single point, press the decidua reflexa to the uterine decidua, and give rise to the origin of the placenta. It appears then that the chorion forms the placenta.

M. Velpeau forms a different opinion, and one better entitled to adoption. He denies the existence of a membranous fold between the placenta and the uterus in the early part of uterogestation, but so soon as the tomentose or villous filaments of the chorion agglomerated into one mass, it begins to appear as covering their apex and soon becomes confounded with the anhistal or decidua membrane. It is not vascular, it presents the disposition of the arachnoid membrane, adheres to the lobules of the placenta, and dips between them.

The origin of the placenta is the point of vascular connexion between the ovum and the uterus. The ovum may pass along the fundus uteri as the decidua is not very adherent at this part. and in 20 out of 34 dissections the placenta was found near the orifice of the Fallopian tube. The ovum may descend between the decidua and uterus towards the neck of the womb, and adhere to any point of this organ.

Velpeau holds that in the state of vacuity the mucous membrane of the uterus is not separable. The rarefaction which uterogestation induces in the elements of the gravid womb, renders the mucous membrane easily separable in flakes or pieces, offering superb arborizations, of a density equal to the peritoneum, with all the characters of a distinct membrane, firmly united by numerous organic filaments to the womb. I conceive, continues this celebrated professor, that this may be mistaken, and taken for the caduca or decidua. Thus may be explained what W. Hunter, Carus, Seiler, Burns, and a host of others, have said in favour of the vitality, the organic state, and of the texture of this last tunic. M. Velpeau maintains that Dr. R. Lee and Mr. Radford of Manchester, have recently fallen into this error, and mistook the mucous membrane of the uterus for the caduca or decidua. (*Ovologie Humaine—Embryologie* 1833. Introduction, xviii. xix.) He holds that the caduca does not pass between the uterus and placenta; and that at the seventh month of uterogestation, there is only a line of demarcation between the circumference of the placenta,

and the ancient folded circle of the decidua of Hunter.

According to Velpeau and Lee, the placenta is developed between the chorion and the decidua vera, that is between the decidua reflexa or the chorion and the internal layer of the tissue of the womb; and the latter relates six examples in which the caduca adhered so firmly to the placenta that it could not be detached without laceration, that no large vessel of the womb opened into the placenta, and that the large oblique openings on the internal surface of the womb are closed by the interposed caduca. Velpeau held this last opinion in his *Tocology* before Dr. Robert Lee published on the subject.

All modern embryologists are of this opinion, Lee, Owen, Craigie, Radford; but it is by no means determined whether the interposed membrane is decidua or chorion, though I am disposed to think with M. Velpeau it is not the former. He also opposes, most successfully, the doctrine of Hunter and his followers, that the blood of the mother is deposited in the cells of the placenta, and thence conveyed to the fetus, on the following grounds:—1. In extra-uterine foetations this opinion is untenable; 2. The placenta, until the third month, consists of agglomerated filaments only, and no sinuses exist between its lobules; 3. When the placenta is attached to a fibrous polypus, or indurated part of the womb, the embryo is duly supplied with nutrition; 4. The uterine surface of a woman recently delivered was hard, healthy, and without orifices; 5. And lastly the sinuses or canals of the womb are veins, and therefore it must be venous and not arterial blood, which is supplied to the fetus. Dr. Robert Lee and Dr. Nimmo of Glasgow, deny that arteries or veins enter the decidua (chorion, Velpeau), and hold that the placenta is made up of the umbilical vessels, and has no internal portion. Velpeau was of this opinion in 1829 (see his *Tocology*), and that the placenta performed the function of lungs. Dr. Lee maintains that the whole uterine blood, except the small quantity which supplies the decidua, is returned by the spermatic and hypogastric veins, and does not enter the substance of the placenta. Whatever change the foetal blood undergoes, must be effected from indirect exposure to the blood of the uterus, the decidua or chorion being placed between the placenta and uterus. The change must be somewhat analogous to that of the blood in the lungs, a membrane being interposed be-

tween the vital fluid and the air, and between the foetal circulation and that of the mother. It is also remarkable that the umbilical vein, like the pulmonary conveys arterial blood to the fetus. Dr. Blundell asserts that the colour of the blood in the umbilical vein and arteries is the same, and it contains an equal quantity of carbon in both. Upon the whole this part of physiology is not understood at present. See page 85 of my *Manual*.

He maintains that the chorion adheres directly to the uterine surface without the intervention of any intermediate membrane, such as the decidua, and when he tells us that he had inspected 400 ova, we are bound to prefer his conclusions to those of Dr. Robert Lee and Mr. Radford, neither of whom had such opportunities. He, in common with, and long before Dr. Lee, maintained in his work on *Tocology*, in 1829, that the sinuses of the uterus were not continuous with the vessels of the placenta, but that a membrane was interposed the maternal or external surface of the placenta and uterus. Others deny this doctrine, as appears by the quotations in p. 75 of my *Manual*. W. Hunter maintained that the vessels of the womb anastomosed with those of the placenta; but his predecessor, the illustrious Haller, and his pupil Donald Monro, were of a different opinion. (*Essays Phys. & Lit.*, vol. i., pp. 404, 408—S19.) See p. 75 of my *Manual of Midwifery*, 3rd edition.

The vesicula umbilicalis is a small pyriform globular sac, observable from the fifteenth to the twentieth day after fecundation (Velpeau), on the forty-first day (Autenreith), is from two to four lines in length (Velpeau), and six lines in diameter (Lobstein). It is about the size of a garden-pea. It becomes smaller after a month, according to Velpeau, and about the sixth or seventh week it is reduced to the size of a coriander seed, becomes flat, and disappears insensibly. In some instances it was not found in the third month, though Hunter and Meckel found it of its largest size at the end of the uterogestation. It is situated between the chorion and amnios, contains a gelatinous yellowish oily fluid. It is sometimes attached to the amnios and sometimes to the chorion. It has been floating in ova of two or three weeks (Velpeau.) A pedicle or duct runs from the vesicle towards the embryal abdomen, and terminates in the ileum or cæcum. It varies in length from half an inch to an inch and a half.

The umbilical vesicle is supplied by an

artery from the inferior mesenteric, and a vein arising from its own parietes, which enters the superior mesenteric vein. These vessels are termed *ompholo mesenteric* vessels, and by M. Velpeau *vitello mesenteric*, and *vitelline vessels*. He denies that they originate or terminate in the mesenteric artery or vein, as he has frequently observed them lost in the spongy tissue of the umbilical stalk. These vessels have been observed by Chaussier and Beclard in the funis of the full grown fœtus, in the form of white filaments.

Use.—According to M. Velpeau, and other physiologists, the fluid of vesicula umbilicalis is a nutritious oil similar to the vitelline fluid in the chick. He says that in the chick it enters the abdomen entirely, while in the human fœtus it recedes from the abdomen as pregnancy advances. It nourishes the embryo until the umbilical vessels and cord are developed.

The *allantois* is a sac found between the chorion and amnios in the cow, sheep, bitch, reptiles, and birds. This was denied to exist in the human embryo. M. Velpeau has detected a transparent layer, of a slightly greenish colour, not serous, but lamellated, like the vitreous humour of the eye, and diminishing in thickness in proportion as the other membranes are developed. As it diminishes in thickness it soon forms a homogeneous pulpy layer, and is finally converted into a mucous coating, and disappears in general before delivery. M. Velpeau designates this substance *corpus reticulatum*, and considers it analagous to the allantois in oviparous animals. He denies that the reticulated body, or the allantois, has any relation to the kidneys or bladder.

The *vesicula erythroidea* has been considered by Blumenbach as analagous to the vesicula umbilicalis. It forms the intestinal tube in the opinion of Dr. Pockels, and it has no existence according to Velpeau. The general opinion of physiologists is, that the erythroid membrane does not exist in the human embryo.

Another part at this period of embryal life is the *Urachus*. Besides the two arteries and the vein in the funis, there is a cord extending from the fundus of the bladder, passing out at the navel, accompanying the blood-vessels, and terminating in a sac between the chorion and amnios, called the allantois. There is an impervious cord running from the fundus of the bladder to the navel which is called the urachus, and does not pass into the

funis or navel-string. This sac is perhaps the vesicula umbilicalis in the human embryo.

When there is a plurality of infants, each has distinct placenta, and a set of membranes. The circulations of the blood are distinct. In some rare cases there is but one placenta for both infants, and hence the application of the second ligature to the navel string, lest the fœtus remaining in utero might bleed to death.

CHANGES IN THE EXAMINATIONS

AT THE

ROYAL COLLEGE OF SURGEONS FOR ITS DIPLOMA.

In our Number for March the 4th will be found an able and interesting communication signed a REFORMER, in which the writer gives a serious, though not the less faithful account of the style in which the examinations of candidates for the diploma of the Royal College of Surgeons, and for the certificate of the Worshipful Company of Apothecaries in London, were conducted by the councils of these learned and scientific bodies. A contrast also was accurately and sensibly drawn by the writer between the examinations at the Dublin College of Surgeons and the London College, in which it was clearly shown that whilst the former corporation required from the student an intimate acquaintance with the fundamental parts of his profession, and conducted its examinations in a public manner, the latter was content at "one nightly sitting with closed doors," to send forth to the world as many as ten or twelve newly

manufactured surgeons, after each having undergone the absurd mockery of what was styled a "*solemn and careful*" investigation into their professional capabilities; which investigation usually occupied *ten or fifteen minutes!*

The effect the communication we have alluded to, together with our own leading observations, had on the council of the College of Surgeons, was to induce that body to take into its deliberate consideration the immediate propriety of making some alterations in the then grossly inefficient method of its examination.

It is but justice to state that Sir Astley Cooper, Sir Benjamin Brodie, and Mr. Lawrence, were the foremost individuals in bringing the matter under the consideration of the council; and although the latter of these gentlemen strenuously urged upon his colleagues the great advantages a public examination offered, and the startling effect he was satisfied, from his former experience, it would have on the medical senate of the NEW REFORM UNIVERSITY, yet he readily yielded to the insinuating arguments of the two worthy baronets, when he had ascertained that all the members of the council, with one disgraceful exception, were inclined to adopt the suggestions offered.

The result of all this has been that instead of the former farce being performed, of a student taking his place in front of the PRESIDENT, and the PRESIDENT, in solemn mockery, desiring him not to be discomposed, at the same time looking as fierce as possible, and nodding to Mr. A. or Mr. B. to commence the probing, during which operation the junior listeners were playfully disporting themselves in convivial conversation, and the seniors comfortably reposing under the influence of their after-dinner orgies—an examination more extended, and infinitely more becoming the college has been adopted.

There are at present three distinct examination tables, at each of which there are, in general, three examiners, and the student has to undergo an examination at each, which usually lasts from fifteen to twenty minutes. A register is kept at each table of the answers given to the several questions by the candidate, and the style of answer is marked good, bad, indifferent, and so on. When the candidate retires those papers undergo a *general* scrutiny, and his admission or rejection is decided upon; but should there be any doubt of the matter, the candidate gets the benefit of it, and receives a series of written questions, and according to the answers he delivers to them in writing, depends his final chance!

Desirable as this reform is, and for the effecting of which we take to ourselves some credit, there are many other changes which must take place before any fair degree of confidence can be placed by the public or the profession in the exercise of the important duties which devolve on the Court of Examiners of the London College of Surgeons.

As a specimen of the new method of examination we subjoin the following:—

CANDIDATE, MR. ———.

FIRST TABLE.

Present—Messrs. Thomas, White, and Vincent.

Examiner—Mr. Thomas.

1. Bones of upper extremity.
2. Nerves of upper extremity.
3. Carpal bones, and sprains of wrist joint.
4. Ligaments and interarticular cartilage.
5. Muscles of the fore-arm.
6. Operation of taking up the brachial artery.

SECOND TABLE.

Present—Messrs. Guthrie, Keate, and
Andrews.

Examiner—Mr. Guthrie.

1. Suppression of urine.
2. Retention of urine, its causes, and treatment.
3. Prolapsus ani.

THIRD TABLE.

Present—Sir A. Cooper and Sir Anthony
Carlisle.

Examiner—Sir A. Cooper.

1. Superior maxillary bone.
2. Branches of internal maxillary artery.
3. Tic doloureux, and incision of infra-orbital nerve.
4. Wounds of knee-joint and extraction of loose cartilages.
5. Enumeration of teeth in the adult and child.
6. Anatomy of kidney.

Thus it appears that the examination is tolerably extensive in theory, but miserably defective in a practical point of view.

HONOUR CONFERRED ON THE MEDICAL ATTENDANTS ON HIS LATE MAJESTY.

Dr. Davies has had the honour of Knighthood conferred upon him, for his eminent services at the death-bed of our late beloved Sovereign; and it is not many months since he received his medical degree from the Archbishop of Canterbury. The learned Doctor having been Knighted on this occasion, must be particularly gratifying, as the same honor has not been conferred on any of the other medical attendants of his late Majesty.

Dr. Chambers got only the Guelphic order of the first class; and Sir Henry Hallford being already a Baronet, received the Guelphic order of the third class.

RE-ELECTION OF MR. WAKLEY.

The friends of medical reform express universal satisfaction at the re-election of this able statesman, although the profession have had as yet to regret that he has been able to effect little for the great cause; yet let us hope that an opportunity will occur of his redeeming those pledges with which he so often and so energetically taunted the corruptionists.

THE ORATION

DELIVERED BEFORE THE
MEDICAL SOCIETY OF LONDON,

AT THEIR

*Sixty-fourth Anniversary Meeting,
March 8, 1837.*

BY EDWARD HEADLAND,

One of the Honorary Secretaries of the
Society, &c., &c.

[The following observations on the present state of the profession deserve attentive consideration, and reflect much credit on the independence of their author. We have, therefore, much pleasure in quoting them.]

The present division of the profession into grades, and the subdivisions in the separate colleges or corporations, you are all so familiar with, that it would be a matter of unnecessary detail to describe them; I would only remind you that there is scarcely one of *you* whom I have now the pleasure to address who is not by their bye-laws excluded from the honours and emoluments of the college or corporation to which he may be attached. Now, I would ask, would not any person unacquainted with the fact, conclude that there must be an essential difference in the

education and consequent competency of the several practitioners in medicine, according to their academical rank? would they not be surprised at being told that so far as medical education is concerned, there is no essential difference between the Fellow of the College of Physicians and the extra Licentiate of that body; or between the President of the College of Surgeons, and the ordinary member of that body; or between either the physician or the surgeon and the apothecary; but that if strict examination be a test of competency, it is more perfect as regards the lowest of these grades than the highest—nay, that the apothecary is required to give evidence of greater knowledge of the sciences collateral to medicine than even the physician.

It has been well remarked, that it is the business of every good government to provide the greatest good for the greatest number; and in that spirit originated a measure, some twenty-two years since, which was considered by the legislature to be a test of competency to practise medicine—yet, after the many toils he has endured to obtain this proof, he who succeeds is contemptuously termed an *apothecary*, from my lord to the shop-boy, and deemed subordinate to all other ranks in his profession—and why? Is it because he has no knowledge of medicine and the sciences that belong thereto—or because he has not the preliminary of a good education? No, for his examination is a proof of the sufficiency of both; but because he belongs to what by custom is considered the lowest grade of his profession. And so it is with the profession itself—each in the ascending scale endeavours to elevate himself upon the supposed inferiority of the one below him, from the Fellow of the College to the Licentiate of the Apothecaries Company.

Now, if any person will only pass his eye over the whole list of the College of Physicians, he will perceive how insufficient they would be, as regards numbers, to the medical relief of the British population; for let their services be ever so equally divided, it is of course impossible that 462 persons can be adequate to the relief of the 16 millions and upwards which England and Wales alone contain, being in the ratio of one to every 34,482 persons. If, therefore, you admit what long standing custom seems erroneously to have established, that the competency of persons attached to this body is greater than that of those who are otherwise qualified, it necessarily follows that the great

bulk of the community are constantly without the assistance of the highest order of medical knowledge; thereby making it appear, that there is to be one kind of medical relief for the rich and another for the poor. Must not this reflect also upon the government, whose duty it is to provide the greatest good for the greatest number, and render the Act of Parliament to which I have referred apparently useless?

The Company of Apothecaries too, be it remembered, is not the only body which provides medical practitioners unconnected with the College of Physicians, for the London College of Surgeons is constantly pouring forth large numbers of highly endowed individuals, who, superadded to their surgical attainments, are constantly affording us abundant proof of their medical sufficiency. Indeed it would be wrong to pass over them as a body, without reminding this meeting, that there are many distinguished men in their list, who may be said to have added by their researches very much to the improvement of modern medicine. I allude not simply to the physiological and pathological labours of these eminent persons, but to the well-known fact, that in addition to the improvement in mere chirurgy and mechanical aids, so much has been effected by them in the adaptation of medical agents for the removal of diseases which were formerly deemed incurable except by a knife, that the number of operations within the last twenty years has been reduced to at least one half—and thus they have contributed greatly to the relief of suffering humanity.

Facts go beyond all theory, and in this simple circumstance therefore I hesitate not to challenge a denial that this body eminently deserves a high rank among British medical practitioners.

In short, on a dispassionate and honest consideration by all who are competent to judge, it must be admitted, that all legally qualified medical practitioners of whatever grade, are, as far as their education is concerned, equally entitled to the confidence of the public. A higher degree of intellect, a greater fund of experience, or a more abundant measure of industry in availing themselves of that experience will constantly raise some men to a just superiority over others—but *these* should be the *only* distinctions—since, I repeat, that as far as education is concerned, all are absolutely equal.

Let me not, in what I have advanced, be supposed to be indifferent to the learn-

ing, to the high medical and philosophical acquirements, and gentlemanly deportment of those distinguished men who are ranked in the list of the Royal College of Physicians, and who so admirably support what I will term the aristocracy of physic. The body to which they belong, in an altered form, I believe it to be desirable should exist; for it should not be forgotten, that since the foundation of that body, there have been many eventful periods in English history, in which the agitations of the state have suspended the march of medical science, and during which periods, had it not been for this learned body, that science would have lost much of the dignity and honour with which it is at present invested,—and quackery would have shewn its protean head in even more murderous forms than it has already done.

But it is now my object to contend for the principle, that all classes of the community are entitled to equal medical aid, and that the present laws assume a difference. We must bear in mind that the distinctions in rank in practical medicine must necessarily differ from those in the other learned professions, law and divinity; the separate members of these professions may possess different degrees of competency without risk or inconvenience to the public—but with ~~us~~ it must not be so—there is not a case in which we are required to attend, but that we ought to be ready at the moment with the best and most efficient remedies; for, if misapplied remedies are not always immediately fatal they must always add to the sufferings of the afflicted, and not unfrequently thwart the more skilful means of relief which may be subsequently applied.

Let us consider, also, the injury which the bare imagination of a different degree of medical competency is likely to produce. How must it agonize the afflicted parent to think, that had better means been used, the life of a beloved child might have been saved—how must it add to the sufferings of the bereaved husband to believe, that the endeared partner of his life has been removed from the want of the due application of the best powers that art affords—or the delicate and helpless widow, cast upon the mercy of a pitiless world, without the means of providing for her numerous offspring, how can *she* support the thought, that there were other and better aids, which might yet have spared the heart that loved, and the arm which would have laboured for her! And yet our present classification really

implies all this; else are we all alike, and there is no real distinction, no difference in the medical education, and consequently in the requisite competency, between the highest and the lowest.

And for the sake of our country, I feel proud to say this is the truth. If it were universally known that such is the advanced state of medical education that the examination for the lowest station, is a test that secures an efficiency of medical acquirements, as completely as the examination for the highest—if this were a fact that was thoroughly known, the comfort of the community would be in no small degree increased.

All else of evil in the present subdivision affects ourselves only. It cannot be denied, but that it is highly desirable that legislative interference, if the course could be well ascertained, should do away with the present distinctions; but until the end of such a measure can be well foreseen, I feel that it is almost “better to bear the ills we have, than fly to those we know not of.” It appears to me, however, that during the time which must elapse before the fittest means can be resolved upon, it is unwise in the legislature to interfere by the adoption of partial measures, the tendency of which will be to create still further distinctions. I allude to a charter, recently granted, incorporating certain persons, for the purpose of granting degrees in physic and surgery. Now, if we put aside the obvious tendency which this has to injure well-established and reputed schools of medicine, still it appears to me, that it may also affect the reputation of the present race of medical men, and may moreover be said to have become law, without the voice of the profession having been heard. So also, I fear, must be viewed another charter, incorporating a Medical Society, which tends to establish a presumed greatness, deterring persons from joining more humble, but not less useful institutions of a similar nature. In this course, Government is perpetuating the great fault of sanctioning partial measures; measures that are not founded upon a thorough knowledge of the whole subject and its difficulties, and calculated merely to benefit particular individuals in connection with certain schools of medicine. These measures, I repeat, appear to me to be premature and ill judged; still, I think, that many will agree with me in believing, that our present system of medical polity stands in need of a thorough reformation.

Taken as a body, the practitioners in medicine, of all degrees, are admitted by the rest of the community to be of the highest respectability and education; they are, therefore, unlikely to raise complaints without just reason. But can we, who are in the early exercise of our practical knowledge, who are now sustaining the burden and heat of the day, can we endure, without complaint, the certainty of being for the rest of our lives, according to general definition, the same subordinate and inferior men? Can we behold unmoved that so many distinguished and learned individuals, in both Colleges, many of whom are rapidly passing to the decline of life, can we behold them sink into their graves, still marked as something inferior in talent and usefulness, when compared with the heads of their Colleges? Does not this apply to many of the highly-respected individuals who are associated with us; and where, I would ask, should we place their names in the scale of science, of learning, and of medical talent, had we the power to render them what they deserve? Go, I would say, to the sceptic upon this subject, bring me the men who are merely graced with high academical honours, ransack your universities, and summon the elite of all your colleges, and I should be proud to compare them with many whose names adorn the list of the Medical Society of London—and are they not of the excluded?

What men, I may fairly ask you who have so much experience of its truth, what men undergo more toil than medical men, who have to submit to more deprivations, who are denied the world's pleasures more than they?—to them there is no rest from their labours; the seventh day, which bestows rest upon all other men, brings little or none to them. It is indeed difficult fully to appreciate the labour and exertion which are required to give the professor of medicine anything like a competent knowledge of his art. Much, indeed, he may acquire from his academical pursuits, but much, also, he must learn by the closest observation. He must be content to spend many years, perhaps the best of his life, in ceaseless endeavours to gain fresh accessions of knowledge; yet perhaps will have the mortification to find himself still very far short of perfection. But, if he be honest in his search after truth, he will not resign his task, but, in spite of all obstacles, will still press forward. But can we endure to think that such an ardent and zealous student of his profession—and many such, I am well

aware, there are among those whom I address—*As* who has spent many a midnight hour in study, and many an anxious day in earnest observation, should yet be condemned to comparative obscurity by the unjust regulations of that profession for which he has sacrificed so much?

Because all this devolves upon the general practitioner, is he the less entitled to the honours of the profession in his old age? Are the children of a man who has so laboured to feel that their parent is lower in rank than other men not more deserving? For it may be safely said, that the greatest probability of the success in a child, is the prosperity and honour of the parent; and if the child has not this advantage, he loses much in his future career; thus, on account our children, we have just ground for complaint.

It will perhaps be said that I am telling you things which are well known to you all, and for which there is no remedy. I have before expressed an opinion that an immediate legislative enactment would be inexpedient, and I believe it would be so, because a measure sufficiently comprehensive to meet the whole difficulty would necessarily do an injury to many persons, whose existence depends upon the present system. There would, perhaps it will be thought, be a more easy course, that of rendering every member or licentiate of each college or corporation entitled upon turn or merit to its highest honours; but in that way you still continue, with respect to medicine, the present absurd distinctions. But one of my chief objects in bringing this matter before you now, is to impress upon your attention that the best interests of our profession are to be promoted by the free intercourse of all its members, without reference to academical rank; all, who have sufficient zeal in the service of humanity to forego distinction, and who feel that it is due to the profession they have adopted, that they should bring forward every fact they can collect which may elucidate its obscurities, and who would be conscious of a dereliction of duty did they deceive the public by professing to be competent practitioners in medicine, unless they had, at the same time, exerted every faculty in the constant observation of disease. For it is only by such a close observation of disease, superadded to theory, that the student becomes really efficient; and it is in societies similar to this, that he learns how to properly appreciate such experience. It is in such associations that we learn how to discern ourselves of that which is useless,

and to select that which is of value ; and it may be fairly said, that he who does not join some institution of this kind not only does not avail himself of abundant means of improvement, but in some measure neglects to give the public the best guarantee he can of his competency, by not constantly submitting his opinions to the scrutiny and revision of his more experienced brethren. In short, I should say, that it is to the extension of institutions like this that we should at present devote ourselves, to uphold the dignity and honour of the medical practitioner : it is by joining such societies that he gives the only proof in his power of his desire to increase his knowledge, and of his fitness to rank among the highest members of his profession. But it is not in its present limited form that it should exist ; it should be increased for all its purposes at least tenfold. An extensive combination of this kind would do more than anything else, at the present moment, to elevate the interests of all, because it would bring into operation the advice and experience of all.

Again, it must be obvious that such societies are eminently useful in softening those unhappy differences and petty jealousies which too often arise among us. It must surely happen that kindness and good feeling will spring up among men who constantly meet together, and who are taught by that association that their occupations and even their habits of thinking, though the latter may be varied by their different constitutions and tempers, are yet in a great measure alike. I do indeed earnestly wish that this, and other excellent institutions of the same nature, could teach us the simple truth that we are all one common brotherhood, so that any public injury, wantonly inflicted upon the character or reputation of a single member, is sure to be felt in a greater or less degree by the whole united body. We are, it must be allowed, very far from having attained to such a happy unanimity of feeling ; but this society appears to be well adapted to promote so desirable an object.

It has been frequently remarked by those who have preceded me in my present honourable task, but it cannot be too often enforced upon our attention, that the society upon whose anniversary we meet to-day, is admirably calculated to soften our animosities by breaking down all artificial distinctions. It is so constituted, that incapacity and ignorance, whether found in those who are of high

or in those who are of low degree, are sure to find their proper level ; while the genuine talent and the deep research which are admired in the physician or the surgeon, are no less honoured when they shine with equal lustre in the general practitioner. What can it avail a man who has to maintain an argument among conflicting opinions—what clearness can it give to his reasoning, or what strength can it add to his position, that he is the Fellow of one College or the Licentiate of another?—all these adventitious circumstances are evidently of no use in arming him for the intellectual contest. And thus it must often happen that the physician is obliged to respect the knowledge and the talents of one who belongs to that class which perhaps but a short time since he secretly judged to be only qualified to compound the medicines which he himself prescribed—while on the other hand the apothecary, (if I may employ that designation which has almost become a *term of reproach*) is often compelled to acknowledge the truth of that which his jealous surmises may have led him to suspect, that the greatest talent and erudition are frequently found united with rank in the profession. By these means the prejudices on both sides are softened, and it is to be hoped often entirely subdued ; so that if it were for this good office alone, this society is well deserving our best regard and support.

But let me revert to an argument which I have before advanced. I maintain, that every British subject is entitled to equally efficient medical aid ; the British dominions possessing no less than twenty-seven millions of persons, it is perfectly clear that the members of the College of Physicians are not equal to their relief : then, either the government must be grossly negligent of human life, or the members of the other colleges and halls are equally competent, and the distinction becomes absurd. I should regret that these observations should be thought offensive to any one ; indeed I have so high an opinion of the good sense of the greater number of the body to whom I allude, as to believe that they are willing to lend their aid in changing the present situation of the general practitioner. I do not believe that the *remuneration* of the general practitioner is complained of—it is simply that means are taken by false distinctions to lower him in the estimation of the public—thereby destroying, for the exaltation of others, that confidence in his capability which in the present state of his acquire-

ments he does not deserve. Thereby also, empiricism obtains one of its greatest aids, and patent medicines their tremendous consumption. Indeed I cannot forbear to say, that if we were less desirous of our own exaltation, and more willing to bear testimony to each other's competency, that quackery would feel a greater blow than it has ever yet sustained; as the prosperity of quacks and their medicines too often arises from the want of unanimity among ourselves.

ANEURISM OF THE RIGHT CAROTID AND ARTERIA INNOMINATA SUCCESSFULLY TREATED BY PLACING A LIGATURE ON THE CAROTID ARTERY.

By M. MORRISON, M.D., Buenos Ayres.*

[We have great pleasure in laying before our readers a case of aneurism of the innominata, treated according to the principle suggested by Mr. Wardrop, of only diminishing the circulation of the blood within the sac, by tying one of the branches of the diseased artery.]

On the 4th of November, 1832, was requested to visit Don José Harruz, ætät 42, a native of Biscay, in Spain, a man of fine proportions and industrious habits. I found him in bed, to which he had been more or less confined during the preceding nine months, labouring under the following symptoms: pain in the cardiac region, difficulty of breathing, which was increased to a painful degree by walking a distance of a few squares, rheumatism of the right shoulder, and of the muscles of the neck of the same side, hemicrania of the right side: in addition to all these, my patient had a large pulsating tumour, extending itself upwards from within the cavity of the thorax, and obliquely outwards behind the sternal extremity of the sterno-cleido mastoid muscle.

The tumour, when pressure was made of the carotid above it, did not diminish perceptibly, but the pulse at the wrist became fuller and stronger. When pressure was made on the right subclavian, the tumour pulsated more strongly, as likewise did the temporal and facial arteries of the right side; by reason of these phe-

nomena, and the relations of the tumor, I concluded that it was an aneurism of the root of the right carotid and arteria innominata.

I stated to this poor fellow the danger of an aneurism in this region, assuring him at the same time that diseases of a similar nature had been cured in Europe and in North America, by surgical means. I gave him a faithful detail of the advantages and disadvantages of the operation, the possibility of death occurring as a consequence of it, and the prospect of cure in case it should not prove fatal. His reply was, that he would submit to any means by which a cure might be obtained. To mitigate his sufferings I bled him, and prescribed a dose of Epsom salts.

On the following Monday, in consultation, it was agreed that he had an aneurism of the arteria innominata and root of the right carotid.

On Thursday, the 8th, I operated in presence of Dr. J. McDonnell and Don Mariano Brio, Surgeon-General. The operation was commenced by making an incision, extending from a point on a line, with the top of the larynx downwards, along the internal margin of the *sterno-cleido mastoid* muscle, as far as possible, without endangering the superior margin of the tumor. The dissection being continued, the *homo-tyoideus* was exposed, and the sheath which involves the primitive carotid and jugular vein laid bare. The patient now became pulseless, and to revive the powers of life a draught of undiluted wine was administered. Upon the recovery of the patient from this state, the sheath of the great vessels was raised with a dissecting forceps, and divided with a scalpel. An aneurismal needle, armed with a flat silk ligature, was passed under the artery, and the vessel secured by the ligature. The wound was brought together by the interrupted suture, dressed with adhesive straps, carefully bandaged, and the patient put to bed.

In the afternoon the patient complained of being much distressed by hollow sounds in the right side of his head; the pulsation in the tumor was tremendous, and by reason of communicating its motion to the shirt collar, the number of pulsations could be taken at some distance from the bed, the artery at the wrist being full and hard, and his skin hot and dry, I bled him to 16 ounces.

Friday, 9th.—The patient has passed a good night; pulse strong and frequent; tongue loaded with a white fur. I prescribed the saline mixture. At 6, P.M.,

* American Journal of the Medical Sciences. Philadelphia. 1837.

medicine had a good effect; patient had some sleep in the course of the day; pulse strong, and beating 110 in the minute; V. S. $\frac{3}{4}$ x.

Saturday, 10th.—Passed a restless night, suffers from pain in the right side of the head; pulse 100, and soft. The saline cathartic to be repeated.

11th.—The tumor pulsates strongly; some tenderness in the region of the wound; pulse 100; skin moist.

12th.—Dressed the wound, the greater part of which had healed by the first intention; pulse 98, and soft.

13th.—Pulse 94; wound doing well.

14th.—Pulse has risen to 108. V. S. ad $\frac{3}{4}$ viij., which produced fainting.

15th.—Pulse 100, and strong; twelve leeches applied to the region of the heart.

16th.—Digitalis and nitre were prescribed, but in consequence of the constitutional disturbance produced by their exhibition they were discontinued.

17th.—The tumor was tender to the touch. From this date the pulsation in the tumor became weaker, the tumor itself began to harden, and to diminish in size; the only symptom that afterwards required treatment was the rheumatic pain of the back of the neck and shoulder.

About the beginning of December the patient sat up to his meals; and on the 9th of the same month, being the thirty-second day from the operation, the ligature came away.

Hurruz, after his convalescence, went to one of the islands up the river, where he laboured hard at the making of charcoal. He came to this city from time to time, and when here invariably visited me, and I was happy to see him doing well. On his last visit, however, which was about the latter end of June, 1834, he complained of an oppression in the chest, which was accompanied with a slight cough, for the alleviation of which I had him cupped, and prescribed a mild emetic. This was the last time I saw Hurruz alive. On the 4th of July following, after walking a distance of twenty squares, upon his arriving at the very same house in which I operated upon him, one year and eight months before, he dropped down dead.

On the following day I examined the organs in his chest, in presence of Dr. McDonnell.

Autopsy.—The sternum, together with the cartilages of the ribs, being raised, the right subclavian artery was traced to its source, at which point it was partially dilated. The *arteria innominata* was

double its ordinary size, and studded with spiculae of ossific matter.

The right carotid, from its origin to the point to which the ligature had been applied, was dilated into a sac, which was plugged up with a dense fibrous deposit. The portion of the tumour which was within the chest was much more voluminous than that which rose into the neck.

The anterior surface of the thoracic portion of the tumour was firmly adherent to the sternum. There never was a more splendid specimen than this, showing the manner in which nature cures this formidable disease, when assisted by art.

The lungs were free of adhesions, and of a healthy appearance; the heart itself presented nothing uncommon in its external aspect, but upon dissection it exhibited evident marks of inflammatory action, particularly in its ventricles; the semi-lunar valves at the origin of the *aorta*, were indurated from a deposit of ossific matter; the arch of the *aorta* was completely ossified, and considerably dilated. The pericardium contained from eight to ten ounces of serum.

EFFECTS OF SOLITARY CONFINEMENT ON THE HEALTH OF SOLDIERS IN HOT CLIMATES.

By Assistant Surgeon MALCOLMSON,
Late Secretary to the Madras Medical Board.

[Letter to Sir H. Hardinge.]

The author sets out with the confession that he is no advocate for *corporal* punishment, being satisfied that it is not effective in the prevention of military crime. Yet he cannot shut his eyes to the fact, that the anxiety to avoid the revolting spectacle of flogging is likely to lead to another kind of danger—the substitution of a solitary confinement that is incomparably more cruel at the time, and more detrimental to health afterwards. M. M. has reason to believe that “more real misery has arisen in 12 months from imprisonment in the jails of India, than has been inflicted by corporal punishment in a hundred years.” Here our author adduces statistical reports showing that the mortality in prisons varied from 24 to 57 per cent. per annum! Punishment he acknowledges to be necessary, flogging disgraceful, and solitary confinement destructive of health; but

he is unable to suggest a substitute for either the one or the other mode. Mr. Brown has a doctrine which, if taken in an unrestricted sense, is rather startling. "There can be no doubt of the truth of the principle, that *no punishment* can be just, or in the eye of God, lawful, which tends to impair the efficiency, injure the health, and shorten the life of the soldier—or which produces any effects that cannot be estimated by the judges when they assign a punishment for an offence." A soldier mutinies, and he demurs to any punishment that may injure his health or shorten his life! Greenacre and Meunier might have urged this doctrine against their sentence, as tending to injure health and shorten life! Johnson defines "punishment" as the infliction of pain or death, as atonement for crime. No infliction of this kind, to be of the least efficient amount, can be otherwise than injurious to health, in a greater or less degree. Nor can the judge always predicate or calculate the effects of corporal punishment.—What may be borne with impunity by one man, may be the death of another. Daily experience shows that the judge or the court-martial cannot estimate the amount of punishment which a man can bear, otherwise a surgeon would not be ordered to attend the infliction of the sentence, and arrest the whip when he finds the culprit sinking under its effects.

By these observations we do not mean to advocate solitary confinement and bread and water, as punishments for soldiers in the East Indies, as the injury may be more than was designed, and consequently more than is proper. But we maintain that all punishments are more or less injurious to physical health, and that flogging is a punishment much more detrimental to the moral man than solitary confinement. In the former case, the man feels degraded, and too often loses all desire to retrieve his character. In the latter, he is not exhibited in public, and has ample time for reflection and repentance in his lonely cell, where his messmates cannot pamper him with intoxicating draughts. But we advocate seclusion, we condemn starvation on bread and water. We would mortify the spirit, but not withdraw proper sustenance from the body. If the great object of punishment be the prevention of crime, we know, from observation, that the dark cell is more dreaded than the whip. This we saw exemplified among the French prisoners during the last war. Nothing

was so operative in preventing crime as the dread of the cachot.

Our author's attention was first drawn to the effects of this kind of punishment by two men who were so treated at Hyderabad. These effects resembled a good deal those of sea scurvy. The history of the Penitentiary Endemic, by Dr. Latham, also exemplifies these effects.

"Many men, particularly those of indolent habits, endure a confinement of four or six weeks, on bread and water, without injury to their health; but, in some instances, a shorter period is sufficient to cause a total loss of appetite,—the bread is hardly touched, and on other food being allowed, the patient is unable to eat or to digest it. The stomach becomes weak; there is uneasiness across the region of the stomach, spleen, and liver; the latter is torpid; the bowels are confined, or they are relaxed with slimy discharges unaccompanied with pain, yet the swollen red tongue indicates the existence of irritation of the mucous membrane of the digestive canal. The pulse is quick and feeble, and the clammy skin, vertigo, debility, headach, and sleeplessness, show how much the constitution suffers from diminished nervous power. The convalescence is slow, and the treatment requires to be adapted to the enfeebled state of the system. The effect is, however, more clearly seen in men sentenced to six or twelve months solitary confinement. Two of these were in hospital at the same time, with decided symptoms of scurvy:—one was admitted after five months confinement, during part of which he had been allowed extra diet at my recommendation. It was observed that for some time previous to his removal to hospital his daily allowance of bread was removed almost untouched. He complained of pains of the limbs, along the spine, and across the loins; tenderness of the shin bones; hardness, pain and feeling of stiffness of the calves of the legs, and the skin over the painful muscles was of a dark livid colour from effused blood. The gums were spongy, livid, and retracted, and he suffered from sleeplessness, some pain of the region of the liver, and slight griping. The tongue was yellow and its edges red. The other had been a shorter time in confinement, and complained of debility, disorder of the bowels, pains of the shin bones, &c."

"We wonder indeed how any rational people could think of sentencing soldiers to six or twelve months' confinement on bread and water! The plan must prove

ruinous to the constitutions of nine-tenths of the miserable victims of a mistaken and too rigorous system of retaliation for crimes not capital."—*Medico-Chirurgical Review*.

PROFESSOR LALLEMAND ON SPERMATORRHEA.

The distinguished Professor of Montpellier has recently published a treatise on involuntary seminal emissions, in which he has minutely described the symptoms, most frequent causes, the pathology, and the treatment of this most insidious and offensive disease. He states:—

"In the course of the last fourteen years I have collected upwards of 1500 cases of involuntary spermatorrhea, in all of which the health was seriously affected, and in many death was the consequence. The greater number of the patients had been directed to me *for supposed cerebral affections*. In not a few of the cases, it had been supposed that the patient suffered from chronic gastritis, or gastro-enteritis, from aneurism of the heart, from incipient phthisis, or from some of the multifarious forms of nervous disturbance, and most frequently from hypochondriasis."

The cases, adduced by M. Lallemand, exhibit examples of persons, whose constitutions had been vigorous and robust, presenting at the period of life when the body has acquired its development, and without any appreciable cause, all the symptoms of physical exhaustion, associated with a very marked feebleness of the mental powers.

In examining attentively the probable cause of this premature decrepitude, it was frequently discovered in an existing spermatorrhea, or seminal weakness. The opinion of the author, who recognizes in a protracted spermatorrhea the cause of numerous encephalic distresses, is confirmed by the consideration that, in some fatal cases where cerebral congestion, the decay or perversion of the intellectual faculties, the exhaustion of the physical energies, &c., have existed for a length of time, no signs of morbid change, except in the genito-urinary organs, are discoverable on dissection. The most frequent and the most potent cause of spermatorrhea is, according to Lallemand, an inflammation affecting the secretory and excretory apparatus of the semen—an in-

flammation which, commencing in the urethra and prostate gland, is apt to extend to the vasa efferentia, vesiculæ seminales, vasa deferentia and testicle, as well as to the urinary bladder.—*Ibid*.

THE MISCHIEF OF THEATRICAL SURGERY.

To the Editors of the London Medical and Surgical Journal.

Gentlemen—In perusing the valuable pages of your Journal, I was much struck with the fearless manner and humane view which you have taken of the "*theatrical performances*" of some of the metropolitan pures, and in a particular manner with your remarks of the unprincipled conduct of certain hireling journals, in concealing from the profession the true result of the practice of the London Surgeons. In justice, however, to the candour of an able contemporary, I was much struck with the bold and manly sentiments contained in the following paragraph.

"It is very creditable to surgeons and to science, that much less consideration is now attached to operations than was formerly the case, and that men of great ability and talent for investigation, have applied themselves to what is known in common language as 'medical surgery,' rather than to the acquisition of mere mechanical dexterity." The latter is no doubt a useful and showy accomplishment, but whoever has witnessed the performance of a sow-gelder, or the bloody legerdmain of the shambles, must admit that it is possessed in the utmost perfection by the lowest, the most brutal, and the most ignorant of men.

We cannot conceive anything more revolting to the mind of a man of intelligence and humanity, than the reflection that he is regarded as a sort of human butcher, whose *hand* and not whose *head* is called into requisition, and who like an *executioner* is only wanted when there is *bloody* business to be done. Such a man must feel how cheap he deserves to be held in the world of intelligence and science, and he must own, with humiliation, that he is little better than a handicraft mechanic.

The history of lithotomy and hernia is sufficient evidence of the extent to which mere operative skill may be carried,

amidst the grossest ignorance of all that should regulate the performance of operations."

Should you think proper to insert the above extract from Dr. Johnson's last number of his Review, I presume to think it may still further be the means of giving publicity to professional sentiments which must be valuable indeed, not only to the student, but even to more advanced practitioners.

Believe me your constant reader and well-wisher,

M. R. C. S.

Greenwich, August 1, 1837.

CHARING-CROSS HOSPITAL.

To the Editor of the London Medical and Surgical Journal.

Sir,—I read with much pleasure the just observations you made last week in your independent journal, respecting the Charing-Cross Hospital, and I must say that it appears to me very strange that other journals have not taken notice of the infamous jobbing which has been carried on there by some interested individuals for the last few years.

The praise you have given to Mr. Partridge that gentleman well deserves, and I have now to assure you that Mr. Partridge is using his best and honest endeavours to effect a junction between the King's College and the Hospital, without which union the latter institution will continue to remain a dark and foul spot in the annals of our charitable institutions. Mr. Partridge, as well as ourselves, sees the obstacles which are hourly cast in the way of even rendering our hospital a proper place for clinical instruction; and I have reason to know that changes, which the Director and his satellites do not anticipate, will ere long be effected in the institution, through the powerful influence of many governors now obliged to be out of town, and who fully concur in the views and objects of Mr. Partridge.

I have the honour to be, Sir,
Your constant reader,
A PUPIL OF THE CHARING-CROSS HOSPITAL.

REVIEWS.

On a New Mode of Treatment employed in the Cure of various forms of Ulcer and Granulating Wounds. By Fred. C. Skey, F.R.S., Assistant Surgeon to St. Bartholomew's Hospital, Lecturer on Surgery at the Aldersgate School of Medicine, &c. London: Longman and Co. 8vo. pp. 85. 1837.

On perusing the preface of the small pamphlet before us we were led to expect that something of a novel and very extraordinary kind was about to be introduced to our notice in the eighty-five pages appended to it. The very ingenious and artful manner in which the "proposed remedy" is mysteriously spoken of; "*it* is to invariably supersede *all* operations in the treatment of non-specific ulcers;" the "unqualified belief" the writer has "*in it* as a remedy;" "*it* claims a trial," &c., raised our expectations to the highest pitch; but great was our disappointment, after anxiously wading through thirty pages, to find that "*it*" was neither more nor less than our esteemed friend and ancient ally *OPUM*! What could have induced our author to have made so many apologies and such a fuss in his four pages of preface about little or nothing is but known to himself. However, as these "*parturiunt montes*" offer in originality much more for contemplation than the "*ridiculus mus*" which follows, we propose first to pay particular attention to the "*lady in the straw*," and, as is usual in cases of this kind, having secured her a safe delivery, next to look after the offspring.

In the first paragraph of his preface Mr. Skey premises that "in proffering the results of an extended experience honestly recorded," it is not his desire "to supersede the labours of many eminent predecessors." The modest, though indirect assumption of the term "eminent" in this sentence is very characteristic, and it only required the addition of *other* to make it fully intelligible to the most careless reader; neither was there the slightest necessity of adding "honestly recorded," as there will be found nothing extraordinary or wonderful in the cases related, to raise the slightest doubt of the *honesty* of their detail. But let us see how far "the desire not to supersede the labours of others" is complied with, at pages 7 and 8 of the offspring. In discussing the old question, "why ulcers of the legs predominate in os

large a degree over every other part of the body?" The opinions of Mr. Underwood, Mr. B. Bell, and Mr. Whately, are "deemed unphysiological" in referring their prevalence in these situations to the weight of the lengthened column of blood in the veins, without any satisfactory reason for the author's differing in opinion being given, and Sir E. Home's *honesty* is particularly pointed at in the following: "Sir E. Home speaks of this (obliteration of the saphena vein by operation) his favourite mode of treating ulcers, coupled with varicose veins, as an operation of frequent performance; yet, out of the whole catalogue of cases, he does not refer to a single example in which the operation was attended with bad consequences. This is somewhat remarkable!" Not, however, a bit more remarkable than the sixteen successful cases which our author relates, and which do not form a "detail of even a tenth part of those to which the treatment has been applied!" Next comes Mr. Baynton's practice, the "general efficacy" of which is admitted, but who is complimented with confounding "*ulceration with cicatrisation*," and quotations are made from this gentleman's pamphlet, published in the year 1799, to give Mr. Skey an opportunity of confessing that "all this borders on the mysterious," and that all Mr. Baynton's "reasoning is unphysiological and unsound. So much for the "desire not to supersede."

"Had I been actuated," says our author, "by any other motive than that of communicating to my professional brethren, and through them to the public, an efficient means of curing an obnoxious and often loathsome disease, I should have selected for my subject one more aristocratic in the circle of its influence, and necessarily more profitable in its treatment." Now truly "all this borders on the mysterious," and appears to us quite unnecessary after Mr. Skey having at the very outset assured his readers that his views were "the results of an extended experience, honestly recorded." We must, however, remind our author, who has evidently paid much attention to this subject, that not only are a fair proportion of the aristocracy sufferers from the disease, but that also a far better feeling class of patients, those whose various callings subject them to the inconveniences of city life, present innumerable *interesting* specimens of most varieties of ulcer. Such, for instance, as the foreman in the large distillery visited by Mr. Skey at the request of Mr. Goss, the progress

of whose cure is so accurately noted; and the case of Mrs. S., with the "superficial erratic ulcers."

With respect to the pamphlet itself it may have a tendency to make opium-eaters of a few hypochondrical ulcer-eaten individuals, and this is all; for as far as the profession is concerned the efficacy of opium as a remedial agent in the treatment of ulcers must, at this time of day, be fully appreciated by every practitioner, else the writings and discourses of Bell, Underwood, Baynton, Pott, Home, Cooper, Wardrop, Brodie, &c., have been undertaken or delivered in vain.

We shall conclude this lengthened notice of a short pamphlet with an analysis of a few of the cases, so that a fair estimate can be formed of the merit due to opium as ["the specific," when the treatment with which its administration was conjoined is taken into account.

Case 1.—A labourer, aged 54, *admitted into hospital*, with a deep excavated ulcer of the leg, which was covered with rag, saturated with an aqueous, and apparently acrid, discharge. He suffered *little pain* in the ulcer, except *after exercise*.—*Treatment*:—*Rest, mild aperients, bread and water poultice, spermaceti dressing*, and extract of opium half a grain night and morning increased to three-quarters of a grain. After five weeks the ulcer was diminished to one-third its original size, and had the appearance of a recent ulcer.

Case 2.—A mechanic, aged 42, *admitted into hospital*; an enormous ulcer on each leg; action rapid, and surfaces covered by a foul foetid slough; superficial veins varicose. He exhibited the aspect of *perfect wretchedness*, and was abstinent of drink. *Treatment*: *Rest, a bread and water poultice, three per diem; chloride of soda lotion; meat diet; porter*; fifteen minims of tincture of opium night and morning, increased to twenty-five minims. In hospital from the 22nd of September to the 29th of November, and went out cured by opium.

Case 3.—Mrs. S., aged 50, an ulcer on left leg of a superficial erratic kind, combined with varix, ulcer of two years standing; had worn a laced stocking for many months; pulse low: subject to cold feet, but in other respects healthy.—*Treatment*: *A light roller for the laced stocking; simple dressing; electuary of senna* if bowels were constipated, and *horizontal position during the greater part of the day*, and ten drops of uncture

of opium thrice a day. Sore healed in fifteen days.

Case 4.—“*The most remarkable I have witnessed.*” “Aged 59, suffered from the presence of an open wound in the leg for fifteen years; discards all local treatment; takes half a grain of opium twice a day for twenty-eight days. The sore heals; and, at the present date, five months after treatment I find the cicatrix still firm,” &c. “He continues to wear a loose roller.”

In this case it appears not to be taken into account that “all local treatment” was “*suspended*,” that the wound was “*lightly dressed during the day with simple dressing, and poulticed with bread and water at night*,” that he “*resumed his gin*,” and that he continues to wear a loose roller.”

With this, “*the most remarkable*” case, we stop.

The Royal Society in the Nineteenth Century; being a Statistical Summary of its Labours during the last Thirty-five Years. With many original Tables and Official Documents, (never before published,) shewing the Constitution of the Society, the Character of its Fellows, its various Proceedings, and Pecuniary Expenditure for “Improving Natural Knowledge,” and a Plan for its Reform. To which are added, Alphabetical and Seniority Lists of the Fellows since the Year 1800. (Arranged purposely for this occasion.) By A. B. GRANVILLE, M.D., F.R.A.S., F.G.S., M.R.I., &c., one of the Contributors to the Philosophical Transactions, and for the last Eighteen Years Fellow of the Society. London: Churchill, Gerrard Street. pp. 253. 1836.

We lay the following interesting extracts from this volume before our readers, and shall, in a subsequent number, enter more fully into the *real* benefits the ROYAL SOCIETY has conferred upon Science in this country, more particularly as relates to the medical profession; when we promise to “unfold a tale,” which will make many of its members start!

“Of the 79 doctors in physic, who are at present Fellows of the Royal Society, it would appear then that only 23 have contributed to the Philosophical Transactions, and of this number 10 only are resident in the metropolis, the other 13 Fellows being constant sojourners in the

country. The papers which these 10 metropolitan physicians have produced, out of the total of 66 above quoted, and which have been published, are 23 in number. The rest have been communicated by the 13 provincial physicians constituting, with the former 10, the total of *efficient* Fellows of the Royal Society whose profession is medicine. Here then is a glaring example of the indifference with which almost any claimant is suffered to enter the society. The mischief which is produced by such a practice is manifested in the apathy of the really scientific men, who cease to take any interest in the welfare of an association of individuals so constituted. A certain quantity of scientific knowledge, observes Mr. Babbage, is of course possessed by many individuals in many professions, and to that of medicine a knowledge of chemistry, and of some branches of natural history, and indeed of several other departments of science, affords useful assistance; but it is obvious that this quantum of knowledge may become, when separated from the profession, quite insignificant as the basis of scientific reputation. If this be true, and who can doubt it, then the indiscriminate practice of raising physicians by the dozen to the dignity of members of a society for which the chief qualification ought to be scientific reputation, independent of professional character—in spite of the known fact, that such physicians have not the smallest pretension to pure scientific knowledge beyond what forms the common elements of the profession which gives them bread—may be justly considered as one of the causes of the decline of the Royal Society. Still more injurious must such a practice prove, when physicians, who have never offered to contribute the smallest particle of scientific information to the society, or to the world at large, are allowed to present themselves as candidates for an honour which they have not deserved—for which they do not even urge any plausible pretension—and when it is manifest to the whole society that such candidates cannot prove either “useful” or “valuable members thereof.”

“Of the fellows and licentiates of the Royal College of Physicians in London there are 226 who actually practise in the metropolis, and 10 only of that number have given proof of cultivating science for its sake, and even they, with two or three exceptions, have not acquired a purely scientific reputation by their labours. See then how trifling is the measure of

scientific merit in the medical profession; yet, through the prevailing absurd practice of relying, as to the reality of the claims of candidates, upon a mere certificate, which, it has been proved, may be obtained by any one and at any time, not fewer than 66 out of the 226 physicians practising in London who have been placed on the same rank as F.R.S. with individuals who have far other claims to the dignified appellation of scientific men. The whole concern, in good truth, is a complete farce; and my astonishment is, that when such elections take place the electors do not burst out in roars of merriment at the solemnity with which the secret votes are collected in behalf of a candidate whose whole tenor of life is in overt contradiction with the professions and descriptions read aloud, and with due pomp, by one of the secretaries.

"The number of surgeons who are to be found on the list of the Royal Society is a curious contrast to that of the physicians in many respects—it is smaller by 48—it contains only one member who is not resident in the metropolis—has produced more than double the number of scientific communications to the Philosophical Transactions—and boasts of not fewer than 15 hospital surgeons, most of whom are in the first practice, and have acquired a high character, both in England and on the continent, for their scientific attainments. But how is it, that while M.D.'s crowd upon the list of the Royal Society, the M.C.S.'s are like 'rari nantes' in that overswelling ocean of F.R.S.'s? Why do we not see figure by the side of this small band of metropolitan surgeons in our society a few of the truly eminent surgeons of provincial hospitals? Those can best answer these interrogatories who have managed our affairs since the beginning of the present century, and none better than the 'noisy ones.'

"After such a picture of the medico-surgical section of our list, who can abstain from suggesting to the society the propriety of putting a stop, for the present, to the election of doctors of physic, except under circumstances of the most manifest eminence for science in the candidate? This will gradually restore to the initials of F.R.S., when accorded to a physician, the dignity and value they have lost; while, with a view to maintain intact the existing respectability of our fellows who are surgeons, it should be resolved that none other shall be ballotted for who has not distinguished himself for extra-

ordinary operations, or brilliant and useful literary or scientific productions, whether resident in town or in the country. Woe to the present 21 surgeons, if they from supineness suffer any candidate to be added to their number whose claim to that distinction is far different from their own;—and still more, woe to their character, if such unworthy additions be made hereafter through the influence of their own names inconsiderately tacked to certificates for ballot."

TO CORRESPONDENTS.

B. C. B.—Though Sir Benjamin bestirred himself in the last Charing Cross election, and in a way not much to his credit; but we believe that the worthy baronet will be afraid of tarnishing his fingers with a new *Recognition*.

M. R. C. S.—His communication will be always thankfully received.

Morbus Pedicularis.—The patient had better apply to a Skin Infirmary. The Ormond-street, Cutaneous institution was transferred a few months ago to Blenheim-street.

Gammon.—His observations are better calculated for the Anthropological Journal. Except their belonging to the class mammalia, there is no analogy between a pig and the human species.

A Country Student.—Mr. Liston will not deliver a course of his luminous lectures at Sydenham College; that classical seminary being within the prescribed boundary. The University Hospital College Lion is daily exhibiting more and more interest in the fate of both Professors Wilson and Dalrymple.

* * The Director disclaims all relationship with the butcher—the propriety is however established.

A King's College Student.—We believe that some of the abuses complained of have been already remedied by the manly interference of Mr. Partridge.

Reflector.—The Fullerian professorship of Physiology at the Royal Institution is not finally arranged. The numerous courses in the different schools which the great Professor Sydenham has undertaken to deliver, convince us that the rumour of his accepting the chair, is unfounded.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

London Medical and Surgical Journal.

SATURDAY, AUGUST 12.

Vol. I.—(1837.)

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

M. Biett is the colleague of our esteemed correspondent, Baron Alibert, whose valuable lectures appeared in this journal a short time since. A large auditory attends the clinical lectures of M. Biett, which are delivered every year at the hospital St. Louis, and these discourses have been taken down by two of his most distinguished pupils, MM. Cazenave and Schedel.

The classification adopted is Willan's, with some modification. This is the most simple and correct. It excludes all doubtful terms, as darte, teigne, &c., which are often applied to the most opposite diseases. After free strictures on the classifications of preceding writers, M. Biett offers one of his own, which he thinks most correct, and is based on Willan's, which embraces all elementary lesions, independently of the products of inflammation. These form eight distinct classes: 1. Papulæ; 2. Squamæ; 3. Exanthemata; 4. Bullæ; 5. Vesiculæ; 6. Pustulæ; 7. Tubercula; 8. Maculæ.

This arrangement is liable to objections, for we find purpura in the exanthemata, erysipelas in the bullæ, itch in the pustules, acne and sycosis menti in the tubercules, &c. Moreover there are many cutaneous diseases, which cannot be referred to any of the genera of Willan, as we shall see immediately. M. Biett and his followers class diseases of the skin according to their external appearances, and forms—

Order I. EXANTHEMATA, which in-

cludes, erythema, erysipelas, roseola, rubella, scarlatina, and urticaria.

Order II. VESICULÆ, as miliaria, varicella, eczema, herpes, and psora.

Order III. BULLÆ, as pemphigus and rupia.

Order IV. PUSTULÆ, as variola, vaccina, impetigo, acne, sycosis menti, and porrigo.

Order V. PAPULÆ, lichen, prurigo.

Order VI. SQUAMÆ, lepra, psoriasis, pityriasis, ichthyosis.

Order VII. TUBERCULA, elephantiasis of the Greeks, molluscum, frabesia.

Order VIII. MACULÆ, colorations, bronze tint, spilus, nævi, declorations, albinism, vitiligo.

The following diseases do not belong to any of the preceding orders:—

Order IX. Lupus.

Order X. Pellagra.

Order XI. Syphilides.

Order XII. Purpura.

Order XIII. Elephantiasis of the Arabians.

Order XIV. Chelodea, or keloide.

These elementary lesions are constant for all the eruptions of each order:—

Exanthemata; spots more or less red, of divers forms, more or less extended, disappearing under the pressure of the finger, terminating by delitescence, resolution, or desquamation.

Vesiculæ; small blisters or elevations of the cuticle, formed by a collection of a serous and transparent fluid, which, under some circumstances, may become opaque, or even sero-purulent. Absorption of the effused fluid, slight desquamation, excoriations or small fine crusts may succeed vesicles.

Bullæ; blebs. These differ from the last only in being much larger, and a small superficial tumour, formed by the effused serosity under the cuticle.

Pustulæ, are purulent collections formed on the surface of inflamed mucous ti-

sue. The fluid they contain gives rise to incrustations of more or less thickness, and these leave chronic indurations, or inflamed or exuriated surfaces.

Papule; small, hard, solid, and resistant elevations, never containing any fluid, susceptible of ulceration on their summit only, but terminating most commonly by resolution, or a furfuraceous desquamation.

Squame; this term is applied to the scales of the epiderm or cuticle when altered, most commonly thickened, dry, whitish, and friable, which surmount small elevations, like papule, which are more or less red or inflamed. These are susceptible of being detached, and of being reproduced for an indefinite time by successive desquamations.

Tubercula; tubercles are small hard tumours, more or less prominent, circumscribed, and permanent, partially ulcerated, or which may suppurate at their summit. In cutaneous pathology they are considered as elementary lesions, and as not having been preceded by any purulent collection.

Macule; spots are permanent colorations or decolorations of certain points of the skin or of the whole of this tissue, which, are unconnected with any constitutional disturbance.

Most of the diseases of the skin are referrible to these eight orders, so grouped and presenting close analogies between each other. We make some changes in the classification of the species. Thus, pemphigus and pompholix appear to us to be one and the same disease. Acne is evidently not a tuberculous disease, erysipelas evidently belongs to the exanthemata, itch to the vesicles, &c.

The diseases in the last six orders cannot be referred to any of the preceding, as they develop with special symptoms. There are also other diseases excluded, as anthrax, burns, &c., which properly belong to general surgery, and whose descriptions would lead to serious digressions in lectures, though necessary in systematic works.

The special symptoms of diseases of the skin are very much complicated with each other, and many different elementary diseases are frequently met with on the same individual, especially those of an acute kind. They are also often accompanied by constitutional disturbance, by more or less irritation in the mucous membrane of the respiratory and digestive organs. But there is a great number of eruptions of a chronic kind, which

continue for months or years, without being complicated with any constitutional irritation, and without the least internal derangement. Cutaneous diseases are susceptible of great modifications in their progress, coloration, and termination, according to constitution, age, hygienic conditions, and complication with internal inflammation. Thus we often observe a chronic cutaneous disease which has continued for months, disappear during the presence of an accidental gastro-intestinal irritation, and gradually return during convalescence. We may therefore say that the eruption is conveyed to important organs. Nevertheless the internal inflammation had preceded the disappearance of the eruption; the return of the latter was gradual when the inflamed organs return to their normal or healthful condition. These cases are, however, of rare occurrence.

Diseases of the skin are developed under very different circumstances, so that their etiology is not the least obscure part of their history.

Some of them appear from direct causes, as from stimulant applications in certain professions, certain hygienic conditions, &c. Thus we often observe a vesiculous or vesiculo-pustulous eruption appear after vesicatories, frictions, and irritant lotions, after the application of irritating powders, or when the part has been exposed to great heat. Exanthematous complaints are often suddenly excited by the application of irritant substances to the skin, and prurigo often appears from the same causes. But there are many other eruptions which appear without the influence of any external cause, from some derangement in the economy, with alteration of some internal organ. Thus chronic pemphigus declares itself in old age, in poverty, and every kind of privation; erythema and purpura often occur in plethoric persons, or when the menstruation is deranged; roseola and urticaria often accompany or supervene on fevers, and many others are excited, as in children, and even adults, by gastro-intestinal irritation. There are, however, many cutaneous diseases unconnected with enfeebled digestion, or even bad health, when no causes can be assigned for them.

Again, many diseases of the skin are hereditary, and there are individuals in whom they are frequently renewed at certain periods or seasons, on the slightest change of regimen, the least excess of any kind, and on any moral emotion.

In fine, there are certain eruptions con-

tagious, as the itch, porrigo, &c., variola, syphilis, &c.; others are induced by climate, as the elephantiasis of the Greeks, frambœsia, molluscum, &c. As to the causes of the difference in appearance of eruptions, as the vesicular, pustular, &c., they are as yet unknown, and must remain so until the ultimate structure of the skin is better understood.

The differential diagnosis of diseases of the skin requires great attention and study, for it is not sufficient to say this is itch, that is syphilis, &c., as is too commonly the case. It is a point of the greatest importance to form an accurate diagnosis. The following method enables us to determine the nature of a disease:—

We should study the elementary lesions, and determine whether a certain eruption is papulous, vesiculous, squamous, &c.; and this is in general easily done by a slight inspection, and if the primitive lesion is observed, it is easy to determine the form, seat, progress, &c. Thus, for example, if a patient presents on the internal surface of his arm, in the spaces between his fingers, on his wrists, groins, &c., distinct, acuminate, transparent, small serous collections, accompanied by pruritus or excessive itching, it will be at once seen that the fluid is not pus, that there is no solid resistant elevation, a circumscribed elevation, a redness disappearing on the pressure of the finger, in a word, that it is not a pustule, a papula, a tubercle, a squamous disc, an exanthematous spot, or patch, but a *vesicle*. We can now readily decide what disease it really is. It is not, for instance, miliaria or varicella, for these are accompanied by general phenomena; in the one the vesicles are globular and innumerable, in the other they are larger and inflamed; the disease is not herpes, for this is characterised by a re-union of the vesicles in groups, while here they are distinct and scattered. The only other diseases of this species with which it can be confounded are *eczema* and the *itch*; the vesicles of eczema are flattened, those under consideration are acuminate; they are more or less agglomerated in great number in eczema, here they are distinct, &c.—then the disease is the itch.

There is little difficulty in diagnosticating, on the first appearance of cutaneous eruptions; but this is not the case when the primitive elementary lesion is masked by consecutive alterations; and even the itch, which is usually easily known, may be so modified in appearance by the action of the nails, that it is rendered very ob-

scure, and by no means readily determined until we refer to its particular history, when we can speedily discern the real nature of the disease. We must study the primitive and consecutive appearances of any cutaneous disease; and these will be found in the history of each malady. Thus the fluid of a vesicle may become thick and form a small scale, a pustule forms a scab or crust, and this may leave an ulceration; so that it is important to know the particular characters of the consecutive phenomena, and more particularly to what elementary lesions they correspond.

To form a correct diagnosis it will be necessary to decide on the nature of the consecutive lesion, and to what primary disease it belongs. Before we can arrive at a correct conclusion it must be manifest that we should be well acquainted with the primary and consecutive appearances of each disease, so that however complicated we may recognize them. The characters are sometimes so slight that the diagnosis is extremely difficult. We can always distinguish the febrile from the non-febrile, and generally the different forms of eruption. There are cases, however, which puzzle the ablest observers. Certain eruptions pass from their primitive forms very rapidly; and it is therefore most important to study them in their first appearance, which may be done by referring to any standard work upon the subject.

The treatment of cutaneous diseases is still too empirical. This was to be fairly expected from the inattention paid to dermophysiology and pathology. Here we cannot say "a knowledge of the disease is half the cure." The nature and causes of cutaneous diseases being little understood, it is clear to any medical practitioner that the treatment must too often be empirical and erroneous. Tonics, sulphurous preparations, mercury, antimony, sarsaparilla, Plummer's pill, &c., were the great remedies. But it often happened that these were either ineffectual or useless. The treatment must vary according as the disease is acute, or chronic, or febrile, or not. It must be local or general, that is, it embraces internal and external applications. Some cutaneous diseases are cured by internal remedies, and others only by external applications.

Among the general means are blood-letting, which may be effectual in abating fever and internal inflammation, while leeching may be necessary to fulfil the same indication, or to relieve inflamma-

tion about the eruption. Venesection is also beneficial in plethoric habits before the local treatment is commenced.

Purgatives are also valuable, and after some time they may be given in small doses, as if to act as alteratives.

Acids, alkalies, bitters, sudorifics, as antimony, sulphur, guaiacum, &c., are often employed with advantage.

In obstinate cases, which have defied all ordinary means for months or years, we find tincture of lytta and arsenic the most effectual remedies, but they must be administered with caution. When used with care they effect a cure of the most obstinate cases, and without producing any bad effects upon the constitution. They are freely exhibited at the hospital St. Louis with the best effects, and patients have returned, after the lapse of years, whose constitutions are by no means impaired. Nevertheless a free and long use of arsenic undermines the health and acts as a slow and certain poison, a fact attested by every toxicologist and medical jurist. The preparations of iodine are also valuable remedies, as well as sarsa, guaiacum, &c.

The local treatment consists in determining a vivid excitation in the affected parts, and among the various ointments employed those composed of iodine, mercury, and sulphur are the best.

In other cases the direct application of blisters to the diseased surface, to modify or change the vitality of the part, will be found beneficial.

In some diseases it becomes essential to alter the state of the affected part, or to limit the ravages of a disease which tends to destruction; and this is best accomplished by the arsenical paste, the nitric acid of mercury, the chloride of zinc, &c.

Among the local means various baths are most efficacious, and as many as 150,000 are used annually at the hospital St. Louis. These included local, general, vapour, douche, and all kinds of baths in use. These are given to the poor, who apply at the dispensary of the hospital, and the annual number of applicants of this class is 25,000 persons.

EXANTHEMATA.

The term exanthemata is derived from *ἐξανθῆμα*, *ἐξανθίω*, effloresco, and applied to acute inflammation of the skin, characterised by more or less redness, which instantaneously disappears under the pressure of the finger, and is usually accompanied by febrile symptoms.

Erythema, erysipelas, roseola, rubeola, scarlatina, and urticaria present these characters.

Symptoms. All the points of the surface of the skin may be affected, but some exanthemata develop themselves more frequently on the whole body at once, whilst others are limited to a greater or less extent. The special seat of the diseases is in the superficial layers of the derm or skin, and sometimes the whole tissue is involved in the inflammation.

The progress of the exanthemata is generally acute and continued, with the exception that sometimes urticaria, erythema, and even erysipelas, are chronic and intermittent. Their duration varies from one to three weeks. Urticaria may, however, persist for months or even years.

Irregular shiverings, spontaneous lassitude, a fever more or less intense, thirst, and nausea, are the usual precursors of this class of diseases; but each exanthema presents peculiar symptoms. Thus the redness is more or less diffused or circumscribed, irregular, or assuming a certain form. Redness, heat, tumefaction, and pain accompany erysipelas, whilst urticaria is remarkable for vivid itching. In the progress of the exanthemata it is often complicated with inflammation of some internal organ, and especially of the brain, and the pulmonary and gastro-intestinal mucous membranes. The fatal termination of these diseases almost always depends upon these complications.

Resolution, desquamation, and delitescence are the most common terminations of these diseases, but they may end in death. Suppuration and gangrene are sometimes consequent on erysipelas.

Necropsy.—The examination of the bodies of those who die of exanthemata often give very unsatisfactory results—a sanguine congestion more or less intense in different organs is the lesion most frequently observed, and sometimes we find evident traces of inflammation.

Causes.—Measles and scarlatina are developed by a contagious principle, the nature of which is entirely unknown, and which seldom attacks the same individual more than once. The causes of the other diseases of this class may be direct, but they depend, in general, on a particular disposition of the economy, very difficult to appreciate. Without affecting in any way their reciprocal influence, they constantly co-exist with inflammations of internal organs. Erythema was epidemic in Paris in 1829.

Diagnosis.—The distinctive character

assigned to exanthemata prevents them from being confounded with any other cutaneous affection, and enables us to distinguish them from purpura and ecchymosis, in which the pressure of the finger never obliterates the coloration. The red tint which characterises exanthemata does not exist in the negro, in whose case the black tint is most intense.

Various papulous, vesicular, and bulbous eruptions may be confounded with the exanthemata, and the frequency of these complications with erysipelas led Willan to place this last disease among the bullæ.

Prognosis.—The prognosis varies according to the seat and extent of the inflammation, the age and constitution of the patient, and according to the severity of the concomitant disease.

Treatment.—The treatment of exanthematous inflammation ought to be antiphlogistic, more especially when any internal organ is congested or inflamed. We should not hesitate to have recourse to sanguine emissions, both general and local, in proportion to the intensity of the disease.

The convalescence of some of the exanthemata is often tedious, and may be complicated with other diseases, as hooping cough, chronic cough, anasarca, chronic diarrhœa, &c., which will require proper treatment long after the disappearance of the cutaneous inflammation.

LECTURES ON SURGERY

By JOHN HUNTER, F.R.S.

Diseases peculiar to Ages.

Particular ages have their particular diseases. These diseases peculiar to age are perhaps more of the specific than of the common kind; and age is little more than a natural or remote cause, there being some immediate cause acting so as to produce the disease, as in scrofula. But this is not the case with all of them, e. g. cancer, for this appears often to arise without any peculiar immediate cause. How far particular ages are more or less susceptible of particular poisons we do not know.

The age of man is divided into three parts: 1st, The age of growth; 2nd, The stationary age; 3rd, The age of decline. The first and last are absolute, but the second is not so easily ascertained, it not

being very easy to say where the first ends and the last begins. The young subject and old are more susceptible of many diseases than the full-grown, or stationary, but they are not subject to the same diseases. The young are more susceptible of sympathy, both universal and local; more susceptible of scrofula than the middle-aged, but particularly more than the old; and this scrofula may produce consumption, which we know is peculiar to youth. Children are more disposed to have affections of the bowels, and worms, perhaps, from a peculiarity in their way of life. They are also more subject to water in the head than those who are older. The young have few affections of the mind, excepting those arising from natural passions, or immediate sensations of the body.

The middle age would appear to have but few diseases peculiar to it, excepting nervous affections and hypochondriasis, &c. The middle age gets into an imaginary region, a region of romance, which produces diseases of the mind, and also affects the body. However, it is, as it were, accidentally affected with the diseases both of youth and age, with which it is gradually intermixed. The foundations for the diseases of old age are often laid by intemperance during the middle age.

In the old we have perhaps as great a variety of diseases as in the young. In the old the power and necessary action are not well proportioned, even in health, much less, therefore, in disease. This produces a degree of irritability often increasing inflammation, and terminating frequently in mortification. In the old we have the gout, which seldom takes places in the young. Cancer is peculiar to the latter part of the middle age, and still more to the old. Gall-stones are to be found chiefly in the middle-aged and old. Ossifications of arteries are rarely found in young persons. The bladder becomes less disposed to stretch, and more irritable; hence old people make water oftener than young. The prostate gland is more subject to indurations. The mind gradually becomes more attached to [Quære, *detached* from?] this world and the things that are in it the nearer it approaches to a separation from it.

Effects of Climate on Disease.

Climate in general only becomes the immediate cause of disease; however, it is sometimes sufficient to produce the

whole disease. Climates are of three kinds; hot, cold, and temperate. Hot climates carry on the natural operations both of animals and vegetables with much more rapidity than either of the others.

It is almost impossible to rear young animals in cold weather; therefore most animals bring forth their young in spring and summer. Animals of the same species do not grow to the same size in cold climates as in warm. It is almost impossible to fatten an animal while it is kept in the cold.

Warmth produces action beyond its power of generating strength.

Parts more readily yield to any power in summer than in winter. Mr. Jones, the inventor of the machine for correcting distorted spines, observes that they produce more effect in summer than in winter.

Hot climates produce diseases in the liver, but these diseases are more frequent in the West Indian islands than on the continent of South America or India. They also produce violent vomitings and other disorders in the stomach; also violent affections of the bowels: and fevers and diseased actions, like the natural, are much more rapid than in temperate climates, it being no unusual circumstance for diseases to run through all their stages in a few hours, ending in death, which is speedily followed by putrefaction. Heat produces indolence in the voluntary actions, which is injurious to health, but generally increases the involuntary action or actions of life, which is always hurtful. Cold climates retard many actions, both of vegetables and animals; but cold, when only in a certain degree, and continued for a certain length of time, excites action; but that is the action of strength, the action of resistance or defence, not the action of luxury or ease. Cold climates produce their diseases, though it would appear that they have not equal effects with warm, nor are capable of producing such variety. Whatever diseases are produced by cold are not so rapid as those produced by heat; and after death putrefaction does not take place so rapidly. We may observe a curious gradation in this process: in cold climates, after visible death, absolute life will remain for some time; the muscles will retain their power of contraction, and the blood be kept from coagulating. But in hot climates death is as rapid as disease; for it is action that consumes life. In cold the action is less; in heat it is so great that the body can hardly support it, and

death comes on. Cold climates lead to voluntary actions, which generate heat, and this is much more healthful than heat derived from external sources.

In temperate climates there is perhaps a greater variety of diseases than in either the hot or the cold; for the temperate is a very irregular medium, sometimes very hot, sometimes very cold, and often in the middle state; and these changes are not at regular periods. This irregularity produces some irregularity in the wetness or dryness, so that in such climates we have a great mixture. These changes in temperate climates give rise to scrofula, colds, &c., which are the forerunners of a thousand diseases. Agues are also much more frequent in temperate climates.

Seasons.—Seasons which arise from the variations of heat in a climate, produce diseases which will be in some degree similar to those both of hot and cold, and also temperate climates; for seasons are, as it were, a change from one climate to another. Seasons have, besides, diseases peculiar to themselves; they produce an increase of old diseases, arising simply from the change, and call forth those diseases which only want an immediate cause to produce them. The spring and autumn are two of the most unhealthy seasons of the year; the spring the most so, although from reasoning alone, without observation, it is supposed to be the most healthy, and therefore people do in the spring whatever will allow of a choice of time, as inoculating, &c. This idea probably took its rise from observing vegetation, that at this time the plants appear to come into life and action. But, even in vegetables, this season is the most unhealthy: blights much more frequently take place in spring than in summer. Of every disease that can be called constitutional, that is, where there is a strong susceptibility for such disease, we find spring becomes the immediate cause, exciting it to action; thus, scrofula shows itself or increases in spring; the same with rheumatism and scurvy; hence spring is said to set the humours afloat by those who are favourers of the humoral pathology.

I should doubt much whether there is any diurnal influence on our body, further than that which the habitual modes of acting produces; consequently, I doubt if daylight or darkness produces any effect. It is, however, certain that the increase of action which commonly takes place in the day, increases diseased action, producing exacerbations in continuous diseases. It

is probable, therefore, that it may bring on the paroxysms of those diseases which are periodical, and may bring on the first fit of a disease for the same reason.

Effects of the Moon.—The moon has certainly considerable effects on the human body. We find it often become the immediate cause of diseased actions, especially those of the mind. Mad people are certainly more affected at particular periods of the moon than at other times. The full of the moon has the greatest effect; it not only affects those who have a natural predisposition, but also some who have had injuries done to the brain by external violence.

A lamplighter, by a fall, injured his head; upon examination I found a fracture, which appeared to run through the foramen magnum of his occiput; he recovered, but he was seized every spring with a phrenzy at stated intervals, and this was found to be at the full of the moon.

A gentleman had ankylosed knee and ankle-joint from scrofula, and he is always deaf at the full of the moon, except in autumn, when his sores discharge plentifully.

This effect of the moon is increased at certain seasons; in spring it is often greatest. Intermitting and remitting fevers often arise, recur, or become exasperated about the time of the full or new moon, more especially in climates fitted for giving rise to such diseases.

Of Humours.

The term humour has been applied to the animal body, especially the human, both literally and metaphorically. When literally, it is used in two senses, either as expressive of an extraneous substance existing in the blood, or as meaning the blood itself. When used metaphorically it is applied only to the mind, and is therefore more applicable to the human than any other animal.

Nothing can be more vague, nothing more unphilosophical, nothing more misleading in science, than to employ the same term to express two or more different meanings. In whatever sense the term is used, however, whether as applied to the mind or the body, it always is meant to express the cause of an unnatural or uncommon action or effect.

At present we shall only consider humours in their literal sense, in order to ascertain how far the notion is just or imaginary. I have just said that the word is used in two senses, either as

something in the blood, but foreign to it, or else as implying a vitiation, of the whole mass of the blood itself. Among physical people we find such expressions in common use as "the humours are afloat in the blood;" "sharp humours in the blood;" "the whole humours being in a bad state;" "the whole blood must be altered or corrected;" and a variety of such expressions without meaning. They even go so far as to have hereditary humours, as gout, scrofula, &c., and make us the parents of our own humours, saying that we breed bad humours. Accidents, or even the application of poultices, have been supposed to bring bad humours to a part, because the part in which the accident happened, or to which the poultice was applied, would not readily heal. Humours are even supposed to gravitate to the legs slowly; and, in short, the whole theory of disease has been built upon the supposition of humours in the blood, or of the blood itself being changed. I cannot conceive what is meant, unless it be that a strong susceptibility to a specific disease exists; as smallpox may bring on scrofula, or a strain the gout: if in these cases by humour is meant a susceptibility of either of the diseases, I can conceive that any kind of accident may bring it on. The smallpox introduced may excite action, and so bring on the scrofula.

I shall now consider the notion of humours afloat in the blood. If I have a just idea of the meaning of this expression, it signifies something extraneous or foreign, something that does not belong to the blood itself. That foreign matter is received into the blood-vessels is certain, and that so received it produces disease also certain; but simply foreign matter being introduced into the blood, either produces no effect or no permanent and specific disease: the constitution, or some part, can be disturbed only as the constitution or part would be disturbed from any accident. Medicines applied either externally or internally, is a proof of this, for all enter the circulation more or less, therefore are in the state of something extraneous, or of humours in the blood. Indeed, chemical analysis of the blood shows the existence of foreign matter, for it discovers substances that form no part of the animal, as sea-salt, iron, earths, &c.; yet these substances produce no ill effects by their presence.

The following experiments show the effects of foreign substances in the blood.

Experiment 1.—I injected into the

crural vein of a dog, towards the heart, a weak solution of sea-salt, which produced no effect. I then made as strong a one as possible and threw that in also, but no effect was produced. The quantity of salt thrown in might be about two teaspoonfuls.

Experiment 2.—I threw a strong solution of Glauber's salts into the vein of a dog,—about two drachms of salt. It produced no effect. The dog ate and drank and had his stools as before.

Experiment 3.—Two ounces of saturated solution of salt of tartar, thrown into the vein of a dog, had no effect.

Experiments 4, 5.—Two drachms of sal polychrest in solution produced no effect.

Experiment 6.—An ounce of water, in which a scruple of borax was dissolved, was thrown into the veins without effect.

Experiment 7.—An ounce of vinegar and water, in equal proportions, was thrown into the veins of a bitch half gone with pup. This brought on an immediate disposition for miscarriage, which took place in about six or eight hours.

Experiment 8.—Water, rendered about as acid as the vinegar and water, with vitriolic acid, was thrown into the veins, and produced little or no effect.

Experiments 9 and 10.—The same experiment was made with nitric and muriatic acids with the same result.

From the above experiments it is evident that substances of considerable power may exist in the blood and produce little or no effects of any kind. We shall find, from other experiments, that there are many substances which have considerable effects when thrown into the blood; still, none of them produce any particular disease, though by repeating them, and increasing the quantities, a man may destroy his health, or even his life, by destroying the natural actions of the body.

But all this is not producing any specific disease; it is reducible to the effects of local applications, which is similar to any accident, producing no specific or permanent disease but what an accident would do, nor lasting any longer than the application lasted.

Experiment 11.—I threw about two teaspoonfuls of a strong solution of opium, two parts water with one of opium, into the crural vein of a dog. The dog seemed to be very sensible of it at first, for he was extremely uneasy, and soon became convulsed, but did not lose sensation, for when touched he started and seemed frightened, and drew back his face when

a hand was presented to it; so that irritability was rather increased. I then threw in as much more, which made him still more quiet, and in great measure produced loss of the use of his limbs, so that he could not stand; his breathing became slow and labourious, but his pulse very quick; when he attempted to get up he reeled, and came down as if asleep or drunk.

Experiment 12.—I threw into the veins of a dog two teaspoonfuls of common gin. He showed no sense of uneasiness, but became soon vastly quiet, and not in the least irritable, showing no signs of fear when touched. He seemed wholly relaxed; his breathing was easy, and his pulse slow. He continued above an hour in this way and then began to recover.

Experiment 13.—I threw about two teaspoonfuls of laurel water into the veins of a dog. The pulsation in the vessels became tremulous; he seemed very ill, and could hardly raise his head, but he recovered.

From these last experiments it appears obvious that many substances, having peculiar modes of stimulus, will, when taken into the blood, produce their effects there; but this effect will last no longer than the presence of the stimulus; and we shall find in general that their effects in this way are similar to what they are when taken into the stomach. We find, also, by the above experiments, that many substances thrown into the constitution by the veins, produce the same local specific effects on the intestines with those produced by the substance when taken by the mouth.

Experiment 14.—I threw into the veins of a dog an ounce of infusion of ipecacuan, made with five grains of the powder to two ounces of water. The dog immediately became very sick, and was retching before I could untie the mouth, and as soon as it was untied he threw up all that was in his stomach. He continued sick for some time, and gradually recovered. I can hardly suppose that the injection had gone beyond the heart, or even to it, when it began to act.

Experiment 15.—An ounce of infusion of jalap, made with twenty grains of jalap to two ounces of water, and steeped for twelve hours, was thrown into the veins of a dog. In less than a minute he vomited a little and then seemed well. Thinking that no more effect would be produced, I threw in the remaining ounce. This did not produce any vomiting, nor did he at first seem much affected; but

at last he grew weak on his legs, lay down at times, and then rose again. About two hours after the infusion was thrown in he had a stool, and after this another, which was loose. He remained sensible the whole time, and then got well.

Experiment 16.—In a similar experiment the dog vomited, had some loose stools, and in a few hours got well.

Although many substances do produce similar effects on the stomach and intestines when thrown into the blood as when taken by the mouth, as appears from the above experiment, yet this is not the case with all. In the second experiment, for instance, we find that Glauber's salt had no such effect when thrown into the blood as when taken in the stomach. In like manner,

Experiment 17.—An infusion of rhubarb, thrown into the veins of a dog, produced no effect but that of increasing the urine, which it did plentifully.

Many substances thrown into the blood produce much more violent effects in this way than when taken into the stomach, and even cause immediate death.

Experiment 18.—I threw into the veins of a dog, a little æther, and he died immediately. On opening the body the thorax had a strong smell of æther. However, this effect may depend on the strength of the medicine, as we shall see by the following experiments, that the reason why death did not take place in experiments 6, 7, 8, 9, was the weakness of the solution.

Experiment 19.—I threw some common vinegar into the veins of a dog towards the heart. He died before I supposed it could have got to the heart. Now vinegar, when diluted, as we found before, had no such sudden effect. In the same manner, nitrous and vitriolic acid, diluted to about the strength of vinegar, produced almost immediate death.

Air killed immediately. We should therefore be very careful in making experiments, when we inject substances into the veins, that air does not enter with the substances, and cause the death which we impute to the latter. The Abbé Fontana committed many errors in this way: in short, before any man pretends to determine what will kill, he ought to have killed at least a thousand animals. A poor devil was lately hanged at Warwick upon no other testimony than that of physical men whose first experiments were made on this occasion.

Experiment 20.—I threw into the veins of a bitch half gone with pup a quantity of serum, taken from the blister of a person who was ill of a putrid fever, and soon after died. It made her instantaneously sick, and she vomited. She soon miscarried, but in two or three days recovered perfectly.

From all these experiments we may, I think, at least draw, as a probable conclusion, that extraneous matters taken into the constitution do not produce any specific or permanent disease, that they operate as direct stimuli, producing immediate effects, and that when these are violent they arise from too great a quantity of the stimulating or irritating substance being thrown in.

SKETCH OF THE PRESENT STATE OF MEDICINE, AND OF MEDICAL INSTITUTIONS, IN RUSSIA.

By GEORGE LEFEVRE, M.D., late Physician to the British Embassy at St. Petersburg, &c.

OF THE MEDICAL PROFESSION AND MEDICAL INSTITUTIONS IN RUSSIA.

1. Classification of the Medical Profession.

It is now generally allowed that there is no essential distinction between medicine and surgery, although practitioners of medicine may be divided into different ranks and classes. Perhaps there is no country where this indivisibility, as regards the practice of the profession, is more strictly maintained than in Russia. The division of medical labour, which in former times simplified the duties of the respective practitioners in England, has never been adopted in Russia, where a physician embraces all the branches of the healing art, and acts as physician, surgeon, and accoucheur. If he do not practise his profession so generally as here stated, there is nothing to prevent him from using his own discretion in such matters. The physician in Russia is, in fact, identical with the general practitioner in England, save and except that in no instance does he dispense his own medicines. I employ the term general practitioner, because in reality the apothecary, at least in the English acceptation of the word, does not exist in Russia. Persons bearing this designation are mere venders

of drugs and licensed preparers of physician's prescriptions; they are not supposed to be acquainted with more than the nocuous and innocuous properties of the drugs in their rough state. In no case are they allowed to compound medicines, or even sell the most innocent drug, without a written order from a medical practitioner. Their shop, or *apteka*, is no laboratory; for they are not wholesale chemists and druggists, but mere makers-up of prescriptions.

Many of the English physicians in Russia formerly persisted in adhering to the customs of their mother-country, as to the division of labour in the profession. In some instances, however, even the most orthodox have waived this point of etiquette. Dr. Dimsdale tried the experiment of inoculating the Empress Catherine for the small-pox; which same operation Dr. Halliday performed on all the Emperor Paul's children, though unquestionably this task appertained to the province of surgeon.

This combination of medical duties is not now a matter of choice, it is one of necessity, inasmuch as the interests of the mass of the community are to be considered of more importance than the ideas which a few individuals may form to themselves of medical orthodoxy; and in the present day all the English physicians residing in Russia are, as already stated, *de facto*, general practitioners.

Although in a practical sense, then, there is little difference in the duties performed by the different practitioners, of whatever rank they may be, still the superiority of rank is, in point of etiquette, most rigidly enforced in all cases where form is allowed to exercise its prerogative. There are several classes of practitioners, but the deference paid to each is not in a ratio with their medical, so much as their military or civil ranks. The degrees conferred by the universities are the following:—Physician; Surgeon in chief; Surgeon in ordinary; Staff Surgeon; Surgeon's mate; Hospital mate; Barber surgeon; Apothecary.

In general practice there is no positive distinction in the labours allotted to the three first ranks. The physicians and the surgeons, in most cases, practise indiscriminately in all branches of the profession. If they hold official situations in the military or civil service, then the difference of rank becomes immediately sensible. The physician receives homage from the surgeons, takes precedence as he passes through the wards of the hospital,

signs documents, and makes valid his rank by several operations. The hospital mates, dressed in military uniform, march up and down the wards, halt, face about, and stand attention, as their superiors command them; for all society in Russia is divided into ranks and classes, and medical men are included in this category. Schlätzer informs us that, in 1781, "a physician ranked with a major in the army, and, as such, could drive four horses to his carriage, while those of inferior rank could drive only two. An apothecary at court had the rank of captain, and his apprentices the rank of ensigns. The surgeons of the district had the rank of lieutenants." In the present day physicians are ranked with the eighth class of the nobility, and surgeons in the seventh.

There are few instances, perhaps, where any practical use or abuse of such a division can be allowed to operate, but in some cases the possibility may exist. It is almost a law of the realm that no individual holding superior rank, whether civil or military, can be in the wrong in case of dispute with an inferior; and the spirit of this law is not without its influence in medical concerns. The superiority here alluded to is the honorary rank conferred by the crown, and not the medical one granted by the universities. Two physicians, of equal standing in medical honours, may be widely separated in civil or military rank; and he who bears no insignia of the order of St. Anne or St. Vladimir must give way in consultation to him whose breast is adorned with stars or crosses.

The physician, when called to the service of the imperial person, the *Leibmedicus*, or body physician, takes precedence of all his brethren, and his opinion must prevail in all cases where there is any official duty concerned. In the former part of this sketch it was mentioned that one of the Czars, suspecting that the illness of an illustrious individual was rather to be construed into a disinclination to appear at court, sent his body physician to ascertain the fact. Very similar proceedings take place in the present day. Patients, attended by ordinary physicians, are occasionally visited by body physicians, in order that they may enjoy every possible medical advantage, and this frequently without their request.

The hospital mates and surgeon's mates are completely under military control; although attached to civil institutions. They are subjected to punishments of

various kinds, for any impropriety of conduct.

The apothecaries, as before observed, are not to be considered as the same class of men who are so denominated in England. They are mere venders of drugs and preparers of recipes, and their shops are all licensed by government.

The first court *Apteka* was founded by an Englishman of the name of Frenshman, who arrived in Russia in 1581. He is reported to have brought with him an immense quantity of drugs; but it was some time before the natives understood the necessity of having recourse to medicine. The high price at which drugs continue to be sold in Russia would almost be proof sufficient that the *aptekas* were established by one of our countrymen; for, if apothecary's gain be synonymous with exorbitant charge in England, it is equally so in Russia. There is no country in which medicines are so highly charged; indeed, the price is almost double what it is in England. The apothecary's charge in Great Britain is not supposed to be in relation to the cost of the material; the value of his prescription is embodied in his draught, and is the means of his remuneration for his time and talents. The matter is very different in Russia, where the apothecary is the compounder only, and should be satisfied with a fair profit upon the material, as the prescription has already been paid for; whereas, the prices he pleases to put upon it allows of no consideration on his part. It is true that there is a tariff for the price of medicines, to which he is compelled to adhere; but this is excessively high, and not regulated by the current prices of the drugs imported into the empire. The proprietors of these *aptekas* are almost all Germans.

The regulations which were promulgated by the court physician, Dr. Blumentrost, in the time of Peter the Great, have, with very slight alterations, been handed down to the present time, and many of these are very excellent in their kind. To prevent mistakes arising from an imperfect knowledge of the Latin language, it was ordered that all prescriptions should be translated into Russian, and deposited in the chancery. The name of the physician and of the patient, together with the date of the day and month, were also registered in a book. The necessity of translating the prescription is now abandoned, but all the recipes are deposited in a drawer, and are not allowed to be given back; notwithstanding that each

is copied into a day-book, which is subjected to the inspection of proper authorities, who pay regular visits to the *aptekas* for the purpose of examining into the nature of the recipes. Not only are the original prescriptions not allowed to be returned, but a repetition of the same medicine cannot be procured without the physician's signature. A copy only is permitted to be issued from the *apteka*. From the same conservative principles, wholesale dealers in drugs are not allowed to sell them in small quantities. No medicine is allowed to be dispensed without being sealed with the private seal of the owner of the *apteka*, or with the seal of his establishment; for each shop is licensed under some specific name, generally taken from the name of the street in which it is situated; and the number of these is limited. This limitation in the number dates also from a remote period, and proceeded from good intentions; for it was asserted that the number of *aptekas* should be in a ratio with the demand for the medicines, and that, on the one hand, there should be a sufficient competition to prevent the public from being overcharged, and, on the other, not so great a supply as to allow the drugs to remain too long on hand, and be spoiled by age.

It is difficult to legislate in such matters; but the practitioner in Petersburg will find the advantage of sending his prescriptions to the *aptekas* which are in vogue, for the same recipe prepared in a frequented shop, or in one not much frequented, may show two very different things.

If poisons are prescribed in any dangerous quantity, the physician is compelled to sign his name in the *poison-book*, and state for what purpose he has prescribed the poison.

When these establishments were first instituted, they were all under the direction of an officer of state, who was styled the *Apteka Bojar*. They are now under the superintendence of a Chancery (*Physicant*), which is a court of appeal and punishment. If a physician can prove that any mistake has been committed in the preparation of his recipe, or that the drugs are of good quality, it is the apothecary who suffers. If he can prove that the physician has made a mistake in the writing of the prescription, the apothecary is at least absolved, unless he magnanimously consent to take the blame upon himself. If the shop-boys are in fault, they are subjected to corporal castigation.

The last class is the *Tsirlunik*, or bar-

ber-surgeon, and is a numerous and thriving brotherhood. It falls to their lot to bleed, cup, draw teeth, apply leeches, and perform other little jobs of minor consequence. They are well paid for their trouble: five roubles, or 3s. 6d., is the common fee for their operation, and they are in great request.

There are no distinct aurists; aural surgery forming part of the practice of the ordinary surgeons. There are likewise but few oculists who devote their whole time to the diseases of the eye. Many physicians and surgeons include the treatment of these diseases in their general practice.

Dentists abound in every street, and their profession is perfectly distinct, and not within the pale of the medical faculty. There are no distinct chiropodists in Russia.

II. *Remuneration of the Medical Profession*

This subject allows of several divisions, viz., the pay of medical officers serving under government, either in the army or navy, in civil institutions, and in the universities, and the remuneration of private practitioners.

In regard to the remuneration of the private practitioners, it may be summed up in a few words,—it is almost optional with the patient. He pays in a ratio with his means, with his liberality, or with the estimation in which his attending physician is held by the court or by the public. In this respect custom has not fixed any regular fee; but the law obliges a medical man to attend any patient who demands his services, for which the practitioner can claim a fee of five rubies (3s. 6d.) per visit. This is an extreme law, which however has, within my knowledge, lately been enforced. In most instances, private attendance is paid for at the termination of the case. The payment is often in the shape of presents, as snuff-boxes, diamond rings, and plate of various kinds. It is by many considered not quite delicate to offer a physician money, though few would consider themselves aggrieved by this species of remuneration.

The more common mode of procedure is the following:—A nobleman's family is committed to the care of a physician, who receives annually about 50*l.* for his attendance upon the superior members; while the servants, and the whole of the domestic department, are committed to a practitioner of less eminence, who is

styled *house doctor*, and receives about a fourth of this sum. It is incumbent upon them both to be at the daily call of the persons committed to their care, and, as the fee is the same for attendance under all circumstances, they are generally well employed in their respective vocations. In cases of severe illness, (if any of the nobles are in such predicament,) the opinion of those whose constant attendance should warrant the conclusion that they are conversant with the constitutions of their patients is little attended to. Consultation is crowded upon consultation, and the family physician is merely a spectator in the scene. To these consultations, however, he will not much object, for the responsibility will be thereby divided. The consulting physician is paid at the rate of a guinea or upwards per visit, by those at least who are in affluent circumstances. But there is all possible gradations as regards the scale of remuneration; generally speaking, however, the revenues of the first physicians in Russia are much lower than those of the same class in England.

Of all classes of the profession accoucheurs are the most liberally remunerated, and they enjoy an advantage over all their colleagues, viz., that, by a species of habit, almost equal to law, they receive their fee when the patient leaves her chamber. Fifty pounds is the usual remuneration with the higher classes for an attendance which is in most cases nominal; for the accoucheur is in an adjoining room, and is never required to attend except in cases of danger or difficulty. All the attendance is intrusted to midwives, when none is in reality required. This fee also admits of great fluctuation, but an accoucheur of standing and reputation will not receive less than 10*l.* under most circumstances.

When midwives are employed it is usual for them to receive from 2*l.* to 5*l.* for their attendance, even from the mercantile classes, and much more from the nobility. The system adopted is frequently unfair to the regular medical attendant. He is often requested to be within call, but unless there is danger, and the midwife demands his assistance, he receives no remuneration for the loss of his time or sleep. If he be called to the bedside then he is entitled to the full fee; but this places him in the situation of being responsible for all the bad cases, and deprives him of the counterbalancing advantages of all the ordinary ones. Among the middle classes of society these

attendances are stipulated for in the annual salary, which seldom exceeds 14*l.* sterling.

As regards surgical operations, I have no information which I can venture to give as authentic upon this subject. All those of a minor order are not paid for separately from the annual stipend. I am inclined to believe that such operations as lithotomy, amputation, &c., when successfully performed, would be requited with a liberal hand by the higher classes.

The pay of medical men in government employ, whether civil or military, is upon too low a scale to ensure to the individuals even the necessaries of life. In the hospital establishments the head physician receives only Ro. 1500, or about 65*l.* sterling per annum, with lodgings upon the premises, and the usual perquisites of fuel and candles. Such remuneration can ill requite the time which he is obliged to devote to his duties; and were it not that, in general, a hospital physician has private practice, is attached to the court, and probably is a professor in the university, such pay would not entitle him to any respect or consideration. The visiting physicians, who act under his directions, have not the advantages which he enjoys of gratuitous lodgings, nor of the other perquisites; and they receive Ro. 800, or about half the sum of the superior. The service which they perform for this salary is a great demand upon their time.

The hospital mates (Felschers) receive nothing worthy of note; they are lodged and boarded in the hospitals.

With respect to the manner in which professional services in the universities are remunerated, some new regulations have just been issued. The salaries of all the professors are derived entirely from the crown; the students contributing nothing to the maintenance of the teachers. Their education is wholly at the expense of government.

The professors enjoy the privilege of importing, free of custom-house dues, all foreign pamphlets and journals which are published abroad upon those subjects which they teach in the universities, and all such books are not under the control of the censorship.

It is difficult to ascertain precisely what is the value of situations about court in the present day. There are many perquisites attached to such situations, and their value can never be ascertained. The physicians in immediate attendance upon the imperial family are supposed to

receive from ten to twelve thousand roubles per annum (500*l.*)

The pay of the medical military staff is the same with that of the hospital civil staff, and varies, according to rank, from 600 to 1,500 roubles per annum. This pay is quadrupled in active service, when out of the country.

There is a distinct class of court physicians. They perform active services alternately, and are obliged to remain the whole twenty-four hours in the palace. Each of these is called upon to serve about every fifth day. They receive 1,200 roubles (50 guineas) per annum as salary. They have no other duty than that which accident and emergency procure them, and are upon the spot to attend until other physician arrive.—*British and Foreign Medical Review.*

BIOGRAPHICAL SKETCH OF THE LATE BARON DUPUYTREN.

The life of such a man as Dupuytren ought to be well known to every young candidate for professional fame, as affording an admirable example of what energy, perseverance, and ability will do. He was born of very humble parents, in the year 1772.

At the early age of twelve years, he was induced by an officer of a regiment which was quartered in his native village, to go to Paris. Here he became acquainted with the late M. Alard; and the two young fellow-labourers commenced and prosecuted their studies with the most devoted and unwearied zeal. They had but one paltry room between them; and this served for a sleeping, as well as an eating apartment. All the furniture they had, was a table, a couple of chairs, and one bed; and their cupboard was often but very scantily provided, even with the necessaries of life. Dupuytren used to take great pleasure in his after-life, when in the zenith of his fame and success, to talk of the "res angusta domi," and various hard-ships which he had to submit to at the commencement of his career. He used to mention an anecdote of his being visited by the visionary enthusiast, Saint Simon, who had early perceived the vigorous talents of the medical student, and was anxious to make him a convert to his doctrines. After a long but ineffectual conversation, the *Saint* rose to take his leave; and, while Dupuytren's

attention was withdrawn to another part, he took the opportunity of putting down a purse, containing 200 francs, in a corner of the apartment.

The proud spirit of the youth refused all such assistance, although he afterwards confessed that, at this time, his pecuniary means were scarcely sufficient to procure him the ordinary comforts of life.

It was in 1794, when he was only seventeen years of age, that he first had an opportunity of giving proofs of ability, and an earnest of his future fame. At a public concours, he was appointed one of the "prosecteurs," or anatomical demonstrators at the Ecole de Medicine, then recently established by government. During the next five years he laboured most assiduously in the dissecting-room, and thus laid the foundation of that intimate knowledge of minute anatomy, which, perhaps, more than any other acquirement, served to render him, like Baillie, one of the greatest masters of diagnosis in disease. In 1801, he publicly contested with Dumeril for the place of "chef des travaux anatomiques," but lost it by only one vote. Six months afterwards, however, he was elected in the place of Dumeril, who had been raised to a professorship. He now commenced to lecture upon anatomy, physiology, and pathology. In 1802, Bichat, still in the flower of his age, died; and thus the field was left almost undisputed to Dupuytren, who had been educated in the same school, and had followed out the same method of investigation, as his immortal predecessor had done. In 1803, he was elected "chirurgien de seconde classe," to the Hotel Dieu, the largest hospital in Paris. His rivals on this occasion were Roux, Tartra, and Hederloffer. In 1808, he was made "chirurgien en chef adjoint," and three years afterwards Sabatier, the senior surgeon, having died, Dupuytren was appointed the colleague of Pelletan. At the same time he succeeded to the chair of medicine operatoire, vacant by the death of Sabatier, after a vigorous contest with M. M. Roux, Tartra, and Marjolin. The concours upon this occasion was one of the most animated and protracted, which has been ever known in Paris. For forty days, "les concurrens furent tenus en haleine;" they were required to give in written answers—in Latin as well as in French—to a multitude of questions proposed, to deliver extempore lectures on surgical and anatomical subjects, to perform operations on the dead body in presence of the ex-

aminers, and lastly, to write a thesis on a theme which had been given them.

Dupuytren had very nearly lost the election, in consequence of some delay in completing the thesis! He was generally a very slow composer, and at all times much fitter for the active practical duties of his profession, than for the meditative occupation of the study.

He was now a prominent man in the eyes of the public; surgeon of the Hotel Dieu, and professor of operative surgery at the Ecole de Medicine. Soon after his appointment as one of the chief surgeons to the Hotel Dieu, Pelletan withdrew, in consequence, it was said, of frequent quarrels with his junior colleague. This is not unlikely, as Dupuytren was naturally haughty and ambitious; and all who knew him, were well aware that he never could endure a rival near his throne. While yet a boy, he was fond of repeating Cæsar's saying, "that he would rather be the first man in his own village, than the second in Rome;" and throughout his afterlife, the Napoleon of surgery (as Bouillaud calls him) seems to have always acted on this rather unamiable maxim. The energy, the unceasing assiduity, the devotedness of zeal, and the eminent ability with which he performed the duties of chief surgeon of the Hotel Dieu are above all praise. He spent between four and five hours there daily, visiting and minutely examining his patients, performing operations, superintending dissections, and lecturing. His first visit was usually paid about seven o'clock in the morning, and he seldom failed to return in the evening, to watch the progress of the more interesting cases. Most faithful reports of all these were drawn up by the "internes," and afterwards corrected and arranged by himself. There are at the present time upwards of 700 thick folio volumes of these reports, the cases being all arranged in alphabetical tables, preserved at the Hotel Dieu!

In making his rounds through the hospital, he was generally reserved and taciturn; spoke little, and that little not in the most urbane manner, to the students. In all his actions, and upon all occasions he was the same calm, imperturbable being; ready and prepared for every emergency, never taken by surprise, or moved by any unforeseen danger. "Cette paix, ce calme de l'esprit, ce premier element de tout bonheur, cette divinité de l'épicurisme, Dupuytren le cherchait en tout. Aussi, dans ses leçons, dans ses opérations, rien n'était remis à la fortune;

tout était muri, calculé, approfondi, prévu."

If there were any unusual symptoms in a case, if the diagnosis was obscure and uncertain, he refrained from giving any opinion at first; he hesitated for some days, thinking and reasoning upon it; and when at length he had arrived at some satisfactory conclusions, his clinical lecture on the subject was a model of excellence, full of impressive thought, and stored with the soundest practical wisdom.

Dupuytren was unquestionably one of the most *medical* of all surgeons. It was not the *art* alone, it was the *science* of surgery, which he explored so much more deeply than his contemporaries. Having his mind enriched with the most consummate knowledge of general and descriptive anatomy, and being intimately acquainted with the whole range of physiology and pathology, he took an enlarged view of every case, tracing it back to its source, discovering the cause which had produced it, the effects which the constitution, temperament, or casual circumstances had occasioned, the changes which it had already produced, and the probable event of its progress and termination. Although one of the most accomplished operators of his time, he never sought for occasions to display his dexterity; it was a greater triumph to him to supersede the necessity of an operation, than even to have performed it well. In the use of the knife, he was always cool and calm; bold and rapid when there was no uncertainty or possible chance of mistake, as in performing amputation of the limbs, and the excision of certain tumours; slow, but steadily sure in the more delicate operations of his art.

No casualty ever disturbed his equanimity. On one occasion he had the misfortune to open an aneurismal tumour, supposing it to be an abscess.—Without hesitation and embarrassment, he at once proceeded to tie the artery higher up—the case did well. Every one has heard of the case of sudden death about sixteen years ago, during the excision of a large tumour from the neck of a young woman; the air entered the external jugular vein, and the girl, after uttering a few moans, died on the table. Dupuytren was the operator: "il est jeté dans une méditation profonde; le malheur devient pour lui le texte d'une des plus belles leçons qu'on ait jamais entendues: l'apropos l'inspirait; le sujet avait saisi les esprits; et surmontant ainsi son propre trouble

pour expliquer ce tragique événement, rejette sur les capricieuses lois de la nature ce que la malignité eut imputé à son imprudence." Dupuytren was remarkably adroit at reducing dislocations. No one knew better how to divert the attention of the patient, and thus to take off in part the resistance of the muscles. We shall mention only one case.

A woman was brought into the hospital with dislocation of the shoulder. Several unsuccessful attempts to reduce it had been already made. Dupuytren, when the apparatus was ready, began to question the patient how she had met with the accident, and as she was answering, said, "your son told me you were drunk at the time." "A ces paroles, la mère indignée tombe dans une sorte d'anéantissement, et le bras est remis."

The immense private practice, which Dupuytren enjoyed, increased the sphere of his observation.* He was the "facile princeps" of his time. His reputation was not confined to his own country; it was European. Patients from all parts of the continent came to Paris to consult him.

He was honoured with the confidence of two kings, elevated to the rank of a baron, decorated with various titles of distinction, and courted and caressed by the most lofty and distinguished of his country. "Que manquait-il donc," exclaims his eulogist, "à son bonheur. Mais le bonheur n'est point dans la situation; il est dans le caractère; et Dupuytren n'était pas né pour être heureux. Tout ce qu'il avait souhaité, il l'avait à profusion; et n'y sentait que vide et désespoir."† In 1833, his health suffered a severe shock; and in the following spring he was induced to travel into Italy. At Rome he met with M. Esquirol, who observing the restlessness and impatience

* Besides his private and hospital practice, Dupuytren had ample opportunities of studying gunshot wounds, and the other casualties of military surgery, in 1814, when he was appointed surgeon to his wounded countrymen, after the battle of Montmartre. The "glorious days" of July 1830 also furnished him with a vast field for displaying his consummate surgical abilities.

† We suppose that M. Pariset alludes to the domestic infelicity of Dupuytren. His lady, it appears, left her home;—and from that hour, the haughty spirit of his temper seemed to have taken on all the austerity of a misanthropic melancholy.

of his colleague to return to Paris, asked of him the reason. "Qui vous presse? —Je songe à *Motel Dieu*, repond Dupuytren. Vous l'avez laissé dans d'habiles mains, reprend Esquirol. Oui, replique Dupuytren, mais mon devoir." He soon returned to Paris; but it was only to linger out a few months of suffering. He died in the February following at the age of 57. On dissection, a considerable effusion was found in the cavity of the thorax, and the brain exhibited some traces of "foyers apoplectiques."

The fortune which Dupuytren had amassed was immense; equal perhaps to what had ever been made by professional exertions. It amounted to nearly £250,000. He bequeathed the sum of £10,000 to the establishment of a museum, and a professorship on pathological anatomy.

We have not alluded to the writings of Dupuytren. He has not done much himself as an author. With the exception of some memoirs on fractures of the fibula, on artificial anus, on calculus and the operation of lithotomy, and of several reports and "eloges" delivered at the Academy, we must look for the record of his doctrines and practice in the writings of his pupils and associates—in the *Repertoire d'Anatomie* of Breschet and Royer Collard, in Sanson and Begin's edition of Sabatier's *Medecine Operatoire*, in the great work of Roche and Sanson, on *Medico-Chirurgical Pathology*, in five volumes, and in his own *Leçons Orales*, published by Buet, Briere de Boismont, Marx, and Paillard.—*Med. Chir. Rev.*

AND

Surgical Journal.

Saturday, August 12th, 1837.

NORTH LONDON HOSPITAL.— EXTORTION FEE.

All the information which we have from time to time hazarded to bring before the readers of this Journal, relative to the machinations of the *liberal* professors of the Gower Street Company, in their scheme to augment the price of the stu-

dent's attendance at their hospital, after a very protracted, and no less difficult, gestation, has been delivered to the world in the form of an "Advertizing Sheet, or as our commercial friends would term it, "Price Current," of the various dishes which are to be served up at the approaching session. It is enough for us, on this occasion, to draw public attention, and to excite the attention of the professional reader, more particularly to the terms on which they offer, what the Company consider their staple commodity—the University College Hospital—the notorious North London Hospital of the old Pharmacopœa. It will be recollected these crafty Gower Street tradesmen endeavoured, and succeeded, in erecting an Hospital, to which they gave the imposing name of North London, in order to entrap, as subscribers, the charitably disposed of that district of the metropolis, whilst the *real* objects of these DEALERS was to form an institution, from which they might be able to extract, by some of their legerdemain arts, a certain quantity of money for their own pockets.

At first, when the hospital was established, the SPECULATORS found that the donations of the charitable, though sufficient for its erection, were inadequate for its support, so that in order to carry their crafty measures into full operation, the medical junta unanimously resolved—and it reflects great honour on their benevolent disposition—that they should give up the whole proceeds of the student's fees for the annual expenses of the charity.

The fact that the hospital of the Joint Stock Company of Gower Street, was offered at a much lower rate, nay, scarcely one-half of the demand of the old recognized hospitals, induced, as the SPECULATORS anticipated, a considerable number of those unfortunate young men, who are

compelled by the cormorants of Lincolns' Inn Fields to pay a sum of money to a recognised hospital, and whose small means made it an object for them to procure the necessary commodity at a cheaper rate, to enter to the North London, and consequently up to the present time has this institution been supported by the students' fees.

But the medical faculty of University College Hospital, having found that the fees of the students were no more than adequate to pay the current expences of the establishment, and perceiving, with their eagle eye, that there was no chance of accumulating *pelf* for their own purses without "reforming" the establishment; they have at last arranged and determined on the following bill of fare, which we here insert for the edification of our readers.

Before concluding our observations, however, on measures which all must agree are little calculated to increase the respectability of our profession,—far less to add to the *fame* of the professors of the liberal University College of this metropolis; and though rumours have been industriously circulated by interested individuals, that the measure on which we have felt it our duty severely to animadvert *has* received the countenance of the Honourable Member for Finsbury, and will receive the support of his talented and influential journal, we will not permit, as far as our humble endeavours go, such a rumour to pass without contradiction, and expressing our sincere belief that they are false, and totally unfounded.

UNIVERSITY COLLEGE HOSPITAL,

(LATE NORTH LONDON HOSPITAL.)

Physicians.—Dr. Elliotson, Dr. Thomson, Dr. Carswell.

Obstetric Physician.—Dr. Davis.
No. 19.

Surgeons.—Mr. Cooper, Mr. Liston, Mr. Quain.

Terms of Admission to the Practice and Clinical Lectures.

To students who have already entered in the medical faculty of the College, to three classes, of which the Courses are of six months' duration;—two classes, in which the Courses are of three months' duration, being considered equivalent to one of six months.—

For perpetual admission to the Medical and Surgical Practice, 26*l.* 5*s.*

For attendance during one year upon the Physicians' and Surgeons' Practice, 21*l.*

For attendance during one year upon the Physicians' or Surgeons' Practice, separately, 15*l.* 15*s.*

For attendance during six months upon the Physicians' and Surgeons' Practice, 15*l.* 15*s.*

For attendance during six months upon the Physicians' or Surgeons' Practice separately, 10*l.* 10*s.*

TO PUPILS WHO HAVE NOT ENTERED TO LECTURES IN THE COLLEGE AS ABOVE SPECIFIED,—

For perpetual admission to the Medical and Surgical Practice, 36*l.* 15*s.*

For attendance during one year upon the Physicians' and Surgeons' Practice, 30*l.*

For attendance during one year upon the Physicians' or Surgeons' Practice separately, 22*l.*

For attendance during six months upon the Physicians' and Surgeons' Practice, 22*l.*

For attendance during six months upon the Physicians' or Surgeons' Practice separately, 15*l.*

(Note) Their proportion of these fees has been relinquished by the physicians

and surgeons of the hospital, and is devoted to the maintenance of the establishment.

Every pupil pays, in addition to these fees, 10s. to the apothecary and 5s. to the secretary.

House-surgeons, physicians' clerks, and surgeons'-dressers are selected from pupils, being students of the College, without additional payments; preference being given to those who, with equal moral character, have obtained the highest honours in the medical classes of the College.

The physicians' and surgeons' visits are made daily at one and two o'clock during the winter term.

Medical and Surgical Clinical Lectures are given several times a-week.

Dr. Davis, Dr. Carswell, and Mr. Quain see out-patients daily in the morning.

THE COURT MEDICAL APPOINTMENTS.

We present our readers with the list of the Court Medical Appointments, by which it appears that Dr. James Clark is placed above the distinguished President of the College of Physicians;—"What a falling off is here, my countrymen!"

ST. JAMES'S PALACE, AUGUST 8.

The Queen has been pleased to appoint the following gentlemen upon her Majesty's Medical Establishment:

Physicians in Ordinary—James Clark, M.D.; Sir Henry Hallford, Bart., M.D., G.C.H.; William Frederick Chambers, M.D., K.C.H.

Serjeant Surgeons—Sir Astley P. Cooper, Bart., G.C.H.; Sir Benjamin C. Brodie, Bart.; Robert Keate, Esq.

Physician to the Household—James Clark, M.D.

Surgeon to the Household—John Phillips, Esq.

Apothecary to the Person—John Nussey, Esq., and Edward Duke Moore, Esq., jointly.

Apothecary to the Household—John Nussey, Esq., and Charles Craddock, Esq., jointly.

The Queen has also been pleased to appoint—

Sir James M'Grigor, Bart., M.D.; Henry Holland, M.D.; Peter Mere Latham, M.D.; Richard Bright, M.D.; and Neil Arnott, M.D., Physicians Extraordinary to her Majesty.

Benjamin Travers, Esq.; Thomas Copeland, Esq.; William Lawrence, Esq.; Henry Earle, Esq.; and Richard Blagden, Esq., Surgeons Extraordinary to her Majesty.

Messrs. Merriman, of Kensington, Apothecaries Extraordinary to her Majesty.

Charles Dumergue, Esq., Surgeon Dentist to her Majesty.

Louis Durlacher, esq., Surgeon Chiroprapist to her Majesty.

Mr. Squire, Chemist and Druggist to her Majesty.

THE ANATOMIST.

MALE ORGANS OF GENERATION.

THE TESTICLES

Are two in number, of an oval form, are contained in the scrotum, and are likewise enveloped by proper tunics.

Tubuli seminiferi are numerous capillary tubes, which form the body of each testicle. They are very long and tortuous, and are arranged in conical fasciculi, which are separated from each other by fibrous bands, derived from the tunica albuginea.

Tubuli recti are from sixteen to twenty in number, are formed by the union of the tubuli seminiferi, and are contained between the layers of the corpus Highmorianum.

Vasa efferentia are five or six in number, and are formed by the union of the tubuli recti. These tortuous vessels pierce the tunica albuginea, arrive at the head of the epididymis, and by their union form the vas deferens.

Vas deferens, or *seminal excretory duct*, is of great length, and is folded on itself by innumerable turns for the first

part of its course. By its convolutions it, and the vasa efferentia, form the *globus major*, or head of the *epididymis*, which is situated at the upper part of the body of the testicle; still convoluted, it passes downwards, forming the body of the epididymis, which is narrow and placed at the posterior part of the body of the testicle, and arriving at the inferior part of the gland, it forms the *globus minor*, or tail of the epididymis. The vas deferens having thus formed the epididymis, escapes from the *globus minor*, and having increased in size and density ascends along the inner aspect of this body, until it becomes connected to the spermatic vessels and cremaster muscle; it then passes through the external abdominal ring and the inguinal canal, and having passed through the internal abdominal ring, it separates from the spermatic vessels, and is conducted by the false lateral ligaments of the bladder to this viscus, along the side and inferior fundus of which it runs, lying internal to its corresponding vesicula seminalis. It here approaches its fellow of the opposite, and both ducts becoming flattened arrive at the base of the prostate gland, where they are joined by the ducts of the vesicula seminalis, their union forming the *common ejaculatory ducts*; these run through the prostate gland and open into the prostatic portion of the urethra at the side of the verumontanum.

PROPER COATS OF EACH TESTICLE.

Tunica albuginea.—A strong fibrous investment, of an opaque white colour, which forms the proper capsule of the gland. From its inner surface it sends two laminae, which project into the back part of the testicle for about two lines, thus forming the body called *corpus Highmorianum*; from the free edge of which proceed the fibrous bands, already mentioned as separating the conical bundles of tubuli semiferi, to be attached to the opposite surface of the tunica albuginea.

Tunica vaginalis.—A serous membrane, consisting of two layers, one covering the testicle called *tunica vaginalis testis*, the other lining the scrotum called *tunica vaginalis scroti*. When the tunica vaginalis scroti is divided, its continuity with the glandular layer may be demonstrated by tracing the membrane, when it will be found to be reflected on the side and fore part of the epididymis and testicle, forming a pouch between these

bodies, and also for a short distance on the fore-part of the chord.

Tunica communis, formed by the fibres of the cremaster muscle and cellular membrane, surrounds the chord and the fore-part and sides of the testicle.

COMMON COVERINGS OF BOTH TESTICLES.

The scrotum, a production of the common integument, is of a brownish colour, slightly studded with hairs, and sebaceous follicles, presenting in the median line a hard ridge, called the *raphe*, from either side of which it is thrown into rugæ.

The dartos, supposed by some to be muscular, is formed by the subcutaneous cellular tissue and the ramifications of numerous blood-vessels, which give this coat a reddish appearance.

The superficial fasciæ immediately under the dartos, is derived from the superficial fascia of the abdomen, and is continuous with the superficial fascia of the preneum.

Septum Scroti—this partition, which divides the scrotum into two, is formed by the dartos and superficial fascia, these membranes being attached to the raphe, and from thence ascending between the testicles, to the urethra.

BLOOD-VESSELS AND NERVES OF THE TESTICLES.

Each testicle is supplied with blood by the spermatic artery, the blood of which is returned by the spermatic veins; it receives nerves from the spermatic plexus, which is formed by branches from the lumbar ganglions of the sympathetic, from the splanchnic nerves, and from the renal plexus.

Rete testis.—Upon separating the laminae of the tunica albuginea, which form the corpus Highmorianum, the arteries, veins, and nerves of the testicle, together with its vasa recti, will be seen to pass to and from the gland. The reticular appearance these present is called *rete testis*.

ON THE ENDERMIC METHOD.

By DR. BUREAUD, RIOFREY.

While the endermic method was employed in France by the most celebrated practitioners, both in the hospitals, and in private practice, it was seldom had recourse to in England, and it is evident from the relation of the cases that have

been given to the public, that English practitioners were not well acquainted with its rules.

When we introduced the question of the endermic method at one of the Medical Societies in London, a member brought forward some cases treated by this plan, and as he did not precisely follow the rules for this practice, the result was unfavourable.

Dr. T. Thompson, professor at the London University, applied one grain muriatis morphiae on a raw part of the thigh of a woman who had long been affected with sciatica, in the course of an hour she lost the use of her speech, she vomited, was in a state of delirium, fell into a gentle sleep, and awoke the following day, cured of her sciatica. Another individual was afflicted with mania and had previously epileptic fits, he was much agitated, and during the night was generally in a state of great excitement. Two blisters were applied to the neck, and two grains of morphia were put on the surface, the following night the patient was quiet, and the next day he was free from pain, and irritability of the nervous system.

A young woman, eighteen years of age, had always good health, till four months since, when she first noticed a black spot under the nail of the middle finger of the right hand; the finger had been since several times swollen, red, and painful; it had been opened several times, but no matter escaped. The pain extended up the arm and shoulder to the spine; there was also tenderness on the nerves of those parts. Leeches were repeatedly applied to the dorsal spine, as well as cupping and blistering, without any benefit. The fingers could not be extended, on account of the pain experienced in the attempt; there was heat and redness up the arm, with occasional pain in the spine; she kept the arm close to her side. On the 26th of February leeches were applied to the spine; these were repeated without benefit; and, on the 1st of March she was admitted into the hospital. As her bowels were confined, she took purgatives without effect, and a blister was applied to the spine. A grain of morphia was sprinkled on the abraded surface. This produced a benumbing sensation down the arm to the fingers, but that ceased in the course of three or four hours. A second application of morphia was made, and produced the numbness of the limb again; soon after which she began to recover motion, and, in the course of a few hours, was

quite well, the morbid sensations having entirely left her.

The three preceding cases are fully in favour of the endermic method. But in the report of the Westminster Society, given in the *Lancet* of the 4th of March, 1837, we find that Mr. Chance inquired if Dr. Thompson had applied morphia by this method in cases of tic douloureux. He (Mr. Chance) had applied a blister in a case of this kind, about the size of a shilling, over a portion of the affected part; and placed four grains of acetate of morphia on the abraded surface; slight numbness was produced, but the pain was not relieved. He had also employed muriate of morphia and belladonna, but neither were successful in removing the pain.

What strikes us most in this case is, the surgeon's boldness, who employed four grains of acetate of morphia; if chance had not served him, or if rather the omission of some of the rules to be followed, had not preserved the patient from the effects of morphia, its toxic effect, no doubt would have been too forcible.

The patient not having been either benefited or injured, it is to be presumed that the medicament was not absorbed, either because the blister did not rise and the skin did not come off, or because the medicament was applied too late, and that a new skin had been formed.

Mr. Pettigrew, at the same meeting, related a case in which castor oil applied to the denuded surface of a blister, had cured an obstinate constipation, which had resisted all other means.

Of all the diseases to which the endermic method is applicable, none offers more chances of success, and greater advantages than neuralgic affections; the very seat of pain may be thus attacked, and followed the whole length of the nerve, and even as far as the nervous centre. Wherever there is neuralgia it may easily be treated by the endermic method. The effects of this mode of treatment are incontestible in intermittent fever. Mr. Chomel placed this matter beyond a doubt by the numerous successful experiments made at the Hôtel Dieu, in Paris: the results of this medication are not less certain in every sort of neuralgia than in intermittent fever; and we may be allowed to give some facts taken from our own practice, or extracted from M. Lember's memoir.

Rheumatic neuralgia—Lumbago.

M., thirty-two years of age, was sub-

ject to lumbago, the least change of temperature, or the least exertion, brought on a fit of lumbago, the mere act of stooping had a similar effect. It was generally on one side of the loins only. The lady, when suffering thus, could not walk without support, or else placing one hand on her knee, and gently advancing side-ways. There is no apparent change in the lumbar region, but there is stiffness in the muscles, they appear contracted, but the patient's endeavours to walk may explain the contraction; under these circumstances the spine seems stretched. In the space of four years, I have treated this patient at least ten times for attacks of lumbago. At first I advised local bleeding, baths, friction; the patient recovered, though slowly. The four last attacks were treated by the endermic method, several small blisters, about the size of a sixpence, were placed under the lumbar region, on the part affected, and as soon as the epiderm was dried up, I dressed the blister with the *murias morphiæ*; in two or three days the patient was free from pain.

The last time I treated the disease with aconites. A grain of this alkali was mixed with an ounce of lard; I only employed about a drachm of this salve, so that the quantity of aconites was not more than the eighth of a grain, and all of it may not have been absorbed; the patient felt a species of numbness, and was cured in two days.

The opinion of authors is not unanimous on the nature of lumbago, but I consider it mostly as a species of neuralgia. I admit, nevertheless, that lumbago may be attended with inflammation, but inflammation may be but a complication. Lumbago sometimes comes on without the patient being exposed to the cold, without pain or swelling, and without the disease following the course of general inflammations. Besides, the pain is so acute, and there are such marked exacerbations, that there can be no mistake as to the nature of neuralgic affection. Even in doubtful cases, the pain depends so much on the nerves of this region, that the disease caused by rheumatism, or a sympathetic state, principally gives way to the action of medicaments employed under the epiderm.

There are pains in the loins extending the whole length of the abdominal limbs, these pains which are always most acute, are caused by a deep alteration of the uterus, the nerves even undergo an alteration. How then are these deceptive

lumbagoes, or sciatica of the same kind, to be treated? Is it certain that narcotic medicines put on the womb will allay the pain? Will medicaments that undergo the digestive action of the stomach succeed? It is at least doubtful, and I have several times very successfully, applied small blisters on the length of the lumbar and sacral nerves, as well as on the branches of the cutaneous and sciatic nerves, so as to relieve the pain of which the womb is the seat.

Sciatica.—In January, 1837, when the influenza broke out in London, several patients complained of neuralgic pains; few authors have signalized the existence of neuralgia, excepting Dr. Lombard, of Geneva, in his memoir on the grippe. In all these patients I found a bilious disposition, which induced me to have recourse to an emetic in the early state of the treatment; several patients were cured by the mere effect of the emetic; but a lady of thirty, was confined to her bed with paralysis, she suffered most severely, and not having been relieved by the emetic in the early stage of the disease, nor by frictions, nor turpentine, recommended by Marünet, nor colchicum, recommended by others, I had recourse to blisters. I placed several on the extremities of the external branch of the sciatic nerve; I employed the *murias morphiæ*, dividing one grain in several parts, and the following day the patient was freed from her sciatica. I must observe, that when I recommend several blisters, they are put on different branches of the same nerve, but the blisters are not larger than a sixpence.

Dr. Lambert relating a similar case, very properly observes, that it is important to distinguish sciaticas which are symptomatic of a disease of the spine. This distinction is difficult at first, as it is possible to mistake the paralysis which occurs, with the immobility to which the limbs are subjected through rheumatic pains; it is important to understand the case thoroughly, as in the latter circumstance, it is essential to have recourse to strychnine rather than morphia.

Paralysis of both hands.—A miner, aged forty-four, had been attacked eight times with metallic colic, during the exercise of his trade, each time he was treated and cured. During his last convalescence the extensors of both hands became paralyzed. Strychnine was given, the right hand could not be held parallel with the fore-arm, if it were not previously shut. When the fingers were half bent the arm

could not be extended, and formed an obtuse angle with the fore-arm; its movements were slow, difficult, and confined in various ways; its temperature was sensibly weakened. The left hand presented the same phenomena in a less degree. The 8th of March, a blister was applied to each fore-arm, and for the first time the patient complained of vertigo.

The 9th March, half a grain of strychnine on the blister of the right arm; an hour afterwards intense heat of the skin, and sensation of traction in both hands. The following day the patient was able to extend them better, nevertheless the usual vertigo came on. This state lasted till the 13th. At this time a grain of strychnine was applied, in the course of an hour a shock was felt in the fore-arm, and in nearly the whole of the body.

The 14th more strength and freedom in the movements, and in nearly the whole body; the left hand seems free, the fingers easily extended.

The 15th the application is only made on the right arm, in which alone the shocks are felt. The use of strychnine is suspended till the 18th, on account of the vertigo.

The 19th a blister was applied to the nucha so as to act more directly on the encephalon; strychnine was given in doses of two grains for several days, and the hands gradually regained their normal state.

Spontaneous Tetanus.—(LEMBERT).—Margaret Broin, of a nervous temperament and nervous constitution, had been five years in the hospital in the ward of incurables, for herpes, seated in the internal part of the thoracic and abdominal limbs; on the 23rd of July, she was walking with an epileptic patient, who fell in her arms in a fit. She was so terrified that she fainted. When she reached her own ward, she tried to relate to her companions what had passed; in the midst of the recital she was seized with convulsions, her face was contracted, the jaws closed so tight that the tube of a pen could only be introduced, the fore-arms stiffly bent, the neck stretched and thrown backwards, and all the body stiff.

There could be no doubt but this was spontaneous tetanus, and I did not hesitate an instant in using the acetate of morphia; at eleven in the morning I placed a small blister on the nucha; I took it off at three in the afternoon, and sprinkled on the surface a quarter of a grain of acetate of morphia. At six in the evening the trismus no longer existed, the other

symptoms were the same. I again applied a quarter of a grain of acetate of morphia; at ten o'clock the fore-arms had regained their powers. In the night the muscles of the face, neck, and eyes, had regained their normal mobility, and the next morning the patient had recovered.

Frontal Neuralgia, treated with Assa-fœtida.—(LEMBERT).—A young woman of four and twenty, robust and plethoric, was, for the last four years, subject to hysteria; and without any known cause was attacked with acute neuralgia of the forehead and temples. The following were the symptoms of this disease. Every afternoon between three and four a fit of trembling came on, accompanied by lancinating pains on both sides of the forehead. On the length of the temporal branches of the nerves of the face, the face was wrinkled, injected, the eye-lids closed and contracted, tears and odontalgia to the left, swelling of the artificial veins of the temple, violent beating of the corresponding arteries; heat, giddiness, heaviness, pain in the pharynx, dysphagia, uneasiness, want of appetite; the catamenia regular. Antiphlogistics give momentary relief, but the tic came on with increased pain; bathing the feet, drinking linden and orange flower-water, acetate of morphia taken internally gave no relief; frictions with acetic ether, and with acetate of morphia, one grain of which to be mixed in a drachm of lard; the draughts with assa-fœtida or musk were not kept on the stomach. The patient seemed to lose all courage and was quite in despair.

I applied half a grain of acetate of morphia on a blister, having left it to suppurate several days, it produced no favorable result. I increased the dose to two grains, the neuralgic pain completely disappeared: the weight of the head, vertigo, palpitations, nausea, fainting, thirst, constipation, contraction of the pupils, particularly to the left, still existed. The next morning hysteria, the tic returned; we had recourse to tincture of assa-fœtida, ten drops were poured morning and evening on the surface of the blister. The following day the shooting pains were slight. The temples were painful on pressure. The dose was increased to thirty drops, and in less than a week the patient had recovered her appetite and was completely cured.

Hemicrania, treated with Sulphate of Quinine.—A young man of three and twenty was affected with hemicrania, while convalescent of gastro-enteritis. During ten days he felt it from five in the

morning till twelve at noon, there were shooting pains and violent pulsations above the right eye, and it is to be observed that this disease broke out in the spring, and during six years the patient knew that at the same period there was slight deafness, and the words resounded painfully in his ears. When the hemi-crania was first felt, the state of the intestinal canal appeared as usual; six grains of sulfate of quinine placed on the blister determined a cure.

To the facts here stated, various others might be added; nearly all French practitioners adopt the endermic method. The wish expressed by M. Bouilland to see this method become popular, has been realized on the continent; no doubt that English practitioners, such able appreciators of all therapeutic means, will adopt this plan, and have recourse to it, particularly when they have become acquainted with Mr. Lambert's and Lesieur's experiments, as well as those of the learned professors of the Parisian school.

ON THE MANNER OF DENUING THE SKIN.

The various means for denuding the skin are blisters, incision, and innoculation.

All animal, vegetable, or mineral substances, which produce vesicles on the skin, to carry off the epidermis, may be employed for the endermic method.

Those most frequently used among animal substances, are cantharides. Among vegetable-substances some plants of the class, such as *daphnia mezereum*, *laurela gnedium*, several species of *euphorbia*, various plants of the class of the *urticariæ* have these irritating powers which deprive the skin of its epidermis, by the anormal secretion of the fluids they induce. Ammonia, caloric, boiling oil or water, are applied for the same purpose, but common blisters are in most general use.

The application of a vesicular agent determines, on the part where it is laid, phenomena of a very important nature, and which should be well understood. In the first instance, the patient feels a burning sensation, which increases till it becomes very painful, it ceases altogether in a few hours, the capillary vessels are injected, the skin red, a serous and abundant exhalation takes place over the surface of the rete mucosum, the epidermis gradually rises from the skin and forms a vesicle, the pain then ceases. The vesicle is filled with albuminous serosity, when,

according to the state of the patient, the blister is either irritating, or sedative, and becomes a useful auxiliary, if the endermic method be properly indicated.

When the blister is taken off the epidermis is detached by a limpid fluid, an opening made in the vesicle lets the fluid escape, and affords an opportunity of introducing the medicament without taking off the epidermis. Absorption is then more active: perhaps, says Lambert, the contact of the air may produce the absorbent and denuded parts, an astriction similar to that determined on the arterial and venous extremities; at the first dressing the transparent pellicle should be carefully removed, to this omission may, in a great measure, be attributed the non-success of several medicinal applications, and the inefficacy of four grains of muriate morphia mentioned by Mr. C.

When suppuration is established, it must be carefully cleansed, and all the matter covering the denuded part cleared away; this observation is applicable to exutories of long standing, which may serve to introduce medicaments without having recourse to a blister. Yet if exutories are callous, wan, atonic, blisters are more desirable, for œdema, pus, and fungosities prevent absorption: sometimes these denuded surfaces may be vivified by cauterization.

When the inflammation is but slight, absorption is frequently very active; if the inflammation be great, absorption is less; if there be mortification there will be no absorption. It is essentially important when the endermic method is employed, to ascertain in what case blisters are or are not prejudicial; for instance in bad typhus fever they cause extensive and deep ulcerations, and are covered with eschars; in œdematous diseases they give rise to sores; this observation may be applied to all cathartic diseases. The time a blister is to be left on also requires the consideration of the practitioner. Is the extent of the surface to be in proportion to the quantity of substance to be introduced? I think not, and my opinion is founded on my own personal experience, and that of others; more advantage is to be derived from the application of medicaments on a number of small surfaces than from only one of large dimensions. Baglivi, Bailly, de Graves, and other learned practitioners, are of this opinion. Small blisters give a stimulus, and cause a derivation which may be useful; large blisters often weaken, than bleeding, particularly when

applied to large surfaces until a considerable vesication is formed.

It is essential to be previously acquainted with the action of medicaments on denuded surfaces; this action is double; local in the first instance, then consecutive. This observation is applicable to various medicaments. Morphia, strychnine, quinine, musk, emetic tartar, and all caustics are known. Humanity and justice require that no medical man should prescribe medicaments unless he is aware of the effects they may produce; all experiments made at the expense of the health or life of a patient is a crime against humanity. The trial of a medicament when all those that are known have failed, may certainly be permitted, as it is for the patient's benefit, but under these circumstances alone: then necessity makes a duty of a trial, which ought nevertheless to be guided by previous knowledge, and a reasonable theory and analogy.

Should there be any reasonable cause for fear after the application of these medicaments, the exutory must be well cleansed immediately, and the denuded surface covered with a substance that will neutralize the effect of the medicament previously employed. Thus M. Lembert arrested the progress of a tetanus brought on by two grains of strychnine, by putting on the same surface two grains of acetate of morphia.

Endeavours have been made to ascertain which substances were most easily absorbed by friction, and which best maintained suppuration. M. Lembert thinks that strychnine and emetics are the best.

These preliminaries being laid down, the skin deprived of its epidermis, and the medicament put on the denuded surface, how does absorption take place? This is an important question, and its solution necessarily demands ample development.—*Continental and British Medical Review.*

GERMAN CONTRIBUTIONS TO PRACTICAL MEDICINE.

Communicated by ROBERT THACKER, M.D., Derby.

(From the *Medico-Chir. Rev.*)

The following interesting observations on the diseases and state of medicine in

Chili, are condensed from Professor Poeppig's "Travels in Peru, Chili, and on the River Amazon."*

"The population of Chili is rapidly on the increase, owing to the many advantages enjoyed by the inhabitants in their political position, and also to the circumstance that they are very little exposed to the diminishing influence of disease. Indeed, whatever has been said by earlier travellers of the remarkable healthfulness of the climate, may be credited in its fullest extent. Neither the extreme aridity of the northern provinces, nor the long-continuing or severe rains of the southern, would appear to exert any particular influence on the duration of life, or on the health of the natives. In Mendoza and San Juan, which are only separated from Chili by the chain of the Andes, all classes of the inhabitants suffer severely from scrofula, and cretinism is not unfrequent; in Chili, on the contrary, the latter is entirely unknown, and some traces of the former are only occasionally observed among the residents of the northern parts of the country at the foot of the Andes. The foreigner who makes a lengthened stay in Peru may regard himself as fortunate if he escape a certain intermittent, which will frequently bid defiance to the most careful and judicious treatment. In Chili, on the other hand, there is no fear whatever of this disease, indeed, many Peruvians affected with it come yearly into Chili with the view of regaining their health. The regularity of the meteorological phenomena, the gradual manner in which changes of temperature take place, the purity of the water used for drinking, the constant winds, and the absence of marshes and damp woods, are the main causes to which the Chilians of all grades are indebted for the particularly good health they enjoy. The infectious diseases occasionally introduced soon lose their virulence under the sky of Chili. The contagious putrid fever of Guayaquil is only remembered to have once appeared at the commencement in some of the northern sea-ports. Small-pox alone is of frequent occurrence, and the fatality occasioned by it is sometimes considerably. The opinion is commonly entertained that this disease always comes

* This excellent work was published not long ago, and is the subject of a highly laudatory article in a late number of the "Foreign Quarterly Review." The author is a talented, observant, and erudite man.

from Peru, probably because it generally makes its first appearance at some seaport station. Epidemics of small-pox usually occur towards the end of the winter, and from July to November, and it is observed that they assume a more malignant character as the weather becomes fine and warm, and the intervals of rain are longer. The mode of life of the lower classes, and the great want of cleanliness in their habitations, are circumstances favourable to the propagation of the disease; and under this head we must not omit to mention the deplorable maltreatment experienced by the sick, who are confined in the most secluded corner of the house, and dosed with all kinds of rubbish, large fire are lighted, all access of fresh air is carefully guarded against, and the poor patient almost smothered under woollen cloths—a proceeding, it may be remarked, which is observed in almost every case of illness. About thirty years ago, the Spanish government transmitted cow-pox matter to Chili by a man-of-war, but the indolence of the inhabitants has hitherto formed a serious obstacle to the introduction of a general practice of vaccination. Companies supported by the government, are now instituted; their object is to extend vaccination, and this benefit is conferred on the poor gratuitously. At eight localities a vaccinating physician has been stationed, with a yearly salary of from 240 to 280 ducats, and one of these gentlemen, named Alvar, fortunately discovered the vaccine pustule in the cows of Chili. In the years 1828, 1831, and 1832, an epidemic of a peculiar malignant character prevailed, and the people, driven by fear, came in great crowds to be vaccinated, so that from 1830 to 1832, the total number of those vaccinated amounted to 37,834. The Indians suffer far more from the ravages of small-pox than the Chilians.

Acute diseases seem on the whole to occur but seldom, with the one exception of typhus, which here, however, is not wont to destroy the powers of life so suddenly as in other countries. In the towns and cities the mortality is greater than in the country. With respect to chronic affections, the secondary symptoms of syphilis are of the most frequent occurrence; in fact, lues venerea may be considered epidemical in Chili; yet such is the beneficial influence of the climate, that in this country, as indeed throughout the whole of South America, this disease, formidable as it is in northern Europe, is almost entirely divested of its terrors.

The countryman pays attention to his diet, drinks infusion of sarsaparilla, and not infrequently recovers completely without the use of metallic remedies. In large towns, however, the disease is not so easily removed, which is partly to be ascribed to the empirical treatment adopted; for here, as in all other countries, how remote soever of the extra-European world, Leroy's celebrated panacea plays a very prominent part, and many other nostrums of Spanish origin are also high in favour. Among the Indians of Chili, lues is not common, and it does not appear to have been ever communicated to the races on the eastern side of the Andes.

It would seem that with the spread of civilization in Chili, diseases heretofore unknown, and which we may feel little disposed to regard as a consequence of our social condition, were at the same time introduced. Thus it is a fact that scarlet fever was not known up to 1831, when it suddenly broke out as a violent epidemic. Yet it was mild, for according to the report of the protomedicus, among 547 cases, there were only twenty-five exhibiting a malignant type (under the form of Febr. scarlat. miliaris), in which typhoid symptoms supervened. Of the latter six or seven died, but of the whole number only a twelfth part terminated fatally.

The science of medicine has hitherto made but small advances in Chili, and it is only within a very recent period that really competent men have begun to enjoy some portion of public esteem. Twenty years ago medicine was practised by men of colour and the most ignorant quacks, the hospitals were entirely under the control of the monks, and the few well-informed physicians, those, namely, who had received an European education, found in Lima a more lucrative field for their exertions than was offered to them anywhere in Chili. This state of things, however, no longer obtains, for the number of physicians is now even greater than necessity requires, and there is a College of Santiago at which medicine is taught, although on a somewhat compendious plan. Still there is a scarcity of educated practitioners in the country, where the healing art is chiefly exercised by matrons and old Indian women. The country people are tolerably familiar with the virtues of the rather numerous indigenous plants, but to many of these properties are attributed which the individuals in question do not really possess, and many other remedies, supposed to be of great

efficacy, are solely indebted for the estimation in which they held to a credulous superstition. When any particular part of the human body is the seat of disease, the remedy is sought for in the corresponding part of some animal, variously prepared; thus, for ophthalmic disorders, the carbonized eyes of birds of prey are administered, the claws of the condor are given for gouty pains of the hands, and the flesh of the smooth-skinned lizard for scurfy affections of the skin. For the treatment of ordinary cases, the simple *materia medica* of the country suffices.”—*Poeppig's Reise in Chile, Peru, und aufdem Amazonenstrome*. S. 524—531.

REMARKABLE CASE OF SPONTANEOUS COMBUSTION.

By Dr. JOLY.

Bernard, æt. 73, and his wife, æt. 65, have long indulged to excess in spirit drinking. September 6th, they both became intoxicated, remained alone the whole night, and were found dead on the following morning. Four hours after they were found dead, Dr. Joly and the “*Procureur du roi*” went to see the bodies. The room which contained them was shut. Several pieces of furniture in it were covered with a grey soot. There was a strong empyreumatic smell, and on the floor, between a table covered with bottles and glasses, which had contained brandy, and the cinders of an extinguished fire, lay the legs of the two corpses and a shapeless carbonaceous mass. Two of the legs, belonging to the same individual, had on stockings of black wool and cloth slippers. One of the stockings only was burned at its upper part. The skin covered by the slippers was but reddened; the tissues beneath, when cut into, presented no peculiar appearance. An inch above the knees, the thighs were reduced to a black, shapeless, carbonaceous mass. There were no traces of the external genitals. Of the pelvis, and the parts contained within its cavity, there remained but the calcined superior edge of the left ilium, and the enlarged left ovary buried in the midst of oily and fetid carbon. There was a separation of the articulation of the lumbar vertebrae; and at this part the body was divided into two, in consequence of having rested upon the other situated beneath it. Two or three verte-

brae, which thus became exposed to the air, were consequently calcined and whitened. These were quite distinct from a mass of spongy and shining carbon, corresponding to the thoracic cavity and its contents. The only portion of this which was at all solid was the vertebral column, to which the calcined cervical vertebrae terminated in the incinerated cranium, which was so extremely friable as almost to fall into dust on the endeavour being made to lift it. The lower jaw alone had preserved more consistence. Beneath the remains of this corpse, and forming an X with it, were those of the second. The left leg, naked and covered with vesicles containing a reddish serum on its anterior surface, was burned to the bone the whole of its length, posteriorly. It was disconnected with the body. A cat had bitten the muscles of the calf, and torn them to the extent of several inches. A fatty and disagreeable liquid oozed from this laceration. The right leg was burned like left. Its whole anterior surface was covered with large phlyctenæ, as well as the sole of the foot, although the latter entirely rested upon the ground. About three inches above the knees, the thighs were converted into a heap of black and unctuous carbon. The pelvic region had disappeared. At the part where the former corpse lay across the latter, the clothes were strongly adherent to the remains of the bodies, in consequence of the slowness of the combustion. In the different layers of charcoal which were interposed, it was easy to recognize the character of the garments. The right lung and the liver could be recognized. They had lost about half their size; their surface was hard, varnished, and brittle; when cut, their consistence was that of soft cheese; but the texture of the liver was closer and more homogeneous than that of the lung. The vertebral column and ribs consisted of a more compact carbon than that which was formed by the soft parts. About an inch and a half from the earth was an entire and sooty head. The prominence of the nose and the orbital cavities were still marked. This bony box was broken by the slightest shock, and in the middle of its cavity, resting on the foramen magnum, was the dried brain, about the size of a hen's egg. Of the superior extremities of these two corpses, a few inches of one calcined humerus, and three united and calcined metacarpal bones, only were found. Allowance being made for those parts which had

undergone slight alteration with respect to their weight,—i. e. the legs and feet,—the weight of the cinders of both bodies produced by the combustion was calculated not to exceed four pounds. The time which the combustion may have occupied could not have exceeded fourteen hours. These remains, lying upon a pavement covered by a greasy and stinking liquid, were surrounded by various pieces of furniture, &c. At the feet, the parts most distant from the fire was a table unburnt. The heads lay towards the hearth, in which there was no fire: a fender and handiron had fallen beneath the woman; and between her head and that of her husband was a brand, still burning. On the right was only a wooden shoe; on the left was a chair, one foot, four oars, and the straw cushion, which had been partially burned. There was also a beehive, reduced to a cinder. A few inches above the bodies was a besom made of rush, which was scarcely singed on one side, and some matches, the sulphurous end of which projected beyond a sabot which contained them.

[The circumstances attending these cases of spontaneous combustion agree generally with what has been hitherto observed in such cases. This account differs, however, from others, in two individuals, of different sex, being simultaneously affected; and it adds another fact to the rare occurrence of spontaneous combustion in man. It offers also an example of two individuals placed in such identical physiological conditions, that the combustion affected them both in the same degree and in the same parts].—*Journal des Connaissances Médico-chirurgicales.*

PROCEEDINGS OF THE ROYAL SOCIETY.

In 1800 several papers by Professor Bode, communicating important facts in astronomy, were rejected. When Schroeter first imparted his discovery of the rotation of the planet Mercury, he met with the same fate which Bode had already experienced; yet not a single astronomer was present at the meeting of the decided Committee! In that same year, Blumenbach was made to withdraw a paper on the *ornithorhynch*, while a paper of Everard Home on the same subject, was ordered to be printed at the same meet-

ing. Professor Crell's various papers on boracic acid, were also rejected by the Committee. A paper on the male Rhinoceros (the single production of an old member), was voted for publication in the following year Committee, which contained not a single naturalist. Every memoir on Piazzi's newly-discovered planet, *Ceres*, by Baron de Zach, Mähelyne and others, were rejected, not an astronomer, or mathematician, or really scientific man, except Renell, being present on these occasions. On the planet *Pallas*, several foreign astronomers communicated papers to the Royal Society—but these were not published—nor anything allowed to be placed on record in the transactions respecting this second interesting discovery of a planet, until Sir W. Herschel took up the subject.

In proportion as we get nearer to our own times, the importance of the papers rejected seems to be in the inverse ratio of the scientific character of the deciding members of the committee;—and subsequent events have proved that those members have as often decided wrong when they decided for the rejection of papers—as they would have decided right had they not admitted some of the papers which appear now in the Transactions, but which are fit only for insertion in magazines and other periodical publications. Could a committee, containing only one physiologist, have judged rightly in rejecting a paper on the relation between the sanguiferous and nervous system, by one of the most industrious physiologists in England? Could they have been right in voting, without the assistance of a single anatomist or natural historian, a paper not to be printed, which was written by an anatomist, to whom one of the royal medals has since been awarded, and entitled, "on the proportions and measurements of the head, and varieties in the form of the bones of the cranium and face?" When a memoir entitled, "A new method of calculating the value of life annuities," read before the Royal Society, was rejected, there were only three members out of ten who could be judges of the matter under consideration. Well may the two last mentioned scientific "fellows" complain of a system which could work such important results, and well may they muster strong in the rank of its most strenuous opponents. What grounds could the committee of papers have gone upon, when, with an insufficient number of competent judges present, they decided on rejecting the memoir of

the Assistant Professor at the Veterinary College, in which he announced his newly discovered method of radically curing chronic lameness in the horse—and at another period, in ordering to be “deposited in the Archives” of the Society, a paper on the composition, nature, and use of certain disinfecting liquids, by the author of three other memoirs published in the Phil. Transactions? Grounds they had none, for no fact has been more triumphantly established than the discovery contained in the first paper; while the second paper alluded to has since been commended by a much abler chemist than any of those who judged in the committee, viz., the Assistant Professor of Chemistry at the Royal Institution. I repeat, therefore, grounds the Committee had none; but there were motives.

REVIEWS.

A Clinical Treatise on the Endemic Fevers of the West Indies, intended as a Guide for the Young Practitioner in those Countries. By J. Evans, Esq. M.R.C.S. London: J. Churchill, 8vo. pp. 309, 1837.

The author of this work very correctly observes, that there is great difficulty in finding an accurate account of the diseases of the West Indies, and that he felt this want when he commenced. He now proposes to supply the deficiency and to record the result of his own operations and experience. He has, in our opinion, accomplished his task with ability, and produced a work which ought to be in the possession of every one who visits the West Indies. He commences his preface by observing

“It is admitted on every hand that of all the diseases which fall under the observation of the physician, none have led to greater discussions respecting their nature, nor to more opposite modes of practice, than those which constitute what is called the ‘*Endemic*’ of the West Indies. Doubts and difficulties beset the path of the young practitioner in these countries, which reading, unassisted by his own researches and experience, only renders the more confused and discouraging. Fascinated, perhaps, by the plausible reasoning and partial views of one author, he sees in the cases which present themselves to him, so many *gastrites*, or *tro-enterites* of various types. Daily

observation destroys the illusion, and his doubts return. Again, he refers to some established authority for information, and is told that these diseases are not inflammatory; that they are general and essential; depending upon a spasm of the extreme vessels; on a disturbance, interruption, or suspension of the alternate uniform action and rest of the irritable and moving parts of the body; on an affection of some part, or the whole of the nervous system; or on a disease of the blood, &c. &c. He is bewildered and confounded, and either ceases to think further upon the subject, or else endeavours to explain the “proximate cause” in the manner his observation teaches him. Such has been my case—and such is the apology I offer to the public for bringing before it the present treatise. My object is to exhibit the cases as they have occurred to me in all their varieties; to detail faithfully their symptoms; to expose the appearances that the different organs presented after death; and to explain, as far as I am able, the physiological operation of the producing causes.”

Mr. Evans gives an account of the discrepancies of writers on fevers, and then proceeds with his work. He commences with the topography of St. Lucia, one of the most unhealthy of the West Indian islands. Next describes the malaria, its effects on the body, the diseases which it produces, their pathology and treatment, and lastly a great number of clinical cases in illustration. His account of malaria deserves attentive consideration by every medical practitioner, and therefore we shall quote fully.

“This name is given at the present day to a peculiar principle, with the nature of which we are as yet unacquainted, but to the effects of which the febrile endemics, particularly those of an intermittent or remittent type, that at different periods have been seen to obtain in certain parts of the world, have been and still are almost universally attributed. By the bulk of physicians it is supposed to arise from animal or vegetable matters, or both united, in certain states and stages of decomposition. It is true that this opinion is not universal. Dr. Fergusson attributes the origin of this poison to water during the process of drying. This gentleman says that ‘one only condition is indispensable to its production, and that is the paucity of water, where it has recently abounded. It is the drying margins of the lake or pool from which this poison uniformly emanates, and never

from the body; and he thinks that it may be fairly presumed that water, for as long as it can preserve the figure of its particles above the surface, is innoxious, and that it must first be absorbed into the soil and disappear to the eye, before it can produce any mischievous effects."

"Others have supposed that the causes which give rise to this poison exist in the emanations from ground of a volcanic formation, produced by the action of the sun's rays. These emanations, they state, contain quantities of deleterious gases, as sulphuretted hydrogen, carbonic acid, and azote, which affect the vital principles of the human frame. We will presently investigate the truth of these opinions. We must now examine the properties of malaria when arising from swamp, or from the decomposition of animal and vegetable matter.

Marsh or Swamp.

Both these terms are used to signify a tract of country of greater or less extent, the surface of which is habitually covered with stagnant water, and the soil underneath is formed of a clay mixed with the detritus of vegetable and animal matter in different stages of decomposition. In the West Indies, the greatest number of these swamps have a communication with the sea. They are covered with mangrove bushes, to the trunks of which myriads of the mangrove oysters are attached, and they also contain marine animalculæ and small fish, in such abundance as to render the mud upon their surface frequently highly phosphorescent. It is this kind of swamp which, according to Humboldt, contains the constituents necessary to furnish the most virulent species of malaria,—viz. tannin and albumen combined.

"By marshy or swampy lands are meant those places subject to occasional inundation, either from the overflowing of a river, from heavy falls of rain, or from any other cause; where, in consequence of their position and the firm and plastic nature of the soil, the water lodges, until carried off by evaporation, and mixes with decayed vegetable and animal remains.

"The mud thus formed, when acted upon by the sun's rays, emits vapours deleterious in proportion to the quantity of organic matter which has been mixed up with it and to the activity of the causes which assist in its decomposition. Many countries which under ordinary

circumstances may be healthy, become under these fruitful in disease.

"In the neighbourhood of Castries we meet with both permanent and occasional swamp, the former being the mangrove fen to the north-east of the town, and the latter is found in all the environs. When both are in full operation, we observe the greatest number of cases of fever: that is when hot and sultry weather has succeeded heavy falls of rain.

"During the months of August, September, and October, the heavy showers which are daily occurring in these latitudes are sometimes alone sufficient to inundate the whole surface of a flat country; but when we take into consideration the peculiar formation of St. Lucia, its succession of hill and valley, we must here add another and more important cause to its partial inundation. The waters rush down the steep sides of the mountains, carrying with them the detritus of animal and vegetable life, and cover the plain or valley with a rich, but unhealthy coat of alluvial soil. The river, instead of acting as a drain to the overflooded valley, cannot discharge its own contents, its mouth being blocked up by sandbanks, further strengthened by the fallen trees, shrubs, and earth, carried down from the neighbouring heights. Thus the whole valley is laid under water, which does not retire until the force of the stream has broken through this barrier. In the mean time, the matters contained in the water depose and remain in the form of rich mud and manure upon the surface of the land, which, however valuable it may be to the agriculturist, is exceedingly injurious to his health.

"The cultivation of the Anse des Roseaux valley began about thirty-six years ago; since this period not fewer than 800 negroes have been placed or born upon one estate; only 270 remain. The proprietors (two brothers) are notorious for their lenient and kindly dispositions. The work performed by the slaves has always been very inconsiderable, and the annual number of births has averaged sixteen. This decrease in persons who are supposed to withstand the effects of marsh better than any other class of the human race, is terrific. A gentleman establishing an estate in the neighbourhood, purchased in the year 1802, fourteen African negroes at Dominique: in nine months there was not one remaining. As it is now almost entirely cultivated, it is much less injurious to health than it then was; but even at the present mo-

ment very few acclimatized Europeans, or even Creoles of other parts of the island, can long withstand its effects.

The old and permanent swamp just mentioned as adjoining Castries, constitutes the upper extremity of the basin of the Carenage. It was formerly entirely covered by the sea, and is partially so now at high water. It may, therefore, with some propriety be divided into two portions: that over which the tide continues to flow, and that which, from its higher situation, is no longer exposed to the action of salt water. The former is thickly studded with mangrove bushes, and contains an immense deposit of decomposed animal matter; the latter is luxuriant with wild canes, guava trees, and logwood, and the proportion of animal matter is less.

"This swamp, for a foot or eighteen inches from its surface, is composed of a black mud of unpleasant smell, containing the leaves and small branches of the shrubs which grow out of it. Below this, to the depth of five or six feet, its appearance was thus described to me by my friend Mr. Taylor:—"It is composed of a solid matter of a yellow colour," says this gentleman, "exactly resembling rotten horse-dung, containing some marine shells, and is principally formed of the fibrous parts of vegetables mixed up with animal matter. The odour emitted by this substance is indistinguishable, but disgusting in the extreme, producing a sweetish sickly taste in the mouth, pharynx, and upper part of the œsophagus, with a discharge of saliva. A thermometer thrust into the sides of a canal five feet deep, rises rapidly to 100° and upwards; the temperature appears to be greater than that of any dunghill, and communicates a tingling, unpleasant feeling to the hand. The vapour which arises from it is very evident, being opaque, like smoke, and though it fills the canal, ascends only four or five inches above the level of the swamp."

"There is another and more extensive, though probably less noxious fen, which extends along the sea shore of Chocq Bay, to the distance of three or four miles. It is cultivated in small detached patches, here and there; the rest is covered with wild canes, and resembles rather the jungles of India or the Pontine Marshes than a West India swamp; for the most part it is firm, and admits the passage of a horse, but in places it is treacherous under-foot and impassable. Its surface is composed of a vegetable debris. I

am unacquainted with its structure underneath.

"Though swamps are composed of vegetable remains mixed with animal matter, they differ considerably amongst each other in their degrees of virulence, which bear an exact proportion to the quantity of organic matter, (particularly the latter,) in a state of decomposition, which they contain, and also to the powers of the agents which promote this effect. Therefore in countries where both these states abound, as in the West Indies, swamps are the most injurious to life."

Our author next describes the chemical characters of the exhalations from the swampy St. Lucia.

"It is to these emanations that we are to look for the causes of the operation of marshes upon the human body, and many wild theories have at different times existed respecting their nature. One of the oldest among them, and which was republished during the seventeenth century, supposes that marsh generates a number of infinitely small insects, which escape into the surrounding atmosphere, and, penetrating our bodies through the pulmonary passages, produce disease. The chemical physiologists supposed that these emanations contained vapours of a saline and sulphurous nature, which corrupted the fluids. Bernardo Ramazzini thought that they were acid, and that they acted upon the body by coagulating the blood. The humoralists attributed the diseases which reign in a marshy country to heat and humidity alone. Hoffmann considered that the vapours from swamps when expended in the atmosphere produced a heaviness of the air, deprived it of its energy and elasticity, and rendered it unfit for the vivification and expansion of the blood and humours, and thus, by coagulating the former and corrupting the latter, gave rise to putrefaction and disease of the whole body. The chemists of the present day have attributed the noxious principle in these emanations to certain gases, as hydrogen combined with sulphur, carbon, or phosphorous, or some of the combinations of oxygen with azote.

"A broad-mouthed glass vessel placed over a cleared portion of swamp, the surface of which is tolerably dry, and on a fine evening, soon becomes filled with a watery vapour, which is condensed on the inside of the vessel in the form of small drops or beads of dew. M. Julia states that this fluid is capable of fermentation, and M. Vauquelin gives us the following description of a quantity collected by M.

Rigaud de l'Isle. 'It is clear,' says the chemist, 'but when agitated we shall see small flocculent particles suspended in it; it has a slightly sulphurous smell, similar to the white of an egg when boiled. Amongst the different reagents employed, the nitrate of silver, nitrate of mercury, and nitrate of lead were the only ones which produced any effect upon it, announcing the presence of a muriate and of an alkali; this was further proved by its changing to blue, litmus paper reddened by an acid. The residue was of a yellow colour, weighing at most two or three grains; it had a salish taste, became blackened by exposure to heat, produced a slight effervescence with acids, and formed with the nitrate of silver a yellow precipitate; this precipitate was partly soluble in nitric acid, and the remainder became white.' From this experiment M. Vauquelin concludes that this fluid contains animal matter, ammonia, and the muriate and carbonate of soda. The fluid was obtained from a swamp in the Papal states, and we may, I think, conclude, *à priori*, that were experiments made upon the vapour collected in this manner from the old mangrove fens of the West Indies, the result would be the same, except that in the latter the active products, as animal matter and ammonia, would be found in greater abundance. From the experiments of M. Julia, however, it would appear that the dew arising from swamps differs only from rain-water in containing a small quantity of animal matter. M. Devèze, as well as Brocchi, found no difference between the air in the most pestiferous places and those noted for their salubrity; but all admit that there is a deleterious something which our present knowledge cannot take hold of.

"Poisonous exhalations arise from other collections of animal and vegetable substances besides marsh; and allowance being made for the circumstances with which each is essentially connected, they seem to be identic. The products from both, as far as chemistry can detect them, are similar, and their physical and physiological laws seem to be the same.

"The gases evolved from the decomposition of vegetable and animal bodies, are oxygen, hydrogen, carbon, azote, in different proportions and in different combinations, according to a variety of circumstances under which collections of this kind may exist,—according as the one or the other may be in excess—according to other matters with which they

may be combined, as water or earth—according to the facility with which they have communication with the atmosphere—to the different *species* of animal or vegetable matter of which they may be composed, and to the activity of the causes which produce decomposition. Thus we meet with sulphuretted, phosphuretted, carbonated and carburetted hydrogen, ammonia, deutoxyde of azote, carbonic acid, &c.

"These gases are exceedingly prejudicial to health, and produce death in different ways when introduced into the lungs, and injected into the circulation. It has been supposed, that to one or other of these substances we are to look for the poison of malaria. Such is, however, not the case, for they cannot, under any circumstances, produce the diseases in question. Though some, or all of them, are continually escaping from such a swamp as I have described, and are expanded into the atmosphere, yet, so far from infecting it, they cannot be detected in the air immediately surrounding their source by any means we at present possess. And where some of them, arising from other causes, exist in such quantities as to be appreciable even to the senses, as is the case in the town of Soufriere, we never find them as agents in the production of disease.

"It is a fact pretty well established, that the emanations from swamp are much more deleterious during the night than during the day. The sportsman wades through the stagnant waters and mangrove bushes which cover the surfaces of the West India fens in search of game, with comparative impunity; but long before the sun has disappeared beneath the horizon, he seeks to place himself beyond the reach of their poisonous effluvia, taught by sad experience the necessity of prudence. The reason is obvious: these emanations consist principally of aqueous vapour, produced by evaporation from the surface which contains within it the deleterious principle of malaria. During the day this process goes on rapidly under the influence of the sun's heat. The vapour once escaped is quickly absorbed by the lower stratum of the atmosphere with which it has come into contact; and this body of air, holding in solution these emanations, becomes heated and rarified, and forms an ascending column, making room for the stratum immediately above it, which, in its turn, after undergoing the same changes, is replaced by a third. These miasms

where they have attained a certain elevation, are carried away by the wind."

"During night things are very different. The swamp has an elevated temperature of its own, dependent upon the chemical actions which are going on in its bosom, the products of which are most constantly evolved, and escape at the surface in the form of a vapour. The influence of the sun has now ceased to be felt, and this vapour, do longer dissolved, as in the day-time, hangs in cloudy menses over its birth-place; the lowness of the swamp, and its own gravity, preventing its being dissipated by the currents of air. The surface of the earth, and most of the substances which cover it, as grass and brushwood, are excellent radiators of caloric, in consequence of which they acquire a temperature some few degrees below that of the atmosphere, when they cease to be acted upon by the sun's rays. This vapour, condensed in part by the coolness of the air, is still further so by the leaves and grass with which it in contact, and is deposited upon them in the form of dew. We must not confound this with common dew; it is purely local, and is rarely found at any great distance from its source.

"The baneful effects of marshes are still further confined by an adhesive quality which these emanations seem to possess in a very eminent degree. Air charged with malaria is filtered, if we may use the expression, by its passage through a screen of any kind, as a plantation of trees, the bushes which grow from the swamp itself, or any similar obstruction to its free transition, which breaks and divides its particles. Under these circumstances, the poison attaches itself to the opposing body, and the air escapes purified and innocuous. Marshes which previous exercised little influence on the health of the inhabitants of a town in their neighbourhood, become instantly the cause of epidemics when cleared of their covering shrubs, or when an intervening wood or forest is cut down."

A Manual of Percussion and Auscultation, as employed in the Diagnosis of Diseases in the Chest and Abdomen. By D. SPILLAN, M.D. 32 mo. pp. 88. London: Jones, Aldersgate-street. 1837.

This is a waistcoat-pocket manual for the student and young practitioner. The author is known, by his talents and industry, as the translator of Andral's work,

the London Pharmacopœia, and other productions. He has given a concise account of Percussion and Auscultation, and in so cheap a form that every student may possess it. It is manual well worthy of a place in the student's library. It is one of those medical trifles now in vogue in this metropolis, not only for the use of junior students, but even for the benefit of the practitioners of the old school.

TO CORRESPONDENTS.

Clinicus.—It appears to us that the case is nervous delirium. Sir E. Home, towards the latter years of his life, always took large doses of calomel, repeated according to the violence of symptoms.

Erinensis.—Our Limerick correspondent is decidedly wrong in supposing that Mr. Crampton is in the seventy-first year of his age. We have reason to know that the worthy Surgeon-general has not yet advanced far beyond his fiftieth year, and is still in the fullest vigour.

Pathologist.—We have not seen the royal specimen; application should be made to Mr. Balderson the *procurator*.

Anatomist.—Sir Astley is supposed to have dissected not less than three thousand mammæ; most of which are preserved. Applications for inspection should be made by letter, post paid. A certificate can easily be obtained.

Aspirant.—We do not know the address of the Erlangen Agent, in London. We believe the fee for a medical degree does not exceed £45, if no agent be employed. The sum of no less than £60 has been exacted in more cases than one. The presence of the candidate is not necessary, but it is requisite for the Senatus Academicus to have "attested copies of certificates."

Diamond cut Diamond.—If our humorous correspondent had taken the trouble to examine the printed list of the London College of Physicians, he would have seen Dr. Jewel's name amongst the permissi lately licensed.

Argentum.—We have again to repeat that all letters are returned to the post-office when not post-paid.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

ERYTHEMA.

ERYTHEMA is an exanthema which is not contagious, characterized by slight superficial redness, irregularly circumscribed, and variable in form and extent. All parts of the body may be the seat of it., but it is observed more particularly on the face, chest, and extremities; being usually confined to one of these regions, it may extend to several, and, even in some cases, it may attack simultaneously the entire surface of the body.

Erythema most frequently proceeds in an acute form, and its duration varies from one to two weeks. In some rare cases it is intermittent, when it accompanies a fever which assumes this type, or when it supervenes during the paroxysms of a bad fever; its duration is then most usually proportioned to that of the diseases with which it is developed.

Symptoms.—Without in general being preceded by any constitutional symptoms, erythema appears in spots of greater or less extent; the faint and superficial redness differs from the deep and more deeply seated tint of erysipelas. This redness disappears under the pressure of the finger, to re-appear immediately after. The form of the spots, which is most frequently irregular, is sometimes entirely distinct. The heat and pain, which in general are inconsiderable, are occasionally hardly perceptible. Finally these spots, which are almost always unaccompanied by any tumefaction, are sometimes,

on the contrary, attended by a swelling either of an indolent or painful character, but always more or less circumscribed, which gives to the eruption a peculiar appearance, and constitutes two different varieties.

One of these varieties (*eryth. papulatum*, Willan) chiefly attacks women and young persons. It is principally observed on the neck, chest, or arm, at the back part of the forearm, and over the back of the hand. The patches are of small extent, irregularly rounded, seldom exceeding the breadth of a centime; they are slightly prominent, and, as it were papular. Though red at the onset they soon present a purple tint, particularly at the centre. In the space of from thirty-six to forty-eight hours, the tumefaction diminishes; there only remains the tint, which is on a level with the surrounding surfaces, and which disappear in one or two weeks. At other times, on the contrary, the tumefaction continues, and the patches appear more prominent. (*eryth. tuberculatum*, Willan)

Another variety (*eryth. nodosum*, Willan) is rather frequent. It is observed in children, women, and young persons of a delicate constitution and of a lymphatic temperament. It may be developed in the different regions of the body, but it generally occupies the chin, the arms, and the fore part of the leg. In the majority of cases, a state of general illness, of depression, and some fever, precede by some days, or accompany the appearance of the exanthema. The latter presents itself under the form of red spots, of an oval appearance, a little elevated towards the centre, the extent of which varies from a few lines to nearly an inch in diameter. On passing the hand over these patches, they are observed to be a little raised above the level of the skin, and to form real nodosities; the tumefaction increases slowly, and some days after their first ap-

pearance, small, red, painful tumours are found, which evince a tendency to supuration; but their size soon diminishes, a bluish tint takes place of the original redness; they become soft, and gradually disappear in about ten or twelve days.

Causes.—Erythema may be idiopathic or symptomatic. Idiopathic erythema arises from the more or less direct action of divers external causes on the surface of the skin. Thus it is produced by the repeated friction of two contiguous surfaces of the body, more especially in children and persons of greater or less embonpoint. It is then observed beneath the breasts, in the axillæ, in the groins, at the upper part of the thighs (*intertrigo*, Sauvages). Under the same circumstances it also appears on the buttocks, and at the inner part of the thighs, after violent exertion in walking or riding. Erythema may also be produced by the action of the Sun and of cold, by the contact of fluor albus, of the gonorrhœal or dysenteric discharges, of the urine and feces. It sometimes appears on the upper lip, occasioned by the contact of the acrid fluid which flows from the nostrils in coryza.

Erythema is oftentimes symptomatic of a gastro-intestinal affection of an acute or chronic nature; and then it is during the paroxysms it is principally observed. It often appears in children at the period of dentition. It attacks plethoric persons and women at the critical period. It often comes on after the ingestion of irritating substances, and it is sometimes observed after the use of balsam copaiba.

Idiopathic erythema in general terminates quickly in resolution, in a few hours, or a few days at most. Sometimes slight desquamation takes place, whilst, in some cases, a sero-purulent sweat of a disagreeable odour takes place on the surface of the diseased part, (in *intertrigo*).

The erythema symptomatic of acute affections sometimes disappears rapidly without perceptible desquamation at the time the paroxysms cease (*erythema fugax*). The same may be said of that which is observed in some cases of intermittent fever; at other times it does not terminate till seven or eight days by a slight desquamation.

Erythema may exist with anasarca of the lower extremities. The surface is then smooth and shining and confluent spots are observed here and there, (*erythema læve*).

It precedes and accompanies a number of eruptions, and in these cases it enters

altogether into the particular descriptions of the latter.

Diagnosis.—Not only the other exanthemes, but eruptions also of a different order might be confounded with erythema. Of all these affections, those which present most difficulty, particularly in some cases, are the following:

Erysipelas.—Erythema, which several writers have even considered as a degree of this disease, differs from it however in many distinct points. No mistake, however, could be made, except in cases where it might happen to occupy surfaces of small extent; for the more or less circumscribed spots of the other varieties of erythema could not admit the slightest doubt. Even then the redness which is entirely superficial, the absence of tumefaction, the absence also of pain, which is constant, burning and acrid in erysipelas; the mild course of the disease, and the termination, which is almost always rapid and always favourable, are so many characters which serve perfectly to distinguish it.

Roseola.—In roseola the redness is superficial as in erythema, but it differs by a more or less deep and very characteristic rose tint. *Erythema nodosum*, which alone might perhaps be confounded with the irregularly circular spots of roseola, differs from it in the redness which is never so well circumscribed and in the accompanying tumefaction.

Measles and Scarlatina.—Measles and scarlatina differ from erythema, the one in the irregularly semilunar form of its spots, and the other in the raspberry-colour of the broad patches which characterize it; these two diseases are moreover contagious, and are accompanied by a group of symptoms peculiar to them.

Urticaria.—The *erythema papularum* is the only form which could be confounded with urticaria. But the latter affection differs from it in the greater elevation of its patches, in the absence of the violent tint observed in the papular erythema, in the itching which accompanies it, and in its irregular and oftentimes rapid course.

Lichen urticatus.—This same variety of erythema may be taken for a lichen urticatus; but in this latter affection the papulæ are less broad, more rounded, and firmer; their colour is not near so deep, and, as in urticaria, there is always an itching, which is often very intense.

Syphilitic spots.—These spots may present, at first sight, some resemblance to erythema; but their duration, their

copper or greyish tint will always be sufficient to distinguish them; they are also frequently accompanied by other venereal symptoms.

Prognosis.—The prognosis of erythema is never unfavourable.

Treatment.—Idiopathic erythema promptly disappears on the removal of the causes which may have occasioned it; soothing lotions, warm baths, and proper care constitute the entire treatment. When it depends on the repeated friction of two surfaces, whether in children or in adults, it is necessary to sprinkle on the affected parts some absorbing powder, the power of lycopodium for instance, and to prevent friction as much as possible.*

The treatment of symptomatic erythema depends on the disease which it accompanies; by combating the gastro-enterite of which it may be one of the symptoms, the necessary indication of cure is fulfilled.†

The erythemes, or morbid red spots which frequently appear in women at the critical period, or which coincide with a retardation or suppression of the menstrual flux, require the employment of blood-letting, of diluents, strict regimen, and of the means applicable to the plethoric state

The *erythema nodosum*, though the most serious form requires, in general, no particular means of cure; topical applications are entirely useless;‡ baths, gentle

laxatives, and in some rare cases, small bleedings, constitute the entire treatment.

M. Biett has described another very remarkable variety, which he has called *erythema centrifuge*, and which very seldom fell under his observation.

This erythema, which appeared almost exclusively in young persons, and principally in women enjoying good health in other respects, seems chiefly to affect the face. It commences by a papular point, which takes on an excentric increase, sometimes large enough to attack a considerable part of the surface. It ordinarily appears under the form of well-rounded patches, about the breadth of a thirty sous piece, red and slightly elevated. The edges are very prominent, and the centre is sound and depressed; the heat and redness are very great. This erythema usually leaves a depression on the cutis.

The causes of this variety are but little known. It several times seemed to coincide with dysmenorrhœa. M. Biett adopts a plain antiphlogistic treatment.

Epidemic erythema.*—During the years 1828 and 1829, there prevailed in Paris an epidemic affection (*Acrodynia*), which presented, as one of the most prominent symptoms, an erythema more particularly confined to the feet and hands, and ordinarily accompanied more or less by a thickening and exfoliation of the epidermis. Whether most of the persons who presented themselves at the hospital St. Louis, were more particularly directed thither in consequence of the erythematous inflammation, or whether this symptom was one of the most constant in the epidemic, certain it is that almost all those treated by M. Biett in his wards, and who came under our observation, as also those seen in private practice, presented more particularly this erythema, which was noted among the most prominent phenomena by all the authors who have described this epidemic affection.

After having experienced, for a longer or shorter period, oftentimes a month or

* Should the affection be attended with a serous or fetid discharge, a lotion made with a weak solution of chloride of lime or soda, or of creosote, will be found efficacious in restoring a healthy state of the affected parts. When fresh irritability of the parts exist, Dr. Bateman recommends the use of a lotion consisting of ten grains of bichloride of mercury, and six ounces of lime water.—*Ed.*

† In order to promote the excretions and assist the digestive and assimilating functions, which are very important points in the treatment of this affection, deobstruent and alterative purgatives, mild tonics, with the alkaline subcarbonates and diuretics, diaphoretics more particularly at bed-time, as James' powder, with small doses of calomel and opium, are to be recommended.—*Id.*

‡ "Entirely useless," not only useless, but they may be injurious. Change of air and light diet are of great benefit in the treatment of this variety. The small bleedings here recommended are more

particularly necessary, when the disease appears to be connected with the catamenia, or of any other discharges; and it may be remarked that the bleeding should precede the employment of any other means of cure.—*Id.*

* Besides the *epidemic erythema* here mentioned, M. Alibert describes an *endemic* form of the disease, to which the inhabitants of the north of Italy are subject; and goes by the name of *pallagra*.

more, some indisposition, headache, inclination to vomit, pains in the limbs, and very generally obstinate purging, the patients felt in their hands, and more particularly in the soles of the feet, a sensation of numbness and of formication, and darting pains, which in the generality of cases, increased during the night. These latter phenomena were almost always accompanied by perversion or diminution in the sensibility of the parts affected. Frequently the least pressure, or the slightest touch, was excessively painful; at other times, on the contrary, the sensibility was so dull, that some patients lost their shoes without perceiving it.

Sometimes the sense of touch was almost entirely abolished; at other times the patients could not touch the smoothest bodies without the latter appearing to them to be covered with rough points. This state, which proceeded to paralysis and wasting of the limb, sometimes existed without inflammation of the skin, but most frequently it preceded, or, what was more common, it accompanied an erythema, which, in the majority of cases, presented itself with the following symptoms:—the hands presented, on their palm or surface, a crimson redness, *which disappeared under the pressure of the finger*. Some points were covered with a hard, yellowish, and very thick envelope. Other surfaces seemed, as it were, depressed, and were much more sensitive. An inflammatory areola, about half an inch in breadth, covered the radial and ulnar edges. Frequently on the back of the hand, and more especially on a level with each articulation, erythematous points of a deep red colour were observed. The feet presented a similar appearance. Only the whole plantar surface was most commonly covered with a harder and thicker envelope, more particularly on the toes and heel. This envelope ceased abruptly at both edges, where the skin changes its structure, to cover the back of the foot, and was exactly bounded in this place by a broad zone of erythematous and well-marked patches. The dorsal aspect, in most cases, presented no trace of inflammation. Sometimes erythematous surfaces were found in other parts, and more especially on the bursæ, thighs, in the axillæ, but without any thickened epidermis.

Finally, in some cases, the skin presented a very remarkable black tint (*pytiosis nigra*), whilst in other cases it was covered with eruptions of a different kind. This affection most frequently ex-

isted without fever, or any disturbance in the digestive functions. But in some cases the latter were sensibly changed. In some patients again, obstinate ophthalmia, œdema of the face and extremities, &c., were observed.

The *epidemic erythema* presented nothing determinate either in its progress or in its duration. It sometimes developed itself towards the last stage, but sometimes later; at other times it continued for several months, diminishing perceptibly; frequently it disappeared after some weeks.

This disease, of which the cause remained unknown, prevailed epidemically. It attacked all ages, but more especially manhood and old age; both sexes, but men more frequently than women. It was observed to prevail among the poor more than among the rich.

Blood letting, and more especially the application of leeches to the edges of the feet and hands; plain baths, alkaline baths, and vapour baths, rest and moderate diet, were the only means employed to combat the epidemic erythema with most advantage.

LECTURES ON SURGERY

BY JOHN HUNTER, F.R.S.

Of Humours.

Poisons come nearest to the idea of humours, but still are not what is meant by humours, nor have ever had this term applied to them. Natural poisons will act somewhat as the substances used in foregoing experiments did, that is, either stimulate the whole, or part, to increased natural action; or irritate the whole, or part, into some unnatural action, but which will last no longer than the poison is present. The sting of a bee affecting some more than others demonstrates that there is a greater susceptibility in some for such actions than in others, and that it cannot be imputed to humours in the blood, unless we could suppose a humour similar to the poison of a bee, which then might act without that cause.

I suppose that bugs bite everybody, but some they do not affect and others they do.

This is not so readily demonstrable in the poisons that enter the constitution, though even they cannot be said to be assisted by any humours in the blood.

Other poisons, which we call morbid, produce a specific disease similar to the original; but all this does not come up to the idea of humours. A humour is something which is supposed to go on teasing the constitution if not extracted, and is even supposed to be capable of leaving one part and going to another.

What comes nearest this idea of a humour, but only so in its effects, is a surfeit; yet though its effects may resemble those which are entertained of humours, we know from the mode of their origin that they are not caused by a humour. It is a mode of action taking place in the skin from a stimulus or irritation being applied to the stomach. Drinking cold water when a person is hot will produce it. In a similar case, I have seen inflammation come on in the heart and lungs; but they being less able to bear the action than the skin, it proved fatal.

The method of cure of those diseases supposed to arise from humours gives us no idea of the disease having arisen from extraneous matter in the blood-vessels. Can we form any idea how bark should extract humours, when it rather stops all evacuations? And yet it cures many diseases. Would bathing in the sea cure those eruptions of the skin which are supposed to arise from humours if they were really caused by them? Can we suppose that electricity extracts any humours, when it cures an ague?

It is not easy to account for the blood having been supposed to be the cause of disease, excepting from it appearing in a bad state after bleeding, and this is always a *secondary* symptom. Sometimes, when this diseased state has not been very great, medicines have been given to sweeten the blood.

On Hereditary Diseases.—Hereditary, in the animal œconomy, is applied to properties or peculiarities communicated from the parent to the child.

This principle, according to the common notions, may be divided into two kinds: the transmission of natural properties, and the transmission of diseased, or what I shall call acquired or accidental properties. The last is not hereditary in all its causes, for it always requires an immediate cause before the action will take place; therefore its cause is not similar to the first. To produce an exact hereditary effect, there must be an hereditary cause or causes; and as in all animals of distinct sexes, in their propagation, there are two causes acting to produce a third, the first and second causes

ought to be exactly similar in all their dispositions and powers of action, or else the hereditary effect must be a mixture of both, either in equal proportions, or one side may preponderate more than the other. And this we find to be the case. A true and perfect hereditary cause is such as will produce its effects under all circumstances of life, not requiring the influence of any external circumstances whatever. It is hereditary for every animal to produce its own species, which may be reckoned the first hereditary principle. It is hereditary for every animal to produce the proper sexes, whether hermaphrodite or of distinct sexes. Of these distinct hereditary species we have varieties; and if the varieties, whether original or accidental, are such as can be communicated to the young, they are then hereditary qualities. Of this kind we may reckon shape, both of the whole body or of parts, the varieties of which come nearest to the original hereditary principle of shape. Size is a similar principle, as we see it is common for tall or short persons to have children of their own stature. Colour is another of these varieties, for we find this may become part of the principle of propagation, though not so permanent as some others. This property belongs to the epidermis, with all its appendages, as hair, nails, &c., which is subject to greater varieties perhaps than any other part: and those hereditary susceptibilities for certain dispositions and actions of the mind are perhaps as much hereditary as any other property in an animal.

These are what we may call permanent hereditary principles, becoming part of the constitution, and as subject to be produced in the offspring as any effect in nature. They are such as will take place under every external influence, as season, climate, &c. It is from these varieties being hereditary that we have a continuance of them from parent to child. When both parents are constitutionally alike, they will produce children like one another, and also like themselves, though this is not absolutely certain, for a less marked hereditary principle may arise so as to produce children very unlike the parents. But if the disposition to produce similarity in the children to the parents be different in the two parents, it is impossible to say what the produce may be like.

Hereditary varieties will often last for some generations, and then become extinct, seeming, as it were, worn out. A large

nose shall be continued in a family for several generations, and then cease. A peculiar gait, the turning in of one or both feet, shall in the same way continue hereditary for some generations; and it is very possible that if such children were to intermarry with one another, the hereditary disposition would never be lost.

There are latent hereditary dispositions, which pass over one or two generations, and start up again in the second or third.

Children are generally more like one another than like either parent, because they have the united principles of the parents, which are dissimilar, but united will produce the same results.

Parents may not be at all times disposed to form children alike. This difference seems to be owing in some degree to the time between the births of the children; for we may observe that twins are more like each other than like those born a year or two apart, and these latter more alike than those born at the distance of several years.

If the varieties, as white, black, &c., are not original, they must be monstruities; and then we may say that the disposition to produce monsters continues and becomes hereditary. The white negro, who may be called a monster of the black variety, being supposed to be born of black parents, and being herself white, with woolly hair, is a remarkable instance of the different dispositions of parents at different times. This woman married to a white man, and had three children, one quite black, and the others tawny.

A gentleman had two children, both born with a disposition to exostosis; the son showed it earliest, and had exostosis on each thigh-bone, and indeed an increase of every bone in his body. The girl was little better off. Neither of the parents had any disease of the kind, but gave the disposition to their children by joint operations.

Of the acquired Hereditary Principle.

—In these cases the principle is such as to require accident, or some external cause, to produce the disposition in such as have the susceptibility. In this case the susceptibility only is hereditary; but the disposition and action require the application of external influence before they will appear, and are therefore accidental. The action in this case is generally some disease.

As the susceptibility is in some degree hereditary, the immediate cause has been in some degree overlooked, and the disease has been called an hereditary disease;

but it is impossible for a disease to be hereditary when one of its causes cannot be hereditary. It may be hereditary for a man to be irritable, one man may be more readily put in a passion than another, but no man goes spontaneously into a passion, there must be some violence committed on the mind; and so various are our minds, that some shall be put into a violent passion at a circumstance which would only slightly, or perhaps not all, excite another.

The natural susceptibility for diseased action is so strong in some as to require only a slight secondary cause to put it into action; in others so weak, that it requires great violence as an immediate cause to bring on the effects.

All hereditary dispositions must be more prominent than those that are acquired or accidental; therefore people who have an hereditary susceptibility for any diseased mode of action will in general have it constantly, at least it will not vary so much as some others. It will not be of that kind which has a great tendency to disease at one time and not at another: such fluctuating dispositions cannot be hereditary.

Scrofula is one of those diseases which is supposed to be hereditary; but is only the readiness to fall into this peculiar action, when properly irritated, that is hereditary; and when such a cause does not exist we find no scrofula.

Gout is another disease which is supposed to be hereditary, and there is often great reason in appearance for supposing that it is so. This is a diseased action which perhaps every one is susceptible of; but some fall into it much more readily than others, and this readiness may be hereditary. But this readiness never takes on action by itself; it must have the immediate cause to excite it, which is a stimulus of a particular kind. We find gout attacking people whose parents for many generations have not had it, and often never. We see it starting up in countries where luxury is introduced, where it was never known before. However, there are many instances where it would appear to be hereditary, as in the case of young men of fifteen, the sons of gouty men. But I suspect that this does not arise simply from the father's having had the gout, but from the circumstance that most people who have had the gout severely deserved it, and that children have inherited the disposition for the way of living as well as the susceptibility for the disease, and with more

liable to fall into the disease than children at large.

On this principle of the hereditary nature of diseases, if it be just, every disease under the sun will be hereditary; but many diseases having a stronger visible cause has made the hereditary susceptibility in them to be overlooked. Thus, the small-pox is as much hereditary as scrofula or gout, but from its arising in all cases from poison communicated, and evidently not in a spontaneous manner, is the reason why the hereditary susceptibility has been overlooked. But on our principle the small-pox is as hereditary as any other, only requiring the immediate cause to act to produce it as in any other disease. We may make the same observation with regard to the venereal disease, for we see some persons much more susceptible of this disease than others are, and suffering more severely from it when they get it.

I do not know that we have an instance of observation which proves that the circumstance of a person's having had the disease renders him more liable to communicate that susceptibility to his offspring than if he had only the susceptibility for the disease, without the action having taken place. If it was a fact that the parents having simply had the disease, in some degree entitled their offspring to it, the human species would soon become extinct in those places where such diseases arose; and if the parents having had the disease increased the susceptibility in the offspring, both small-pox and lues would have become incurable by this time. So that the immediate cause, whatever this may have been, does not in consequence of its having had its full effect either give or even add to the disposition for such action.

The only difficulty I find, in stating this as a universal doctrine, is in the case of madness. This is allowed to be hereditary, and is I believe as much so as many, yet I cannot find the immediate cause in many cases. It would appear that the disposition to produce action is so strong as to go into action without the application of an exciting cause. It would be worth while to see whether people in a state of nature ever go mad; if they do not, then the state of mind in the civilized state is the immediate cause.

A gentleman informed me that he had paid particular attention to the diseases of Indians, and that he never heard of an Indian going mad.

On the Effects of Mind on Diseases.

—When on the animal œconomy, I observed that the mind was formed by the senses, as also the will; that the will produced the voluntary actions, but that the mind produced actions both of the voluntary and involuntary parts, which actions are often very irregular and undetermined. On the state of the mind, therefore, the latter will depend, or at least they will change with it, and even the former may be affected by it; indeed there is not a natural action in the body, whether involuntary or voluntary, that may not be influenced by the peculiar state of the mind at the time, and every particular mode of the mind has some parts that are more readily influenced by it than others. The skin is affected by the feeling of shame; the secretion or even the non-secretion of the testicles takes place under certain states of the mind. Palpitations of the heart and quick respirations are brought on by some states; purging and increased secretions of the urine by others.

In voluntary parts we can also perceive the influence of the mind. It often produces actions independently of the will, especially when these actions are begun by the will, and when the mind is affected by a recollection of them; or even contrary to the will. Thus, fear produces a vibratory contraction of all the voluntary muscles, while the will is doing all it can to stop it. Since the mind has such power over the natural actions of the body, we might suppose it would have considerable effect in disease; and this we actually find it has, especially in those who have a strong susceptibility for such actions as the mind can most easily affect. We should naturally expect that it would be diseases principally connected with the nerves that the mind would most affect, though we do find that there are other diseases, with which they appear to have little connexion, that are much affected by the state of the mind; and I believe that it is principally those diseases in which the alteration is in the action of parts, not in their structure.

Minds which are particularly irritable are most subject to such diseases, having the acting part more under the control of the mind, and less under that of the will; also the involuntary powers are more under the influence of the state of mind, as the heart, &c. These diseases are called nervous, and more peculiarly belong to women, who being less acquainted with the real properties of natural things,

are more apt to imagine preternatural ones; and their reasoning powers not being so strong, they indulge the actions of the mind more, and allow it to take possession of the body; for the mind can often prevent diseases of such a nature as are contrary to health, and depend on voluntary actions, of which take the following instance. A woman, aged forty-six, of a good-natured disposition, had been troubled for some years with a drawing of the neck to one side, by the contraction of one of the mastoid muscles: this it was always in her power to prevent, by contracting the opposite muscle, when she sufficiently recollected herself. The right muscle, the one affected, did not contract of itself, unless by some accident she of her own accord contracted it a little, after which it continued contracting till it produced its full effect. When her mind was agreeably engaged she seldom felt it, or when conversing with an intimate friend or reading; but fear and every other unpleasant state always produced it. If she expected to see any stranger before whom she was particularly anxious to hide her defect, had it always more violent than usual. This circumstance of the mind's continuing action when it has once taken it up, is remarkable in hiccup, which is often produced by laughing; thus hiccupping, which is an involuntary action, is produced by laughing, which is a voluntary one. But as the state of the mind is thus capable of producing disease, another state of it may effect a cure: so the hiccup may be cured by producing fear. There are other diseases which a state of the mind may cure, though they have not been brought on by it, as agues have been cured by charms which have been used with a thorough conviction of their being a sovereign remedy. I am apt to suppose that a spider's web, when taken for an ague, cures in the same way, at least in one case; for on giving it without the patient's knowledge, it had not the slightest effect; but by persuading the patient that it was a spider, the effect was produced, at least the disease did not return. Even tumours have yielded to the stroke of a dead man's hand.

It often happens that there is a suspension of some actions in an animal body and those actions return again. Thus, we have epilepsy, which is a suspension of the sensitive principle's actions. It is perhaps impossible to know the cause of these suspensions, and equally so the cause of their return. I am apt to sus-

pect that suspension of natural action becomes the stimulus to the powers to put themselves in action again; or, in other words, the suspension becomes by its continuance a force imposed on parts to act, and they act to relieve themselves. Thus, by stopping respiration we have such a stimulus raised in consequence that we can no longer live without the action, and the action takes place.

I suspect that opium often produces a struggle between the necessity of action and the consciousness of the preternatural suspension, which rather rouses. Death, which is the ultimate suspension of all actions, seems to explain that, as a person seldom dies without a struggle or convulsion. Convulsion appears to me to be an action arising from a consciousness of debility; as if there was an endeavour to act to preserve life, but not being able to preserve it, they give up the contest.

Of Symptoms.—A symptom is a sensible effect of a diseased action. The first mode of sensation is when disease is shown directly, without the medium of any other reference, and is known only to the patient; of this kind is pain. The second is where it is given by a reference to some other sense, as that of touch, smell, &c., and is common to the patient and others; of this kind is the swelling of tumours, the redness of inflammation, &c. The third arises from a deficiency of sensation, and can be known only to the patient himself. It is by description and the second set of symptoms that the practitioner receives his information. Local disease may produce only the first mode of intelligence, as pain; or it may proceed to the second, as inflammation; or the second may be produced without the first, as indolent tumour, not known till felt by the hand.

Pain is a simple sensation which is common to many diseases, and is divided into several kinds, as sharp, sore, numbing, heavy &c. The sharp pain is that produced by cutting with a knife; the sore, from inflammation and ulcers; the heavy, that which takes place in rheumatism; the numbing, from pressure on a nerve. The sharp and sore depend on what I shall call vibration of pain, particularly the latter. The heavy seems to be a continued pain, or where the repetitions are so quick as to appear continued; but probably all of them are owing to a succession of actions of the nerves. We refer all the sensations we can to those senses which give us the greatest intelligence. We call them sharp

pains from their giving the sensations of anything that bites, or stings, as bees, or acids on the tongue; heavy, from their giving us the sensation of bearing a weight on the part. A gentleman who had a hemiplegia said his sensation was similar to an acid on the part, that is, to that feeling on the tongue.

We have often a bad taste in the mouth, or a bad smell; this is not always a sign that the saliva or mucus is altered in its qualities, as it is in salivation from mercury, which appears to be from the taste and smell of the mercury, but it is sometimes produced by a morbid action of the nerves. We have these symptoms, together with ringing in the ears, commonly in beginning of diseases, and probably they arise from the actions of the diseases in the nerves of the part.

Neither susceptibility nor disposition for diseased action can produce a symptom; it must be preceded by action; though I believe that there will sometimes be an unnatural feel in a part before action has taken place, as before a fit of the gout attacking the foot an indescribable sensation is sometimes felt, and when the action takes place the constitution is relieved.

Symptoms are either local or universal. Local, as chancre, cancer, &c.; universal, when they accompany universal diseases, as fever. Local symptoms may produce universal ones, which is a means either of increasing the local symptoms or of curing the disease. Local symptoms will vary according to the nature of the disease; its violence, or its situation, as inflammation, will produce different sensations in different parts. Universal diseases will produce some of the following symptoms: affection of the pulse, which arises from the heart's sympathizing and partaking of the disease; the alterations are very various, as full, strong, weak, small, &c. The secretions are altered, as in fever; the tongue becomes covered with its own secretion, at first white, afterwards brown, or sometimes black, which last colour arises from blood being mixed with the secretion. The tongue also contracts in size, and we have often thirst without its being dry, and sometimes, as in low fevers, very dry without thirst, which last is owing to a diminution of sensation in the nerves, and is an unfavourable symptom. The urine is high-coloured, without sediment, owing to its being retained long in the bladder, from debility of that organ or from blood being mixed with it. The respiration fails,

from debility in the lungs. The heat of the skin is altered from too great or too little action of the vessels. The colour of the skin in some diseases changes, as from white to yellow, in a very short space of time, not from jaundice, the white of the eye not being changed; nor could jaundice be so quick in coming and disappearing; it is probably a change in the rete mucosum of the skin, such as takes place in the chameleon and some other lizards: veins of the skin are enlarged by any tumour seated beneath them; as in hydrocephalus, tumours of the breast or of the uterus during gestation, the veins of the head, chest, or belly will be found enlarged.

The feeling of the part is the first mode of intelligence. Suppose a stone in the kidney; it may produce three symptoms: 1st. Pain in the part; 2d. Vomiting, which is symptomatic; 3d. Bloody urine. Now these symptoms may occur in other diseases, independently of stone; if they are combined, they afford a pretty certain diagnosis of the presence of stone, but any one or two of them leaves it doubtful. These symptoms attend the passing of a stone through the uterus, as well as when in the kidney; and when a stone gets from the ureter into the bladder, the symptoms abate, and a different pain is felt, and this change occurring confirms us in the opinion we had before formed of the existence of a stone.

Anomalous Symptoms.—These are not immediately expressive of the disease, but make the diagnosis doubtful. They are very numerous, taking in all the symptoms which occur from dentition, worms, &c. Many of them are from sympathy, which we mentioned before.

CLINICAL LECTURE

DELIVERED BY

DR. ELLIOTSON,

AT THE

UNIVERSITY COLLEGE HOSPITAL,

AUGUST 3, 1837.

I have first, said Dr. Elliotson, to direct your attention to a case of amaurosis, which was greatly relieved by iodine; we did not know the exact amount of improvement when the patient left the hospital, but it appears to be a remarkable instance showing the efficacy of long-con-

tinued perseverance in the use of iodine; but of course there are many cases of amaurosis which iodine has no power of curing.

Hysterical affections simulating peritonitis—Remarks on the diagnosis—Cure of the hysteria.

The next case is one in which a mistake might easily be made in the diagnosis. It frequently has been committed, but more frequently formerly than at the present time.

Case.—A female, aged twenty-nine, admitted June 6, 1837, married, fruit-stall-woman, father dead, mother living, of scrofulous habit.

Previous diseases.—She was very unhealthy whilst a child; seven years ago she had phrenitis, and typhus fever three years afterwards; she has not been thoroughly well since. Three years ago she had a large ulcer on one leg which seemed to improve her general health, as the latter was much worse when it healed up. After this the gums sloughed, and the alveolar process at the anterior part of the lower jaw, with it the corresponding teeth; this cicatrized. The stomach has been in a deranged state for some time; this circumstance induced her to apply to the hospital for relief.

Symptoms on admission.—A great sense of oppression and of faintness at the pit of the stomach, tenderness in that situation and all over the abdomen, pain in the back and loins, especially on sitting upright, when there is also a dull, heavy, aching pain, and sometimes a lancinating pain in the abdomen; more especially at the upper and left part and epigastric region; a darting pain along the spine; slight cough, no expectoration; sleeps well at night; perspires abundantly; lies easiest upon the back and left side; pulse seventy-six, compressible; respiration thirty-five; tongue slightly furred; breath foetid; appetite very bad; bowels very costive; uterine functions regular.

You observe her chief complaint was the abdominal pains, pain and tenderness all over the abdomen, and at the pit of the stomach. In peritonitis there is pain all over the abdomen; and perhaps also pain at the back and loins, as in this case; but the most remarkable circumstance to be noticed is, the tenderness over the whole surface of the body; this is not met with in peritonitis. By merely pressing down gently the integuments of the chest upon the ribs, there was great pain felt. There was a dry and slight cough, which

also may occur in peritonitis, particularly if the upper part of the peritoneum be inflamed. In peritonitis patients can frequently lie on either side, but easiest upon the back; such was the case here. There was functional disturbance in the stomach and intestines, which is the case in peritonitis; but the pulse was only seventy-six, the urine plentiful and pale, the expression of the countenance did not indicate that the tenderness was of an inflammatory nature; therefore, as soon as I saw her, I ordered a shower-bath and decoction of aloes compound (3ij) twice a day, to have full diet, and to commence taking the carbonate of iron (3ss) in treacle, three times a day. Now, in peritonitis, this treatment would have been highly improper, not only to have ordered the bath and aloes, but it would have been also improper to have omitted the use of mercury, and local or general bleeding. However the tenderness diminished in two days, and she felt stronger than before. She felt cold for a short time after the bath: and when that is the case it should either be left off or the temperature be raised a few degrees: here it was omitted.

17th.—No tenderness, the sensation of faintness gone.

20th.—The tenderness has not returned. She took by mistake five grains of blue pill, three times a day for one day, which brought on headach and giddiness.

On the 25th she was discharged cured, and went out perfectly well. I have before mentioned that such cases as these were treated, and some years since I should myself have treated it, for chronic peritonitis, not being able to persuade myself that there really was no inflammation in the case.

Chorea treated by carbonate of iron.

The next case is also a disease of the nervous system; the former case was a disease of the sensitive part, this is an action of the motor part of the nervous system. In chorea there is no morbid sensibility, but an inordinate degree of muscular action.

Case.—A female, fourteen years of age, was admitted May 16, 1837. Conformation slender, sanguineous temperament, maid of all work.

History.—Eighteen months ago she was in this hospital for chorea, brought on by fright, and was treated by carbonate of iron for three months. The present attack commenced about two months back with involuntary motions of the left

side. In nervous diseases the affection frequently comes on first, and sometimes remains on one side of the body only. The symptoms were irregular; and involuntary motion of the upper and lower extremities, and of the muscles of the head and neck, with frequent flexion and extension of the trunk, and movements of the facial muscles, all interrupted during sleep; no pain; no weakness. You observe in this case what I have so frequently pointed out; there was no local affection, either of the head, chest, or abdomen; the pulse was natural; respiration good. Many persons say this disease arises from a disordered state of the digestive organs; and prejudice is so great, that it is common to refer an obscure disease to that condition of the digestive function, than to take any trouble in investigating its nature; no doubt a disordered state of the bowels may be a cause of disease. sesquioxide of iron (3ss.) in treacle was taken three times a day; full diet.

June 3rd.—The convulsive motions were much less.

June 17th.—Nearly well; nothing particular having occurred requiring daily entry.

June 26th.—Discharged, cured. The treatment at first did not go on so fast as I could wish; therefore the dose of the iron was increased to ʒvj. three times a day, and the effects of this increased dose were directly seen. The improvement which followed was decided. Here you have the fact of a child taking a large dose of iron, and the fact of rapid improvement from its use in this disease.

Dr. Elliotson made some general remarks on rheumatism, saying that the case only illustrated facts which he mentioned at the last lecture, and which he had frequently an opportunity of stating, viz., that there are two forms of rheumatism, one which, in conformity with popular language, he calls "hot," from being attended by an increase of temperature, or made worse by heat and all stimuli; the other the "cold," or atonic, being removed by heat, stimulants and friction. It is of great consequence, says Dr. E., to make this distinction, not only with rheumatism, but in many other diseases; to distinguish the tonic inflammatory form from the atonic or passive form, in which there is deficiency of strength, for there may be great excitement with want of strength, and stimulants do good. These facts are exemplified in delirium; there is "hot" delirium, so to speak, attended by a flushed face, hot and dry skin, quick

and strong pulse, requiring active antiphlogistic treatment; again, there is a cold delirium, with a pale face, cool and moist skin, a quick and weak pulse, which state is relieved by stimulants and opiates. It is the same with vomiting; it may be inflammatory or not; in one kind attended by pain, increased by pressure, relieved by cold drinks, local bleeding, &c.; in another kind, the pain at the stomach is relieved by stimulants, by warm applications, &c. Now it is the same with rheumatism, and it is an affection of parts near to the surface, we can easily judge of the temperature, and consequently judge very readily as to the nature of the affection. Every body, I suppose, knows these facts. I have known them for years, and have been in the habit of teaching them for some years, and have verified them by the numerous cases treated in St. Thomas's Hospital. Yet I understand that a young gentleman was lately found fault with by the examiners at Apothecaries' Hall for having spoken the truth. Mr. David Unwin, a strictly moral and exceedingly steady young man, has favoured me with the following particulars relating to the conduct of some of the examiners towards him. He was asked, what is guaiacum used for? "In cold or atonic rheumatism." "In what?" "In cold rheumatism." "I never heard of such a thing," said the examiner; "Nor I," said another sitting near, and laughing out; "perhaps you will tell us how often you have heard the term used; will you explain what you mean?" "Rheumatism is commonly divided into acute and chronic." "Al! now I know what you mean, why did you not say chronic?" "Because rheumatism when chronic, may still be active, and require leeches, cupping, cold, &c., and guaiacum would be injurious; but if rheumatism is relieved by frictions, heat, &c., the guaiacum would be beneficial. This I call atonic, passive, or cold rheumatism." The person then who sat near him said he thought he got it from some old woman, for he never heard such a term. Here (said Dr. E.) Mr. Unwin showed his information. Every one should know that when rheumatism is chronic it may be active; the mere circumstance of it being chronic does not indicate its cold nature, and that it requires stimulants, as guaiacum. Chronic inflammation of the liver may be active, and as truly active as the acute. And so with rheumatism, whether it last for two or three days or for years. "He thought he got the term from some old woman." Now this, gen-

tlemen, is a personal insult; but I would not speak of it on that account. He was shewn a bark (*cortex cordifolia*). "What is it used for?" "As a tonic." "And what else?" "As a tonic astringent in atonic diarrhoea, or in gargles." "And what else?" "When it is used in agues it is called an antiperiodic." "That's its use; why could you not say so at once?" Now I can confidently assert that bark, at least quinine, for I now never use bark, is employed fifty times as a tonic to once as an antiperiodic, therefore he was quite right in speaking first of its tonic properties, and afterwards of it as an antiperiodic. "Why are quartan agues most difficult to cure?" "On account of their local complications; but I do not know that they are necessarily complicated," was the answer. "On account of the local complication, Sir, is the answer; you ought to have known that." Now by far the greater number of quartan agues, are more obstinate than either quotidian or tertians, independently of any local complications, and simply because they are quartans; they are certainly complicated sometimes, but it is a more chronic disease, having long intermission, and chronic diseases are in their nature more tedious to cure.

He was asked the symptoms of pneumonia. He said the most certain symptom was the crepitant rattle, heard by the stethoscope. "That's all very well to tell the extent of the disease afterwards; go on." "The cough is short, hard, metallic." "What are you talking about hard metallic; go on." "Sometimes there is a febrile state from the commencement, but it may come on insidiously, and exist at first without much febrile excitement, or scarcely any, unless it be combined with bronchitis or pleuritis, as it often is." "You appear to know little about it." "The pulse is hard, bounding, or oppressed; the sputum is distinct, round, and rusty from blood." He was then asked the treatment. "Copious and repeated bleeding, according to circumstances; if the disease still continued, I would either salivate, or give tartar emetic." "Who did you ever see salivate for pneumonia?" "Dr. Elliotson." "In what diseases is mercury most beneficially used?" "In diseases of serous membranes." "Certainly, and is that a serous membrane?" "No, but mercury is beneficial in all acute inflammations." "What dose would you give of tartar emetic?" "From one-sixteenth to six grains." "Whoever gave six grains?" "Laennec

did, and I have seen Dr. Thomson give a similar dose." Now, gentlemen, it is very important to know that pneumonia often comes on insidiously, and here Mr. Unwin showed his knowledge of the subject. Pneumonia is often present when the practitioner is not aware of its existence; it comes on after operations, after severe accidents, and other diseases: the patient dies, and at the examination the lungs are found gorged with blood, a circumstance which was not suspected during life. This can only be found out by a practitioner who is accustomed to the use of the stethoscope. With respect to mercury, it is just as good in inflammation of mucous membranes as of serous membranes. I ask, is it not a fact that mercury is our best medicine in croup, and is not that a disease of a mucous membrane? and in bronchitis? When the examination was over, Mr. Unwin requested the favour to be allowed to leave sooner than usual, at the same time stating that he had been taking medicine for three months, for a scaly eruption on his hands, and that his bowels and head were in an unnatural state. Upon saying this, one person near him exclaimed, "Oh, secondary syphilis; you have been larking; eh?" The result was as he expected; after that gratuitous insult he was left to wait as usual. He was accused of having syphilis; the eruption was one of simple lepra, for which he had been taking dulcamara and arsenic, as I understood; but it was of an inflammatory nature, and I had recommended him to be bled, take mercury, and live low, and he is getting well. What a want of dignity in such conduct! There are some young men who are gay, and think nothing of such things, but there are others who are brought up in strict morality, and to these, such an accusation is the greatest insult that can be offered. Mr. Unwin's feelings, I assure you, gentlemen, were exceedingly hurt by that conduct, as the concluding remark of his communication show:—

"I solemnly declare that this is a faithful account of some parts of my examination. I will refer to Mr. Cribb, surgeon of Bambridge, for any information respecting my moral habits, with whom I have served my apprenticeship, and where I have attended medical lectures."

The next case is one of inflammatory dropsy. I have over and over again shown you that dropsy may occur independently of organic disease, or any local affection. Cases of inflammatory anas-

arca are exceedingly common. I have pointed out that they commonly arise from cold and wet, and the disease generally commences in the face, comes on suddenly; the urine is often not diminished. In this case it was copious, and natural to appearance. I do not care about the state of the urine. When I see that dropsy has come on suddenly, the pulse is strong, no signs of debility or organic diseases exist, then I know it is inflammatory.

Sometimes it is cured by low diet alone or by hydragogue purgatives, and sometimes by bleeding; this case was cured by bleeding. The patient was in the prime of life, and would bear bleeding very well. The blood was bled and cupped, another proof of the inflammatory nature of the disease. Now, gentlemen, what are you to say, when asked by the examiners at the Hall the treatment of dropsy? Are you to state what you know to be truth or not? Here is an account of the examination of one of my pupils the other day, Mr. Jenner, upon this subject. On stating that he would deplete before giving stimulating diuretics in a case of inflammatory dropsy. The examiner (I shall not mention any names) asked how he would deplete? Bleed and purge, was the answer. "What! would you bleed in dropsy?" "Yes; Dr. Elliotson recommends bleeding in inflammatory anasarca, known by its having commonly arising from cold and wet, and the face swelling before any other part, the pulse hard and quick, and on examination some signs of inflammation are discovered in the head, chest, or abdomen." "Did you ever see any patients treated by bleeding?" "Yes; two or three."

(Mr. Jenner would have stated that he had seen many, but dared not say, as he informed me.)

"I am not here to teach you the practice of medicine, but to examine as to what you know; but I would advise you to look twice before you bleed once."

A person sitting at the side of the table said, "If he has seen two or three cases cured by bleeding, it was as many as he would ever see."

"I presume," said Dr. Elliotson, "he will see many such cases when he gets into practice. Now this is a very lamentable state of things. What are we to do as teachers? either I am unfit to teach, or they to examine. Things are come to a dead lock. It might be said, that I should have complained privately to the

examiners; but as this is the conduct of a public and authorised body, in the execution of their public functions, I consider it right that these matters should be brought forward publicly. I consider that we, as teachers, have been insulted. Reformation can only be had by a public examination at the option of candidates. Many who are nervous will not like public examinations I know, and, therefore, it ought to be left to the choice of the candidate whether he will be examined publicly or privately. One of our best informed young men, Mr. George, was examined the other day, and he has written me the following particulars of his examination:—

"I was examined by Mr. —, and two or three other gentlemen came and sat on the opposite side of the table: this they seemed to do less for the purpose of examining me than for that of saying 'Yes,' to questions asked by the gentleman examining, and throwing in occasional short phrases, such as, 'Very large dose, sir,' and discharging their small wit at the expense of the young man who was sitting under the foolish idea that his future prospects in life depended upon the issue of the present examination. I was asked how small doses of calomel acted upon the liver? I said by stimulating the mucous membrane at the orifice of the biliary duct, which stimulation was conveyed along the hepatic and biliary duct, and thence to the lobules of the liver, whereby they are excited to secrete an increased quantity of bile. 'The reply is so absurd that it only shows your ignorance of therapeutics, and of the abdominal circulation.' His companion at the same time made the acute and witty remark, that 'The gentleman had discovered the north-west passage to the liver.' After I had explained the abdominal circulation, the examiner then gave his explanation of the action of calomel, which was, that as it passed along the intestines, it stimulated the terminal branches of the exhalant arteries, and caused them to secrete a portion of the serum of the blood, which blood so altered in quality, was taken to the vena portæ, and thence to the liver, and caused to be secreted a superabundant quantity of bile." You now know what answer to give, gentlemen. This is quite as absurd an explanation as the first—if I were asked such a question, I should say I did not know. It is only vain and absurd to attempt to explain why calomel acts upon the liver, or why the salivary glands, &c.

We do not know why cantharides acts upon the bladder, and elaterium on the stomach and intestines. When the candidate in Molière's *Malade Imaginaire*, was asked before the "Grandes Doctores doctrinæ," "De la Rhubarbe et du seûe," why opium made people sleep, he replied,

"Quia est in eo
Virtus dormitiva
Cujus est natura
Sensus assoupire."

This very properly gave such general satisfaction, that the assembly exclaimed,

"Dignus, dignus est intrare
In nostro docto corpore."

It is only substituting vague hypothesis for truth. He was asked what dose he would give cream of tartar in? "Two drachms with a scruple of jalap and ginger." "That's too large a dose, Sir." Whilst his companion expressed an opinion that "he could get through any body's bowels with two scruples or a drachm, and the quantity of jalap mentioned."

Now, gentlemen, dropsical patients frequently cannot be purged effectually with less than an ounce or more of cream of tartar. I have often been obliged to give an ounce and a half, two and even three ounces. There is no rule for doses, but their effects and non-effects; a good practitioner will never consider the size of his doses, but the effect they produce.

He was then asked:—What is the name of inflammation of the mucous membrane of the intestines?" "Really, Sir, I forgot the name, but allow me to give you the symptoms." "Certainly, Sir." The symptoms were described. "Well, Sir, you have omitted some of the most important symptoms." They were recapitulated, and I added, "that the pulse was quick, but neither so quick nor so hard as in inflammation of the serous membranes." "Well, Sir?" I said, "I was not aware of any other important symptom." "The pain?" "There is very little pain usually, and that a pricking or a smarting pain." "No, Sir! the pain is very great, and at each evacuation; and the fæces, Sir, are there any?" "Certainly, Sir, but they are very watery." "No, Sir, they seldom appear, and when they do, they are in hard scybala." "You don't know Sir, said the Examiner, "that you are talking of dysentery." "No, Sir, I thought you asked me simply, inflammation of the mucous membrane of the intestines." "Well, Sir, dysentery is the same thing." "Now, dysentery," said

Dr. E. "is by no means the same thing, there may be inflammation along the whole course of the intestines, and the symptom described by Mr. George, but in dysentery there is something besides inflammation; the fæces are retained, there is tenesmus, and the stools are mucous and perhaps bloody. Mr. George declares, that this is a true account of parts of his examination, he also gives the concluding remark of his Examiner. "Well, Sir, I will recommend you to the Court for your certificate, but cannot say you have done yourself any credit by the way you have obtained it. It is evident that you have spent your time in idleness, and probably in dissipation, and have now been learning a few things within the last few weeks. I would recommend you to go over every branch of your studies again." Mr. George, gentlemen, is a highly informed young man, last session he obtained the gold medal in my class, and his answers are admirable. They prove him to have a full acquaintance with the principles and practice of medicine. He has not lost a moment night or day, and has studied so hard that I was obliged to order leeches to his head, and implored him to sleep longer and study less. Some time since, I sent the answers of one of my gold medallists for insertion in the *Lancet*, as a specimen of the kind of answers, but they were too long to be inserted, however, the *Annals of Medicine* have inserted the first answer, (see last number;) they were admirable answers. "I do not give questions which may be answered from mere mechanical memory, but which give the candidate an opportunity of displaying his knowledge upon particular points. Now what is to be done under this state of things? I must teach the same thing again next winter. I cannot distort the facts which occur in the hospital. Some change or reformation must take place, if these statements are true, and let them be disproved. It is generally understood that our best pupils pass the worst examinations at the Hall, while those who only "grind" for a few weeks, and get up particular questions, are sure to receive the compliments of the Court.

THE ANATOMIST.

The spermatic chord is composed of the vas deferens, the spermatic arteries, veins and nerves, and absorbents; all of which are connected to each other by fine

cellular tissue, and are enveloped by a fascia and the cremaster muscle. The chord, thus formed, extends from the epididymis to the internal abdominal ring, where its constituents separate from each other.

Corpus pampiniforme, is the name given to the venous plexus, formed by the spermatic veins after these vessels have escaped from the testicles.

The vesiculæ seminales are two oblong flattened bodies situated at the interior fundus of the bladder, behind the prostate gland, and on the outer side of the vasa deferentia. Each seminal vesicle is about two inches long, and consists of a long tortuous membranous tube convoluted on itself, the small excretory duct of which joins its corresponding vas deferens.

The prostate gland is a flat conoidal body, the base being posterior corresponding to the vesiculæ seminales, the apex anterior corresponding to the vesical extremity of the urethra. It is distinguished into three lobes; two lateral, large and united in the medial line, their union being marked by a slight groove; and a third or small tube situated in the angle between the two lateral lobes, towards the base of the gland. The prostate gland is firm and resisting to the touch, and composed of numerous follicles, with minute ducts, which unite to form larger tubes, the openings of which, ten or twelve in number, are on the under surface of the urethra, on either side of the verumontanum.

Cowper's glands are two small oblong-round bodies, placed before the prostate gland (hence also called anti-prostate glands), and continued between the layers of the triangular ligament of the urethra. The duct of each gland having run a course of about an inch, opens into the urethra a little anterior to its bulb.

THE PENIS.

This organ, the shape of which is familiar, consists of two long cylindrical bodies, named corpora cavernosa, and a body named corpus spongiosum, which contains the urethra, all these parts being connected together and surrounded by the superficial fascia of the common integuments.

The corpora cavernosa, are two cylindrical bodies, united to each other in the mesial line; they are composed of a cellular structure, containing several veins and the arteries of the corpora cavernosa, derived from the pudic artery, all of

which are enclosed in a strong fibrous investment.

Each *corpus cavernosum* commences by the *crus penis*, which is the narrowest part, and which is attached to the rami of the ischium and pubis. At the symphysis pubis both crura unite, forming the chief part of the body of the penis, and terminate anteriorly in an obtuse point, to which is intimately attached the glans penis.

Septum pectiniforme, a partition, imperfect as its name implies, which corresponds to the mesial line, and marks the division of the corpora cavernosa.

The urethra is a membranous canal, extending from the neck of the bladder to the extremity of the glans penis, its length and width varying according to the erect or collapsed state of the penis. In the latter condition its length is from seven to eight inches long, and its calibre about three or four lines. It is lined by mucous membrane, and is distinguished into, 1st, the prostatic portion which is from an inch and a quarter to an inch and a half in length; 2nd the membranous portion which is about half an inch long; 3rd. the bulbous portion which is scarcely an inch, and 4th. the spongy portion which occupies the remainder of its length.

The corpus spongiosum urethrae is a cellulo-vascular tube surrounding the urethra and occupying the under mesial line of union of the corpora cavernosa; it commences in the bulb of the urethra and extends along the canal to its extremity where it terminates in the glans penis, the bulb and glans penis being merely expansions of this structure.

Upon exposing the mucous surface of the urethra by an incision, we observe, 1st. a slit-like contraction at the orifice, 2nd. behind this a dilatation, called *fossa navicularis*; 3rd. the constant diameter of the canal until we arrive at the bulb where it is again dilated forming 4th. the *sinus of the bulb*; 5th. the narrowest part of the canal which corresponds to the membranous portion; 6th. the dilatation corresponding to prostate gland, and 7th. a contracted orifice at its termination in the bladder. In the prostatic portion of the urethra a prominent fold of mucous membrane, called *verumontanum* projects from its under surface, and presents in its centre a large lacuna, the *sinus pocularis*, the orifice of which is directed forwards. On either side of the verumontanum the prostatic sinuses are situated. Upon the upper surface of the

urethra, from the orifice to the bulb, are the openings of numerous mucous follicles, directed forwards, the largest of which is about an inch from the orifice and is called, from its size, *lacuna magna*. The ducts of the seminal glands already described in connection with the genito-urinary organs open on the under surface of the urethra. The orifices of Cowper's glands open a little anterior to the sinus of the bulb, the common ejaculatory ducts on either side of the verumontanum, and the ducts of the prostate in the prostatic sinuses.

The superficial fascia, which envelops the penis, is derived from that of the abdomen, and terminates at the corona glandis. It is strong where it passes from the linea alba upon the dorsum of the penis, forming the suspensory ligament, but is exceedingly delicate and loose upon the body of the organ.

The skin of the penis is remarkably thin and loose, and extending for an indefinite length beyond the organ, is reflected inwards, and is ultimately attached to the corona glandis; the loose fold thus formed is called the *prepuce*. From the corona glandis it is continued along the glans until it becomes identified with the mucous membrane of the orifice of the urethra, having first formed a fold which lies posterior and inferior to this opening, and is called *frænum puputii*.

Glandulæ odoriferæ are a number of small sebaceous glands which surround the corona glandis, and which lie beneath the skin.

THE FEMALE ORGANS OF GENERATION.

The ovaries are two ovoidal bodies placed, one on either side of the womb, in the duplicatures of the peritoneum called the broad ligaments of the uterus. Each ovary, enveloped by a white fibrous membrane, consists of a pulpy brownish-grey substance, highly vascular, and containing from fifteen to twenty minute vesicles, each of which is composed of a thin membrane containing a viscid yellowish fluid; these are called the *Graafian vesicles*.

The Fallopiann tubes are the excretory ducts of the ovaries; each is about four inches in length and is contained in the broad ligament, one extremity being attached to the superior angle of the uterus into which it opens by a small orifice, (*orificium uterinum*), the other being free and surrounded by a fringed slip of peritoneum, (*corpus fimbriatum*), in the cen-

tre of which is the peritoneal aperture (*orificium superius*.)

The uterus is a hollow organ of a pyriform shape and is distinguished into the *fundus*, the *body*, and *cervix*. The fundus is superior and posterior and receives at either angle the fallopian tube: the body is intermediate between the fundus and the neck, the latter being inferior and anterior and surrounded by the vagina: at the extremity of the neck is a small elliptical opening surrounded by a thick margin, which from its resemblance to the mouth of a tench, has been called *os tencæ* as well as *os uteri*. The cavity of the uterus is small compared to the thickness of its walls, and is of a triangular shape; its superior and outer angles presenting the orifices of the fallopian tubes, the inferior angle presenting the os tencæ. The uterus is placed between the bladder and rectum.

The vagina is a membranous vascular tube, extending from the neck of the uterus to the external outlet, where it is continuous with the surface. It is composed of mucous membrane surrounded by cellular tissue, a vascular network, and the sphincter vaginae muscle; its length is about four inches, its breadth one, but being very distensible these measurements vary. Its mucous membrane is thrown into transverse rugæ on its anterior and posterior surface, and is studded with the orifices of numerous mucous follicles. The colour of the mucous membrane varies, at the external orifice being red, and of a grey and sometimes marbled colour as it approaches the uterus.

The mons veneris is a soft adipose eminence, situate on the upper and anterior part of the pubes, covered by common integument, which, in the adult, is thickly set with hairs.

The vulva is the fissure extending from the mons veneris to the perineum.

Tha labia magna are large folds of the integuments which bound the vulva on either side, and unite below in a crescentic edge (*the fourchette*.)

The clitoris, a small oblong conical body, placed between the upper extremities of the labia. It consists of a structure similar to the corpus spongiosum urethrae in the males, and arises by two crura from the pubes; these unite to form its body, at the extremity of which is placed a red protuberance, called the *glans clitoridis*, over which is thrown a loose fold of integuments (*the prepuce*.)

Meatus urinarus is about half an inch below the clitoris.

Labia parva, or nymphæ, are two red crescentic folds of mucous membrane, enclosing numerous erectile vessels; they descend, one on each side, from the prepuce of the clitoris, and are lost about the centre of the vulva.

The Hymen, when it exists, is a crescentic fold of mucous membrane, surrounding the sides and inferior orifice of the vagina.

The carunculae myrtiformes are small reddish bodies surrounding the orifice of the vagina, and which are the remains of the hymen.

THE MAMME

Are two in number, situated at the anterior and superior part of the thorax, and connected to the great pectoral muscles by a capsule of condensed cellular tissue. Each of these conglomerate glands of a hemispherical shape, consists of numerous acini, very small and united together so as to form lobules. From the acini proceed minute tubes, named lactiferous, these unite, forming larger ducts, all of which converge towards the root of the nipple, and expand into conical sacs from which smaller ducts proceed and open on the surface. The nipple is a conical process, surrounded by a brownish areola, and composed externally of the integuments, which are very thin, and internally of the lactiferous tubes, together with numerous blood-vessels, from which the nipple derives its property of occasional erection.

The London Medical

AND

Surgical Journal.

Saturday, August 19th, 1837.

THE GOWER STREET UNIVERSITY THAT WAS TO BE, BUT IS NOT TO BE.—THE APOTHECARIES' COMPANY AND DR. ELLIOTSON.

Nothing can exceed the terror and annoyance at present displayed by the Gower Street Joint Stock Company, at the disappointment of not having attained No. 20.

the power of granting degrees in medicine, which they most unblushingly assure students they actually possess; and also at having been opposed by the NORTH LONDON SCHOOL OF MEDICINE, and SYDENHAM COLLEGE. The immediate effect of the first of these schools was, to lead to the change of name of the North London, to the University College Hospital. The renowned and notorious North London,—far-famed for spilling of blood, and for the performance of desperate operations declined everywhere else, but good theatrical exhibitions, well calculated to amaze and astound green-horned students, and to disgust and horrify every well-informed medical practitioner,—lost its fair name; "But what's in a name?" A vast deal. The name, University College Hospital, was intended to deceive medical students, and lead them to believe that the University College in Gower-street, is the New, or Metropolitan University at Somerset House, not King's College, however, in the Strand, which alone possesses the power of granting medical degrees in London. That is what is in this particular name. Yet to this hour do the authorities in Gower-street impose upon students, by assuring them that the University College has the power of granting the Degree of Doctor in Medicine. The name, University Hospital, is therefore not without a meaning, and there is something in that name.

The second effect of the establishment of the NORTH LONDON SCHOOL OF MEDICINE, and of the SYDENHAM COLLEGE was, that the fees of the first being about one-third, and those of the second one-half those of the Gower-street School, *alias* the real Simon Pure, the New Metropolitan University, it was necessary to oppose the rival schools by enlarging the fee at the North London Hospital of the

old Pharmacopœia, *alias* University Hospital of the new. On this barefaced and shameful proceeding we animadverted in our last number, because the Governors of the North London, *alias* University Hospital, had offered their wares at less than half the price of the old and corrupt institutions, which was a laudable proceeding on their parts, but one by which they attracted a vast number of student's from other schools. As soon, however, as the two schools already mentioned were announced, their fees being so much less than those of the ultra-liberal institution in Gower-street, it was decreed that all students who did not pay the large and most exorbitant fee in London to the said mock liberal establishment, were to pay £10 more for hospital attendance than those students who had. The effect, however, of this sapient law will be the very reverse of what was intended to embarrass the rival schools, and to enrich the Gower-street far-famed London University College, as will appear from the following facts :

The perpetual fee to the medical classes in the University College, is	£72	15	0
The hospital fee to College pupils	26	5	0
Perpetual fee at the North	99	0	0
London School of Medicine	35	0	0
At Sydenham College	45	0	0

Thus the North London School is £37 10s., and the Sydenham College, £27 15s. less than the Gower-street College for the same course of education

The great difference in amount of fees for the same amount of medical instruction, naturally induces many students, to whom money is an object, to pay a low fee instead of nearly treble the sum ; but to correct this great evil, a sum of £10 more is exacted from each student who adopts this plan, by the liberals of Gower-

street. Now this sum is insignificant, and will never draw students to the extravagantly dear school. But unless the Middlesex Staff be demented, they will at once lower their fee, as is rumoured, to that of the old North London, or University College Hospital, increase their pupils tenfold, and leave the Gower-street Hospital nearly deserted. The constant squabbles in the London University College, which led to the retirement of Professor Quain, and in some degree to the death of Dr. Turner, have given a fatal shake to the stability of that institution. Added to these, the scenes at the North London that was, the illiberal raising of the fees, the foolish and knavish change of the name to University College Hospital to deceive pupils, are powerful causes which must injure, if not destroy, an institution, ostensibly well devised, duplicitously established, and really a mockery of the boasted diffusion of knowledge system.

That some of the Professors are men of talent there is no doubt, but not a whit more talented or able instructors than in the various other schools of medicine in the metropolis. That their fees are exorbitant, like those of all the large schools, cannot be denied any one ; and that their tergiversations and system of humbug are equal to those of the old corrupt institutions is now to manifest to be questioned. That the surgical operations at their hospital are more frequent than in larger charities is a statistical fact that must be admitted, and totally at variance with the modern and universally received axiom of all scientific surgeons, "the best surgeon is he who performs the fewest operations." The science of practical medicine may be estimated by referring to Dr. Elliotson, the Professor's able defence of it, against the Apothecaries Company Examiners, which will be found in ano

ther part of this day's Journal. That the Rhabarbarians are a century behind the present state of science is a fact, for not one of them, with the exception of Dr. Merriman, is known in the annals of science. Nevertheless it by no means follows, as one our correspondent's well observes in another of our pages, that their worships are to be satisfied with doses of half-ounces three times a day of carbonate of iron, half-ounce doses of hydriodate of potass, and other equally bold doctrines of our contemporary, Dr. Elliotson. We agree, however, fully with him, that the conduct of the said Rhabarbarians is too often rude, indecent, and tyrannical, of which we have been repeatedly assured by some of our own pupils. But this is to be expected from persons who become examiners on the sole ground of their having been members of the Company of Druggists in Blackfriars, and who, as mere traders, very seldom have received a liberal or gentleman-like, or even a good medical, education. Nevertheless, they are generally tolerably civil, except to the pupils of certain teachers or schools, whom they sometimes annoy, frighten, insult, and reject. We therefore fully agree with Dr. Elliotson that the present system of examination needs thorough reform, and that the Rhabarbarians deserve castigation for their conduct towards those who apply for their licence. Moreover, their insolence in expelling Mr. Ridout and Mr. Bacot from their board, on account of accepting the honourable offices of Senators in the New Metropolitan University, shows their animus towards that institution. They know full well that it will annihilate them in a short time, and hence their virtuous and Quixotic rage against it.

ENTOMOLOGICAL SOCIETY.

AUGUST 7, 1837.

Mr. STEPHENS, President, in the chair. Several persons were announced, amongst which was a programme of the ensuing meeting of the society for the cultivation of science in France, to be held at Metz.

Mr. Hope exhibited some coral beads, which had been perforated in all directions by the larvæ of a small species of *Ptinus*; and also some wood, perforated by the same. Mr. Raddon also exhibited some larvæ of the *Caragena Cubicularis*, the insect destructive to wheat ricks.

Mr. Bainbridge exhibited a singular moth in a state of monstrosity (*Polia nebulosa*), in which a fungus had grown out of the eye, which terminated in two projections. He had also some specimens of the *Ybonemueda padella*, a small moth which had been very injurious to an apple tree at Lambeth, the leaves having been almost destroyed by it, and in some instances altogether. The cocoons are formed inside the leaves, which soon become covered with the webs of the insects, and turn yellow. The webs are so strong that in many cases the young leaves cannot burst through, but many of the large leaved apples escape, and pear trees are rarely attacked. The same insect has been also very injurious in France, where the hedge-rows are much lower than in this country.

Mr. Yarrell exhibited the wood leopard moth, which had attacked a sycamore branch, explaining that the insect eats a hole in the interior, when it evidently turns round, as it is found with its head downwards.

Mr. Bowerbank exhibited some specimens of cork, which had been greatly injured by a species of *Termestes*. The vessel in which the cork was brought over to the docks had contained a cargo of horns, hoofs, and bones, from which they were produced. A great deal of injury had also been done to the masts, which, it was feared, would have to be replaced, and it was even apprehended that the vessel itself was destroyed. They had already commenced their ravages in two localities—Whitechapel and Saffron-hill—where they attacked the posts in all directions, and were very common in Wapping. He suggested for their destruction essential oil of almonds, the vapour of which would probably be effectual. In one case the injury was so great

that a vessel was sunk for some time in order to exterminate them.

Mr. Westwood read an original letter from the celebrated Drury, dated July 1786, containing a notice of an entomological excursion, which was considered interesting, as exhibiting the state of entomological science at that time. He also read a paper on some individuals of the family of Pausidæ, in the cabinet of M. Bouquet, found at Senegal, and the Cape of Good Hope, and interesting as they exhibited the extensive geographical distribution of the species.

A description was read from Mr. Waterhouse of two new species of Coleoptera.

Mr. Westwood detailed at length the result of an entomological visit to Paris, and exhibited several interesting specimens which he had brought over from the collections of that place. One was a larva of the ant lion, and which he had kept alive by feeding it exclusively on flies. In some respects its habits differed from the accounts given by Latreille in the formation of its hole. This it makes in very fine sand, walking backwards with its hind legs, and thus excavating the sand, which falls upon it where it lays, completely hidden, with the exception of its two mandibles. He also exhibited a species of *Coccinella*, which is herbivorous and found on a species of *Brionia*; a new species of *Haleroides*, found on a *Chelodonium*, where the eggs are deposited in a circle on a white downy substance. The larvæ are covered with hair, and when they alight on any naked body, cause a great deal of irritation, which is produced by the hairs being all serrated, or like saws. There was also a species of *Osmea*, not known in England, which is found on stone walls, where it attaches itself so strongly that it can only be removed by a stone or hatched. The most interesting of all was now an insect, exciting at present a great discussion amongst Entomologists in France, the *Bombyx Mori*, or silk-worm, from its being subject to a disease called *Muscadine*. This is a parasite which gradually envelops the whole body in a white fungus, and destroys the worm, commencing at the segments, whence it absorbs the fatty matter, and by which means much injury has been done in the silk-worm houses. The mischief is produced by the explosion of a fungus, which is taken in at the spiracles or pores of the skin, as has been proved by M. Audoin, who has inoculated several worms and beetles with it. There

was also a specimen of the *Scolytus Pygmæus*, and insect which attacks the oak, and which has latterly proved so injurious, that 80,000 trees in the Bois de Vincennes have been destroyed by it. This has in France, excited some discussion, it having, as in this country, been imagined to be produced by heat and other causes. A deal of the injury is produced by their cutting holes round the stems of the young branches, which causes them to fall down, even by a trifling wind. In conclusion, Mr. Westwood made some remarks on the progress of entomology in France, which he stated to be in advance of this country, there being more working cultivators, and the collection at the Jardin des Plantes, being greater than our own national collection. M. Audoin had recently delivered a course of fifty lectures on entomology, at the Jardins des Plantes, which were well attended, many ladies being present. To this establishment were connected five persons, devoted to entomology, whilst in the British Museum there was but one. The Society of Agriculture had just offered a very considerable sum, as a premium for the discovery of a means for preventing the attacks of *Muscadine*. He also mentioned the plan of M. Vallery for the destruction of the *Calandra Granaria*, in which the object was to give constant motion of the grain, in large cylinders made of metallic meshes, perpetually revolving, when the insect creeps through the small holes and falls to the ground.

The meeting adjourned to Sept. 4th.

ZOOLOGICAL SOCIETY.

AUGUST 8, 1837.

RICHARD OWEN, Esq., F.L.S., in the chair. A letter was read from Mr. Harvey, corresponding member of Teignmouth, accompanying some preserved Radiatæ and fish from the Devonshire coast. Amongst the former was a *Comagilla*, a rare specimen, to obtain which he had dredged in five fathoms of water; the feelers and tubercles on the back being quite perfect, and the spawn on the feelers giving it a curious appearance. There was also a *Tubularia Indivisa*, the largest ever heard of, found in a pool of water at the recession of the tide, about twenty clusters being observed growing round its edges. This is one of the most beautiful of the *Polophera*, and is also found in the

river Dart. He however found it impossible to domesticate them as he had done with the *Caryophylla*, from not being able to imitate the action of the tide, and the specimens he obtained lived but two days. Some curious notices in natural history were appended, one of which was, the fact of seeing a carrion crow kill a duck, after having first drawn it out of the water, by trampling upon it; and other, having noticed a young cuckoo fed by a wry-neck.

Mr. Ogleby described two new species of his new genus *Chemas*, which now consists of four, the Chamois of the Alps, the Chamois of the Himalayas, and the two in the room. It differed from the goat, by having a naked muzzle, and by the more singular fact of having four teats.

Mr. Gould described several birds from Mr. Darwin's collection. Of these were a raven, from California, very much like that of Europe, but differing in its elegant form, the tail, wing, and bill being longer, and the hue more beautiful, from which circumstance he named it *Corvus Splendens*. The others were two specimens of *Ortyx*, which he named *O. Guttatus*, from the spotted breast; and the *Dendroceta*, or wandering crow of authors, so called from its restless disposition, differing more particularly from the magpie in Arboreal feet, shorter tarsi, &c.

HISTORY OF THE ENTOMOLOGICAL SOCIETY.

The study of insects has always been a popular and interesting department of Natural History, and its votaries have early associated together for intercourse and the friendly communication of information. The first society for the purpose was known under the name of the Aurelian Society, which was held at the Swan Tavern, in Change-alley: the date of its formation is unknown, and the laws and regulations of the society have not descended to us, but we learn that it existed in 1745. On the 25th of March, 1748, the great fire which happened in Cornhill burnt down the place of meeting, together with the society's valuable collection of insects and books with all their regalia. The society was even sitting at the time, yet so sudden and so rapid was the impetuous course of the fire, that the flames beat against the windows before they could leave the room, and many of them

left behind their hats and canes. This loss so much disheartened the members, that although they several times met for that purpose, they never could collect a sufficient number to form a society, so that for fourteen years there was no meeting. Another society under a similar name was established in the year 1762, arising, phoenix-like, out of the ashes of the old, and four years afterwards it was in existence, as appears from the fact, that in 1766 Mr. Moses Harris, a well-known Entomologist of that day, dedicated to it his work called *The Aurelian*, but we have no further accounts left of its progress.

In the year 1780 another society was established, called the Society of Entomologists of London, the minute book of which was carried down to the first week in August, 1782, at which time appears to have discontinued its sittings. The cabinet of two of its members, Mr. Tinly and Mr. Bently, were rich in *Lepidoptera* and *Coleoptera*. Another association called the Aurelian Society was proposed by the late Mr. Haworth, the author of *Lepidoptera Britannica*, under whose management it was carried on. The collection belonged to this distinguished entomologist, and was to be given up to the society as soon as it should consist of twenty members, which number it never reached. Its objects were to form a complete and standard cabinet of the entomological productions of Great Britain; to ascertain their names, uses, and distinctions, the places and the times of their appearance, food, economy, and peculiarities, and to point out to the public the readiest and most desirable method of destroying such as possess properties which are inimical to the welfare of mankind. Any person desirous of becoming a member of this society was to be approved by every member of the society at the time being; and was also required to give up one specimen of every species of his own collection which the cabinet in the society did not possess. The elected member was to receive in return, duplicate specimens from the society's collection, or money if he preferred it. By these means (observing the rules) the Aurelian cabinet must ultimately arrive at the standard of perfection, and the separate collection of every member of the society will gradually increase both in numbers and value. But unfortunately neither the society nor the collection ever attained perfection, as the former was dissolved in 1806, and the latter returned

to Mr. Haworth. The Entomological Society of London arose the same year out its ashes, and consisted of nearly the same members. No member was compelled to give up unique specimens to a general collection, but a small collection was formed, principally by the generosity of Mr. Haworth. This society made more progress than any of the preceding; it met regularly, and published three volumes of its transactions, the last of which appeared in 1812, after which the death of some members, and other defalcations, brought the society into considerable trouble, and the regular meetings were abandoned in the following year, 1813. The Entomological Society of Great Britain was formed out of its ruins, and was a non-subscribing society, lasting only two years, and then merging into the Zoological Club of the Linnæan Society of London.

An association for the prosecution of Entomology was again formed in 1825, under the title of Entomological club. This was also a non-subscribing society, consisting of eight members, with no power to increase the number. Since its establishment two vacancies have alone occurred, each of which was instantly filled up by the election of another member, and the club has continued to meet every month from the day of its establishment. In the winter of 1831-2, it was agreed at a meeting of the club to publish a "Quarterly Magazine," the management of which was undertaken by the members present, which was to be open impartially to all contributors, no preference being given to the members of the club. The first number of the work entitled, the *Entomological Magazine*, was published on the first of September, 1832, since which it has appeared every three months, with the utmost regularity, treating not only of Scientific Entomology, but devoting a large portion of its pages to the history of insects, as connected with agriculture and horticulture.

The Entomological Society of London was formed in 1833, its first meeting being held on the 4th of November, at its rooms, at 17, Old Bond-street, where about fifty members assembled, the chair being first taken by J. G. Children, Esq., F.R.S., who proposed the election of the Rev. Mr. Kirby, the venerable patriarch of science and entomology, as President. Its first scientific meeting was held on the 2nd of December in the same year, and succeeding meetings have been held on the first Monday of every month from

that period to the present. It has been much more extensive than any of its progenitors, the number of members in November 1834, amounting to 127, including most of the leading entomologists of the present day. Their transactions had also accumulated to such an extent that the first part was published in that month, embellished with seven plates, two other parts having subsequently appeared.

THE RIPENING OF FRUITS.

From the Gardener's Gazette.

A prize having been offered in the year 1821, by the French Academy of Sciences, for a proper elucidation of this important and highly interesting subject, three papers were received; one of which, written by M. Berard of Montpellier, gained the prize, and was afterwards published in the *Annales de Chimie*. M. Berard's memoir is exceedingly long and turgid; the following summary of useful facts is, therefore, presented to the readers of the *Gardener's Gazette*:—

Fruits do not act on the air in the same manner as leaves do: the results of the action of the former (both in light and darkness) are at every instant of their formation and growth, to suffer a loss of carbon; which, combining with the oxygen of the atmosphere, forms carbonic acid. *This loss of carbon is essential to the ripening of the fruit*; for, if the latter be placed in an atmosphere deprived of oxygen, the function of throwing out carbon will become suspended, the *ripening stopped*, and if the fruit remain attached to the tree or plant, it will dry up and die.

Fruits which are enclosed in shells, however, may and do ripen; for the membranes which form the husk are naturally permeable to the air: indeed the communication between the external and internal air is so free, that both have always been found to be of uniform composition; that is, when analysed, the atmosphere within the shell has furnished the same relative quantities of oxygen and nitrogen as the air we breathe.

When fruits separated from the tree (even though capable of completing their own ripening) are placed in atmospheres or media deprived of oxygen, they will not ripen: the power of ripening, however, in such case, is only *suspended*, and may be induced to act, or be re-esta-

blished, by placing the fruit in an atmosphere capable of taking carbon from it. If the fruit, however, remain too long in the de-oxygenated situation, it will have lost the power of ripening: even although it preserve nearly the same external appearance.

From these facts the inference is plain, but highly important, viz., that most fruits, and especially those which do not require to remain long on their parent trees, may be preserved for a considerable time; and thus their utility and the pleasure which they afford be prolonged. The most simple process consists in forming a paste of lime, sulphate of iron and water, placing the same at the bottoms of glass or stone bottles, or jars, and then introducing the fruit pulled a few days before it would otherwise have become ripe. Such fruits, however, are to be kept from the bottoms of the bottles or other vessels, and as much as possible from the other: at the same time care must be taken to close each bottle or jar with proper corks and cement, either with or without bladders or tin covers, according to circumstances. Persons at all acquainted with chemistry, will perceive that fruits thus placed, are situate in an atmosphere entirely freed from oxygen (which has been absorbed by the paste) and, consequently, that they may be preserved for a longer or shorter space of time, according to their nature:—peaches, apricots, prunes, and several species of plums, from *twenty days to a month*;—pears and apples for full *three months*.—If either of these fruits be withdrawn from their confinement, after their respective periods, and be exposed to the air, they will ripen extremely well; but if these periods be much exceeded they will undergo partial alteration and will not ripen at all.

It is well known that when ripe fruit is long exposed to the air, it will rot and decay; in such cases the fruit first changes the oxygen of the surrounding air into carbonic acid gas; and then the same gas is evolved from its own substance in large quantity. Indeed, the presence of oxygen gas is necessary to the rotting or decay of fruits; for, when it is absent a different change takes place. When the fruit cannot ripen except on the tree, its ripening is not caused by any chemical change of its substance, whilst still *green*; but by the change or addition of *new substances* furnished to it by the capillary vessels of its parent stem; and it is a remarkable and well ascertained fact, that *when fruits*

appear to have lost the acid taste and qualities which they possessed in their unripe state, it is because that taste is hidden by the large quantity of sugar they have received during the progress of ripening.

In those fruits which ripen *after separation* from the tree, likewise, the quantity of sugar is found considerably to increase: in such cases, however, it must be formed at the *expense of the substances previously composing the fruit*. Gum, lignin, and water, are the only substances present; the proportions of which diminish during the process: it is, therefore, natural for us to conclude, that it is those portions of these substances which have *disappeared*, that have been converted into sugar; and as the *lignin* contains the greatest quantity of carbon, we must conclude that it is from it, the oxygen takes the carbon in order to form carbonic acid,—a change so essential in the ripening of fruits.

It is difficult to suppose that in those fruits which ripen early on the tree, *all the sugar* should be sent into the fruit from the plant; it is much more probable that the substance of the fruit acts upon the air—or *vice versa*,—and thereby forms sugar, like those fruits which have been separated from their parent stems; but not in sufficiently large quantity to render them *identical in quality*. In such cases, it is necessary, that recourse should be had to the tree itself, to complete the process of ripening.

In conclusion, it remains to be stated, that the alteration which the *lignin* undergoes during the process of ripening, or *saccharification*, continues during the decay of the fruit, under any circumstances. During the process of decay, the *lignin* becomes brown, and its decomposition, as well as that of the gum and the water, occasions the formation of comparatively large volumes of carbonic acid gas. The sugar, also, (if any exist) becomes decomposed at this time; and, to its *disappearance*, in a great measure, is to be attributed the peculiar taste of decayed or rotten fruits. The sugar, during its decomposition, likewise, doubtless gives rise to the formation of carbonic acid; a great part of which, combining with the hydrogen evolved from the decomposing water, forms *carburetted hydrogen*, which is the main source of that ill or miassmatic taste and smell, so characteristic of vegetable putridity.—C. MACKENZIE.

SITTING OF THE FRENCH INSTITUTE OF THE 31ST OF JULY.

Monsieur Savart, Dulong, Becquerel, and Blainville, were appointed a committee to examine the essays for the great prize on physics. The problem to be resolved is, to determine, by anatomical and physiological research, what is the mechanism of sound in those animals which are capable of producing it.

AGRICULTURAL ECONOMY.—*Ravages of Insects that destroy the Vine.*—It will be remembered that the academy nominated, at its last sitting, a commission to repair to Argenteuil, and examine into the disasters caused there by a species of insect which destroys the vines. Messrs. Dumeril and A. Hilaire visited the place, and went over an extent of ground of a league in length, and half a league in breadth. All the vines which covered this space were entirely desitute of leaves and grapes, and nothing is to be seen but vine props supporting blackened stalks that are almost in a state of atrophy, owing to several sorts of insects, among which the first place must be assigned to the pyralis, of which Monsieur Duméril presents the Institute with specimens of the caterpillar, chrysalis, butterfly and egg. The presence of all these metamorphoses, and, above all, the deposit of eggs on the leaves of the vine, indicate that the pyralis is continually reproduced, and that in consequence it would be difficult to destroy it with fire, as is generally done with other insects. Monsieur Duméril gave notice of his intention of concerting with his colleagues MM. St. Hilaire and Dumas, on the means of preventing the return of this scourge.

METEOROLOGY.—*Falling Stars in the Mauritius.*—Monsieur Louis Robert, who has for a long time inhabited the Mauritius, and occupied himself with meteorology and astronomy, addresses from a journal kept in that country an extract relating to shooting stars. The coincidence between the appearance of these luminous bodies in an isle of torrid zone and those which have been observed at the same time over a great part Europe, is not without interest. Towards 3 o'clock in the morning of the 13th November, 1832, during calm and somewhat cloudy weather, there was seen, from all parts of the heavens where there were not clouds, and especially towards the zenith, at some degrees to the south, a great variety of shooting stars, which traversed the hea-

vens in all directions. The number was so great that it was impossible to count them. Their courses were not in straight lines, as those of shooting stars generally are, but they described all sorts of curves in the sky. This phenomenon was at its height about four in the morning. A little before the rising of the sun, but few of these meteors were to be seen. The mercury of the barometer was at its usual height, and the thermometer of Réaumur was two degrees lower than for some days preceding.

ORGANIC CHEMISTRY.—*Researches on Sulpho-naphtalic Acid.* A paper by Monsieur Regnault.—In 1836 Mr. Faraday had obtained two isomeric acids by heating ordinary concentrated sulphuric acid and naphthaline. According to this chemist, both ought to be composed of one atom of naphthaline and of two atoms of sulphuric acid. Messieurs Liebig and Wohler, having employed anhydrous sulphuric acid, obtained only one acid, resembling, in composition, the two acids of Mr. Faraday, which, combined with baryta, gives a soluble salt. Monsieur Regnault having repeated in his turn these experiments, obtained only a soluble salt, after heating the sulphuric acid and the naphthaline to seventy or eighty degrees. His sulpho-naphtalic acid is soluble in water and alcohol, and forms, by evaporation, a crystalline deliquescent mass. Its taste is highly acid and metallic. Submitted to the action of heat, it melts between eighty-five and ninety degrees, and is decomposed at about 120 degrees. It is composed of twenty atoms of carbon, twenty of hydrogen, eight of oxygen, and two of sulphur. The sulpho-naphtalate of baryta is composed of one atom of baryta, two atoms of sulphur, five atoms of oxygen, twenty atoms of carbon, and fourteen atoms of hydrogen, which correspond to one atom of hydro-sulphuric acid, and two atoms of naphthaline, having lost an atom of hydrogen, which has combined with the atom of oxygen of the sulphuric acid to form water.

PALEONTOLOGY.—Monsieur Geoffroy St. Hilaire gives in a paper "On the changes produced at the surface of the earth," and which appear to depend originally and necessarily on the pre-existent, incessant, slow, and successive variation of different and consecutive ambient mediums of the terrestrial globe.

DR. ELLIOTSON'S ATTACK
ON THE
SOCIETY OF APOTHECARIES.

To the Editors of the London Medical and Surgical Journal.

Gentlemen,—I trust to your well known impartiality and love of justice to give insertion to the following observations. In the *Lancet* of last week is a long report of part of a clinical lecture delivered by Dr. Elliotson and headed, "SPECIMENS OF THE MANNER IN WHICH THE MEDICAL STUDENTS ARE EXAMINED AT APOTHECARIES HALL; WITH COMMENTS, BY DR. ELLIOTSON. The arrogant and self-sufficient manner in which Dr. Elliotson thrusts himself, at this particular season, before the public, cannot but create feelings of disgust and contempt in the minds of every rational member and student in the profession.

The two-fold object Dr. Elliotson evidently has in his rash and shallow charges against the Worshipful Company of Apothecaries is very apparent. First, He wishes to make an impression on the members of the New Metropolitan University at the expense of the Apothecaries Company; and second, finding that the Medical session is fast approaching, the *experimental professor of the practice of physic in the falling and jobbing school of Gower Street*, feels that a good part of his income, which he has been in the habit of deriving from the pupils of the University College, will be materially diminished by the presence of Dr. Ryan and Dr. Marshall Hall, who are to lecture next session in the immediate vicinity of Gower Street; the former at the North London School of Medicine, the latter at Sydenham College. In order then to bring himself before the public in the capacity of a moral, conscientious, able, and indefatigable teacher, Dr. Elliotson with a hope of catching the malcontents amongst the medical students on their arrival in town next October, puffs himself off at the expense of the Apothecaries Company, trumpeting forth to the country, "I am DR. ELLIOTSON, the professor of the practice of medicine of University College, I INVITE (?) you all to see MY practice, for "I am sir oracle, and when I speak let no dog bark!" Justice shall be done you! and notwithstanding all the grievances we have received at the hands of the Apothecaries "I must, NEXT WIN-

TER, go on teaching as I did the last!" The speaker should have added "and I shall be happy to receive your fee for attendance on my discourses, which is only £9 perpetual.

Gentlemen, although I admit that much reform is required at Apothecaries Hall, particularly in the method of examination, yet I must say that the ipse dixit of any public or private lecturer should not be taken by any court of examiners as a proof of the candidates abilities and pretensions to practice, and much less the ipse dixit of so young a man, both in practice and years, as Dr. Elliotson. Young aspirants in general are led away by novelty, and to gain notoriety usually deviate from the safer paths of practice which older heads cautiously follow.

"Fools rush in where angels fear to tread."

Suppose, for instance, the Apothecaries Company had asked the *abstemious* Mr. David Unwin, the *timid* Mr. Jenner, or the *extraordinarily industrious* Mr. George,

Pray Sir, what is the dose of the carbonate of iron!? or what dose of creosote would you administer!? or what shape blister would you apply to the organ of philoprogenitiveness in the case of a working man who had too large a family!!!! or what are the diseases in which animal magnetism is of use!!!! or what is the dose of spiders web in intermittents. What would have been the answers of Dr. Elliotson's pupils? "I pause for a reply!"

I am Gentlemen,
your constant reader,
A LOVER OF MY PROFESSION.

REVIEWS.

A Clinical Treatise on the Endemic Fevers of the West India, intended as a Guide for the Young Practitioner in those Countries. By J. Evans, Esq. M.R.C.S. London: J. Churchill, 8vo. pp. 309, 1837.

The great importance of this work induces us to notice it very fully for the information of all interested in the study of the formidable diseases of which it treats.

The author continues his account of Malaria as follows:—

"These vapours are clearly heavier than the atmosphere; they always travel upon the ground. and are incapable of rising to

any considerable height, perpendicularly, though they are found travelling up hills of moderate elevation, the ascent of which is very gradual; and this holds good, from whatsoever source they may have arisen. Whilst excavations were making at the Cimetiere des Innocens at Paris, this poison was found in the cellars of some of the neighbouring houses, in such quantities, mixed up with other gases, as to produce asphyxia in those exposed to them; and of those who recovered from the first effects, many died from malignant fevers produced by its absorption into the body.

"Though we must come to the conclusion, that we know nothing of the nature of this poison, we must not, on that account, deny its existence, nor its identity in every case, from whatever source it may have risen. When we study its physiological effects on man, or some of the lower animals, we shall still farther be convinced of this truth, that in no respect does it present any other difference than that of intensity, or perhaps some slight modifications arising from its source, its producing causes, and the substances with which it may in different cases be combined."

Our author next proceeds to explain the physiological effects of malaria, and his remarks will be perused with interest and instruction.

"This subject may be divided into two heads. First, the effects of marsh effluvia expanded through the atmosphere on the mass of an acclimated population. Secondly, the effects produced on individuals by this poison in a concentrated form.

Effects of Malaria on an Acclimated Population.

"These effects are not the same in all countries, for each climate has its own temperature, and other causes which powerfully influence those of malaria. The people of Holland have not the same character and appearance as those near Rome; nor do the latter resemble altogether the inhabitants of St. Lucia.

"The inhabitants of marshy countries, where the temperature is moderate, present the following appearances:—The skin is pale, livid, or yellow, the eyes dull and heavy, the movements of the body slow and languid, the eyelids and face puffy and somewhat swollen, or shrunk and wrinkled at an age when they ought not to be; the abdomen large, the extremities small, shrunk, and wanting

consistence in the muscles; the sensation both of pleasure and pain seem deadened; common events produce little effect, exciting neither joy nor sorrow. They present the lymphatic, or, as it was formerly called, the leuco-phlegmatic temperament, in its greatest development. Cadaveric inspection shows us chronic engorgements or morbid changes of structure in some or all of the viscera. Acute inflammations are rare, but living in an unwholesome atmosphere, they never enjoy health; they are always valetudinarians. How can it be otherwise, attacked as they so frequently are by intermittent or remittent fevers, which though so slight as to be treated by the unfortunate beings who have served a long apprenticeship to suffering, with indifference, nevertheless ultimately produce premature old age and death? They suffer from neuralgic affections; sciatica and tic-doloureux are common; their blood is thin and watery, giving rise to ulcers of the legs and scurvy.

"As we approach the tropics, though the lymphatic temperament still obtains, we find it combined with a greater excitability of the nervous system; and within these regions are added irritability of the skin and of the abdominal viscera. There is a strange mixture of indolence and love of excitement: a wish to be roused from the listlessness of every-day life, but requiring a powerful stimulus to effect it. Slight causes produce affections of the nervous system which terminate in death. Colic, followed by paralysis of some part of the body, is common; and hysteria and other diseases of this class are frequently combined with the ordinary disorders of the country. We can account for this only by admitting a peculiar modification of the ordinary morbid agents, or a peculiar idiosyncrasy in the people.

"When acclimated individuals are exposed to the emanation from marsh in a more contrated form, or in a greater quantity than their powers are capable of resisting, they are attacked by the same diseases as the unacclimated.

"Differences in the manner of, and situation in life, influence the temperament of the inhabitants, and consequently their diseases. The population of St. Lucia consists of English, French, Creoles of both white and mixed races, and negroes. The better classes, who live well, drinking good old wine and eating food both nourishing and easily digested, preserve a temperament more of

sanguineous; and though occasionally attacked with fever or affections of the abdominal organs, are not subject to those chronic engorgements of the viscera which I have mentioned. Some of the poorer French or their descendents, white or coloured, who are badly fed and naturally abstemious in their mode of living, taking only small quantities of an inferior red wine mixed with water, present examples of a developed lymphatic temperament, and their diseases are of that class. Dram-drinkers of all races are subject to organic lesions of different viscera in a chronic form, and to derangements of the nervous system; they are liable to fevers, and when attacked generally sink under a train of ataxic symptoms.

"An English gentleman of a sanguineous temperament married a French lady. He was attacked with a mild intermittent, which was cured by diet and demulcent drinks. Fancying that his former method of life produced his disease, he determined upon living very abstemiously for the future, and his resolution was strengthened by the advice of his wife and her family. Madeira was exchanged for a common poor French wine, which he took diluted in large quantities of water; animal food, for the indigestible vegetables of the country, and a small proportion of fish. This system was continued for some time, until his abdomen and fat began to swell; to combat which he discontinued his wine, took large quantities of tisanes, several clysters, and a smart purge twice a week. In about a month he came up to town, and I saw him with my friend Dr. Drivon, when he presented the following appearances:—Anasarca from head to foot, effusion into the cavity of the peritoneum. He was sitting up, his back supported by a chair, the body bent slightly forward; his breathing, short and rapid, consisting of a succession of gaspings for air, could not be performed in any other position. Percussion of the chest impossible, from the immense effusion into the cellular tissue; neither the pulse at the wrist nor the stroke at the heart could be felt, for a similar reason. By change of diet this patient recovered and returned to England, where I lately saw him in rude health, and effectually cured of tisanes and abstinence.

"By abstinence from a sufficient quantity of nutritious food and a moderate allowance of good wine, instead of dropsy we occasionally find that some painful neuralgic affection arises, and is only

made to subside by returning to the former manner of life.

"Dr. Levacher, in his "Guide Medical des Antilles," describes a peculiar kind of dysentery occurring in negroes or other people who have passed their lives in the neighbourhood of marshes, which he denominates, from its combination with other symptoms, "*scorbutic*." It may be added that where these dysenteric symptoms are not found, others arising from the same cause occupy their place.

We are next informed of the effects of malaria in a more concentrated form on individuals, and caves are given in illustration which abound with interest.

"Two ways of examining this subject present themselves to us; the first by observing its effects upon men and animals exposed to its influence; the second by experiments made on those animals which, like man, suffer from these emanations.

"An European, or a native, after a long residence in a temperate and healthy climate, arriving in St. Lucia, complains of a feeling of weight in the atmosphere, —a something which resists the wish for exertion or exercise. Both his mind and body are oppressed; his intellect is clouded; his spirits are low and desponding, and all pre-existing love of enterprise vanishes. If his residence be protracted he has slight febrile movements, which come on regularly or irregularly, not sufficiently severe to prevent him pursuing his usual avocations, but which, nevertheless, are sufficient to induce him to throw himself upon a sofa, and require a powerful effort of resolution to combat. In this manner his body may gradually accommodate itself to the climate, but he may consider himself fortunate if he escape so easily; in general, particularly if he be guilty of any imprudences, he feels restless at night, and can only sleep during the cool of the morning; he feels out of sorts; has pains in the back and extremities, as if from fatigue; he complains of head-ache, sickness, and nausea; and if these symptoms are not attended to immediately, suffers what is vulgarly called an attack of seasoning fever.

"When the constitution is affected by malaria in a still more powerful manner, the effects are often immediate, and I will describe them as they occurred to myself. I had occasion to visit an estate in the neighbourhood of Castries about midnight, and my road obliged me to pass the swamp which lies to the north of the town. There was a lovely moonlight,

the sky was unclouded, and a heavy dew was falling. On approaching the swamp I was sensible of an extremely disagreeable odour, arising from its emanations, and from the dank and foul vegetation on its surface and in its neighbourhood. I then perceived a peculiarly unpleasant, but indistinguishable taste in my mouth and pharynx, which produced slight vertigo, nausea, and even efforts to vomit. On my arrival at the estate, which was shortly afterwards, I took a glass of hot punch, with the hope that it would allay the nausea; I was, however, mistaken, for it was immediately rejected, and an ague came on, which obliged me to go to bed, where I remained until the afternoon of the following day. After a profuse perspiration I was enabled to ride to town, though still very unwell. At night the symptoms returned with such severity as to require a bleeding from the arm and leeches to the epigastrium; by these means the paroxysm subsided eighteen hours after its commencement, and a return was prevented by the free use of the sulphate of quinine. Both before and since I have passed this swamp at all hours without inconvenience, except from the unpleasant smell which always existed. I have also twice passed the Pontine Marshes at night, at a time when fever was raging in the Campagna, in Rome, Velletri, and Terracina; the only effect I could perceive was a slight odour, not unlike champagne.

"The two following cases were related to me by my friend Dr. Chevalier, of Martinique, but who at the time they occurred was practising in St. Lucia:—About eight o'clock in the evening two boatmen, after finishing their day's work, before returning home, were occupied in hauling their canoe high up on the beach, close to the most dangerous part of the swamp mentioned above, when they perceived immediately to windward a small cloud of vapour gradually approaching them, and in a short time they were enveloped in it. One of them fell down, apparently in a state of asphyxia, and the other, was so affected as to be unable to render him any assistance. The vapour passed away quickly, and the one who had been the least incommoded recovered sufficiently to look after his companion, whom he found lying in the mud, apparently insensible. He continued in this state only a short time, and gradually became sufficiently well to be led home. In the course of the night Dr. Chevalier was called to see him, and found him

suffering from an intense ague. The surface of the body was cold, the countenance expressed great anxiety, the pulse was small and scarcely perceptible, the patient was insensible to surrounding objects, and in a state of coma, only interrupted by severe convulsions. The cold stage continued altogether about three hours, and as reaction took place the convulsions subsided; but the coma continued, and alternated with delirium. There was occasional vomiting of mucosities with great effort and apparent pain. Pressure on the epigastrium made the patient wince and contort his countenance. About eighteen hours from the commencement there was remission, or rather a slight mitigation of symptoms, with a partial return of consciousness; it continued only a very short time, and was followed by another paroxysm, equal in violence to the last, except that the cold stage was scarcely perceptible. The patient died about forty hours from the period of exposure. The body was examined whilst warm; the blood was found fluid, and a small quantity of troubled serum was effused between the arachnoid and pia-mater on the surface; the lungs were somewhat engorged, and the stomach intensely inflamed, containing about two or three ounces of blood in its cavity.

"The other man never suffered inconvenience; he said that the vapour had no perceptible smell; that it was warm and moist, like steam, stopped the respiration for a moment, and produced a sense of faintness and trembling of the whole body.

"In the year 1826, a schooner put into St. Lucia, with three men ill, out of a crew of four men and a boy; two of them were dangerously ill with all the symptoms of yellow fever, and one died; the third suffered from a gastro-enteritis of a mild form and remittent type. They were attacked two days previously to their arrival. The vessel was from Bermuda, loaded with onions, most of which were rotten, and emitted an insupportable smell.

"Mr. Taylor, after the hurricane of 1817, being then harbour-master of the port of Castries, contracted with the agent for Lloyd's to get afloat a vessel which had been thrown high up among the mangrove bushes, to the north-east of the town. As she lay fifty or sixty yards from the water's edge, even at the highest tide, this object could only be accomplished by cutting a canal from the vessel to the carenage. The appearance of the swamp as evinced by the canal, I have already described;

it remains for me now to mention the effects produced upon the workmen, which I shall do, as near as my memory will allow me, in the words of Mr. Taylor himself. A number of negroes were employed at the commencement, but they abandoned the work to a man, declaring that they could not support the stench. As there were several foreigners in the town at the time, eighteen of these were engaged being principally Spaniards and Portuguese, but the undertaking was abandoned, when nearly two-thirds finished, for want of hands. The men fell ill day after day, and the greater part of them died; they first complained of faintness and vertigo, then the feet and legs began to swell and be inflamed, and the swelling and inflammation quickly extended above the knee; fever came on, and death ensued in two or three days."

A Treatise on Painful and Nervous Diseases, and on a New Mode of Treatment for Diseases of the Eye and Ear. By A. TURNBULL, M. D. Third Edition. London, 1837.

The fact of this work having now reached a third edition in so short a time from its first appearance, is no inconsiderable argument in proof of its merits. The subject of which it treats is one involved in so much obscurity, that any light which can be thrown on it, cannot fail to be received with gratitude by the profession. The inductive method adopted by our author, and to which the modern improvements, as well in medicine as in the other departments of knowledge, are, in a great measure, to be referred, induce us, *a priori*, to judge favourably of the merits of the book. Perhaps it might look like hypercriticism, were we to object to certain abstraction introduced into the very first page, such for instance, as "disordered state of the nerves." Such abstractions involve hypothesis, and hypothesis, when gratuitous, has ever proved to be the bane of science, and is totally at variance with the inductive method of proceeding. We do not like to hear of such a thing as "Communicating a healthy action to the nervous system,"—to us it appears to be neither more nor less than nonsense. These little blemishes, as we at least are disposed to consider them, we regret the more, as by their appearing at the very commencement of the book, they may be calculated to disparage its merits, and to make an unfavourable impression on the reader's mind.

In the former editions the author confined his observations to the use of Veratria; in the present, he has submitted to the public his experience of the powers of Delphinia and Aconitine. He gives the following account of the way in which he first became acquainted with the powers of Veratria in the case of *tic douloureux*, and other nervous diseases. We shall give it in his own words:—"My general habit is to make experiments upon healthy persons. I rubbed upon my arm for a few minutes, an ointment consisting of two grains of veratria and a drachm of lard, which caused great heat and tingling. At these sensations I was much astonished, and expected either redness of the skin, vesication, or eruption to follow, but to my great surprise nothing of the kind took place. The ointment was washed off with soap and warm water, which increased the heat and tingling: about an hour afterwards these were followed by an agreeable cool sensation. Finding no injury to my health from it, I repeated the application upon the arm, when a sensation, similar to that produced by electricity or galvanism, ensued; and on passing my finger rapidly over the part, an electric feeling followed its tract. These new sensations immediately attracted my attention, and their long continuance and powerful impression on the nerves of sensation, without redness, blistering, or destructive action being produced upon the skin, led to the idea, that I might, with safety, try the veratria externally in nervous diseases."

Our author employs the term *electro-stimulation*, to express this combination of heat and tingling, or electric-like feelings, and any substance producing these sensations he calls *electro-stimulant*.

Chap. I, treats of the *external application of veratria in tic douloureux*. Veratria may be used in the form of ointment, embrocation, or plaster. He lays great stress on the necessity of attending to the directions given for using it. The hand he directs to be kept moist with the application, and it should be moved with considerable speed, but not lightly. The time during which it should be used cannot, he says, be defined, "as it must be continued until as much electro-stimulation has been produced, as shall be sufficient to remove the paroxysm." By which we suppose the author means to say, that it must be continued as long as any pain continues to be felt—we like plain English. He recommends the substance to be used twice a day as long as

the disease continues, and then for a week after the cessation of the paroxysms, and afterwards to be gradually discontinued; and if the intervals of the paroxysms are not lengthened after the application has been continued four or five days, it should be increased in strength, or changed for another alkaloid, "as a repetition of the same application daily, without lengthening the intervals, soon fails to cure the disease." We do not half like the reason assigned by our author for changing the alkaloid and substituting another; however, who can know better than the doctor? He states facts, of course, and facts are stubborn things.

The expense of purchasing veratria for external use, induced our author to institute experiments in order to ascertain whether it might not, with safety, be administered internally. In the first experiment instituted for this purpose, he gave a guinea-pig half a grain of veratria, which, he tells us, "had no apparent effect, except producing an uneasy sensation about the mouth and throat, but there was no evacuation from the bowels." Its not acting on the bowels was a thing that any ordinary person might see; but to be able to ascertain the fact of its producing "an uneasy sensation about the mouth and throat," required an observer of no ordinary acumen.

Our author cautions us against giving the veratria in a liquid form, in consequence of the acid and insupportable sensation which its solution produces on the mouth and pharynx. Dr. Turnbull here takes occasion to question the correctness of Magendie's opinion with respect to the action of veratria. Mr. Magendie asserts in his formulary that veratria is principally serviceable in cases where it is desirable to effect a prompt evacuation of the bowels, whilst he, on the contrary, uses it to stop diarrhoea, and that with decided advantage. Had the doctor reflected for a moment, we feel inclined to think that he would soon see the discrepancy between him and Magendie was more apparent than real, and that, according to the Homeopathic doctrine, in which some truth may be found amidst a great quantity of rubbish, a medicine whose primary effect was purgative, may be advantageously and successfully employed to check diarrhoea. With respect to the circumstance of a sluggish state of the bowels being induced by the internal use of veratria for some days, it not only does not militate against Magendie, or for the doctor, but it has quite the contrary effect.

The doctor remembers the old adage—"after a storm comes a calm."

In the next part of his work, the doctor cites several cases to show the efficacy of veratria in tic douloureux; we shall present our readers with an analytical selection of the most important of those cases;—

Case 1.—A lady, fifty years of age, has been affected for the last thirty-six years with tic douloureux in the cheek, and in the forehead above the eye-brow, on the left side. From the commencement she has had a paroxysm generally once a week, and at no time does she remember the interval to have been greater than fourteen days. Her sufferings during the continuance of the attack have been extreme, and have compelled her to confine herself to bed until its termination, and it has never lasted a longer time than two days. In the intervals, however, she has been perfectly free from pain, and her general health has been tolerably good.

She had a paralytic affection of the levator muscle of the upper eye-lid, and of the left side of the face. Morphia, strychnine, and other means had been used to a great extent, but without any other effect than to induce debility. She was directed to rub over the forehead and side of the face an ointment made of twenty grains of veratria to an ounce of lard, till every uneasy sensation was gone. In about fifteen minutes this effect was produced: but the paroxysm made its appearance within two hours, and by a renewal of the friction for a few minutes, it was extinguished instead of continuing two days as usual. After this there was an interval of perfect ease for ten days, when the attack returned, but not violently. On this occasion the same plan was pursued as in the preceding paroxysm. From this time the patient had only one or two very slight accessions, which were cut short by the use of the ointment for a few minutes, and the disease entirely left her.

The disappearance of the paralysis simultaneously with the tic douloureux, is not the least remarkable feature in this case.

Case 5.—A lady, twenty-five years of age, had been labouring under tic douloureux for the last seven years, the site of which was the right supra orbitary foramen. The duration of the paroxysms was from sixteen hours to two days, and the intervals from ten days to three weeks, but when a paroxysm came on in a shorter time, it has generally, in two or three days been followed by another.

Small doses of acetate of morphia had been giving during the paroxysm, which sometimes caused it to cease immediately; if however this effect was not produced, all the symptoms became worse. Purgatives, and subsequently large doses of carbonate of iron, were then prescribed, without any benefit, when the veratria was commenced. At the commencement at one of the accessions, she rubbed over the eye-brow and forehead of the affected side, an ointment made with twenty grains of veratria to an ounce of lard; and after the friction had been continued for about twenty minutes, the paroxysm was cut short. During the interval she was directed to apply an ointment made with morphia and lard, in the same proportion as the other, twice a day, in order to prevent a return of the attack, but without producing the intended effect, for it again made its appearance in ten days.

In order to make a decided impression on the disease, an ounce of ointment, containing forty grains of veratria, was prescribed for use whenever the pain should come on. In a few minutes after its first application, the symptoms became much increased; they continued for about two hours and then subsided, leaving no trace of the affection behind, nor did it return.

Veratria in Neuralgia.

Case 7.—A gentleman, aged thirty-five, of a spare habit of body, subject to nervous feelings, and accustomed to sedentary occupations, has for the last seven years been seized with excruciating fits of pain, confined to the right half of the head, and returning at the end of every third week. A short time before each attack he suffers much from restlessness irritability, his pulse becomes more frequent, and his memory impaired; and after its cessation he does not return to his usual state of health for two or three days.

He was then directed, during the paroxysm, to make use of frictions with veratria ointment, over the seat of the pain; he first applied it to the forehead, and one rubbing was all that was requisite to remove the pain in that situation, but it still continued with unabated violence in the remainder of the affected region. To this part he was also ordered to apply the ointment, and the pain there, in like manner, yielded to one application. No return of the symptoms has taken place, and he is now in good health. This patient also laboured under considerable palpitation of the heart, which, with the

hemicrania, was entirely removed by a few frictions over the left side, for five minutes every night, with an occasional aperient pill.

It is not improbable that the aperient pill had some share in producing the favourable result in this case.

Veratria in Affections of the Heart.

Dr. Turnbull has found veratria beneficial in certain heart affections, viz., angina pectoris, nervous palpitation, and in the distressing symptoms of hypertrophy of the heart. In angina pectoris the veratria ointment, or embrocation, must be rubbed over the region of the heart, and along the affected arm for a quarter of an hour twice a day; and besides this, whenever there is a paroxysm, the applications must be continued until the pain and difficulty of breathing are removed. In nervous palpitation the application need not, in general, be continued for more than five or ten minutes, once or twice a day, according to the severity of the affection. In hypertrophy the whole front of the chest must be well rubbed with the application ten minutes twice a day. In some recent cases of this disease the doctor has used, with decided advantage, a combination of veratria and hydriodate of potass. This should be rubbed over the region of the heart for a quarter of an hour twice a day. In these heart diseases he has found the internal administration of veratria as beneficial as the external. The following is his formula for the ointment of veratria and hydriodate of potass. Take of veratria one scruple, hydriodate of potass half a drachm, prepared lead one ounce. Add a few drops of water to the hydriodate of potass, and rub it to a fine powder; then add the veratria and lard, and mix well.

The following is the author's account of the operation and *modus operandi* of veratria in rheumatism:—

Veratria in Rheumatism.

“In the acute form of rheumatism the external use of veratria had not been suggested before the publication of the first edition of this work. Since that time my confidence in its powers over the inflammatory stages of rheumatism, as well as over inflammation in general, has been much increased; for when it has been rubbed upon an inflamed surface, and sufficient electro-stimulation produced, a diminution of pain, heat and swelling,

and a secretion of moisture here followed. The heat and swelling of inflammation arise from a previous diseased action of the nerves of the part, and veratria removes these effects, as well as the pain of inflammation, by its electro-stimulation inducing in the nerves a healthy action, and thereby displacing the diseased one."

The last sentence which we have given contains as curious a piece of pathology and therapeutics as any which has come under our observation for some time. Were we not satisfied of the same state of the writer's mind from other parts of the work, we certainly might feel disposed to recommend to him a voyage to the cradle of his favourite veratria, according to Horace's very concise formula, viz. *Naviget Anticyram*.

Among the other diseases to which our author conceives veratria applicable, he enumerates dropsy, paralysis, cramp of the stomach and legs, scrofulous swellings in the neck, &c. &c. He then proceeds to detail the mode of preparing and using delphinia and aconitine. For this, however, as well as for the application of these new remedies to diseases of the eyes, we beg to refer to the work itself, from the perusal of which we promise our readers that they will derive no inconsiderable share of information.

Handwörterbuch der Praktischen Arzneimittellehre. Von Drs. Sachs and Dulk. 8vo. Königsberg. 1836.

This is a very complete dictionary of the materia medica. The leading articles contain numerous judicious critiques on the multifarious absurdities which pervade most works on the subject. Indeed, we know of none more replete with the twaddle of empiricism than our existing treatises on the materia medica. Impressed with this belief, we strenuously recommend the perusal of the German *Handwörterbuch* to all the compilers of Dispensatories.

TO CORRESPONDENTS.

Hibernus.—We cannot inform our correspondent whether or not IRISH students will be admitted to the hospital at the old price, until Mr. R. Quain returns from his continental tour.

Hypochondriac.—The immediate application of ANIMAL MAGNETISM, under the special superintendence of the Pro-

fessor himself. We doubt if it be a case for creasote.

Medical Jurist.—The body should not be opened, according to law, until twenty-four hours after death. Vesalius, the great anatomist, was banished for opening the body of Spanish nobleman before the heart had ceased to move.

A Dresser.—We cannot insert the cases from the NORTH LONDON, unless the facts be known to our own reporter. Cases written by an operator, or any of his dependents, are too often deficient in essential particulars.

Lithototist.—We believe that it has happened to inexperienced lithototists that the percussor has been thrust into the abdominal cavity, so that water which was employed to inject the bladder has found its way into the abdomen. It has also happened that a bougie has been thrust through a diseased rectum into the cavity of the abdomen, causing a fatal peritoneal inflammation.

Censor.—We thank our correspondent for his information—it accords with that of our own reporters. We wait however for Mr. Liston's own words, which have been sent to, and are to appear in, this day's *Lancet*. We shall reply to his outrageous and unjustifiable attack on this Journal, for honestly noticing his fatal case of lithotrity, the exact particulars of which his conduct may compel us to publish, when "he who runs may read." We have no enmity or ill-feeling towards Mr. Liston—we consider him a dexterous surgeon—but we shall publish his unfavourable, as well as favourable, cases, just as we do those of the surgeons of all the other hospitals, because many of the hospital operations performed in London are beneficial to science and humanity, and too many, we regret to state, a disgrace to modern surgery, and some few destructive of human life. The pages of this Journal afford ample evidence of the truth of this statement.

T.—Will our worthy correspondent favour us with his communications?

Medicus.—It is an illegal and dangerous proceeding.

J. S.—The Harveian Prize Essay has not reached us.

Justus—The article is too severe, and is a libel.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

ERYSIPELAS.

Erysipelas is a non-contagious exantheme, characterized by a deep red tint of the skin, with heat and swelling of this membrane, and often of the subcutaneous cellular tissue, always occupying a greater or less extent of surface, and which may, in some very rare cases, become general.

Though it may attack all the parts of the body, the face and extremities are most frequently the seat of it.

Symptoms.—In erysipelas, sometimes the inflammation of the skin is limited to this structure, or only accompanied by a slight inflammation of the subcutaneous cellular tissue; sometimes this tissue is inflamed to a variable extent, and gives rise to symptoms, of a more or less serious nature.

From these considerations we shall distinguish two varieties of erysipelas: the true, and the phlegmonous. In a great number of cases these two varieties exist simultaneously; but as perceptible differences are observed between them, as well with respect to their progress as to the treatment, we deemed it necessary to give a succinct description of each.

Spontaneous lassitude, general depression, shivering transient, though severe, hardness and frequency of the pulse, nausea, epigastric pains, thirst, loss of appetite, and constipation, are precursory symptoms common to these two varieties. It is towards the second and third day of this febrile disturbance, that the erysipelas

becomes developed; it sometimes shows itself much sooner.

The true erysipelas, that in which the inflammation scarcely extends beyond the skin, generally presents itself with the following characters: intense redness becomes developed to a greater or less extent, and it is easy to see, by the elevation of the edges, that the surface thus inflamed, is at the same time swollen: this redness disappears for a moment under pressure of the finger, which pressure by the way is very painful; there exists at the same time a pain more or less acute, accompanied by a sensation of acrid and burning heat; the pulse is accelerated, there is some nausea, and thirst; bitter taste in the mouth, and a yellowish coat on the tongue. The epidermis covering the inflamed skin may be raised to a greater or less extent by a yellowish serum, and these bullæ may attain considerable size. They usually appear towards the third or fourth day sometimes they discharge themselves on the day after their appearance, sometimes later; they then discharge a viscid fluid which often coalesces, so as to form crusts.

The general symptoms usually follow the progress of the exantheme, they increase and decrease in the same proportion; sometimes, on the contrary, they are but little developed, notwithstanding the extent of the erysipelas, and *vice versa*.

Towards the fifth or sixth day the redness diminishes and assumes a yellowish tint; the swelling becomes less, and the epidermis becomes covered with a number of small rugæ; by degrees the morbid colour disappears, and desquamation takes place in the parts where it was seated. This is the most frequent as well as the most favourable; but when a number of bullæ exists, the skin becomes covered with small brownish crusts, which in some cases continue for a considerable length of time.

Instead of running through its stages over the region where it is developed, erysipelas may successively attack several parts of the body, according as it disappears in the part primarily affected. At other times it extends over a greater or less extent of surface, without disappearing from the part which was the primary seat of it, and may thus simultaneously cover the entire surface of the body, though this is a very rare case. M. Renaudin has cited an instance of general erysipelas in a woman fifty years old. The disease was soon cured.

In some cases it leaves its original place rapidly in order to attack a part more or less remote, without leaving any other traces except slight desquamation. (*erysipèle ambulanti*).

In persons of a delicate and lymphatic constitution, it attacks the lower extremities; in this case the redness, which is not so bright, is sometimes scarcely developed; the skin, smooth and shining, retains the impression of the finger for some time (*œdematous erysipelas*). The termination of erysipelas thus accompanied with œdema, is favourable and should not excite any alarm; but this is not the case, when the inflammation is consecutive upon œdema, as is observed in persons labouring under anasarca, and more particularly after scarifications made for the purpose of giving exit to serum; for then the termination in gangrene is to be apprehended; it is announced by the livid tint which the enflamed skin assumes; the raised epidermis forms large irregular phlyctenæ filled with a brownish serum, and death soon takes place in persons already exhausted by previous disease. It is chiefly on the parts of generation and on the lower extremities that erysipelas thus appears after anasarca.

The *phlegmonous erysipelas*, that which is accompanied by inflammation of the more or less deep seated layer of the cellular tissue, may become developed over all the parts of the body; but it is more particularly observed on the extremities; it is sometimes limited to a single region, whilst at other times it attacks at the first onset an entire limb.

In this variety the symptoms are always more severe than in the true erysipelas, but they differ according to the extent and depth of the inflammation and the anatomical structure of the parts affected.

When the cellular tissue is not very deeply inflamed, the erysipelas is accompanied with a very acute burning pain, and with a well marked swelling; there

is also considerable fever. Pressure is very painful, and the skin recovers but slowly its morbid colour.

The termination in resolution may take place towards the fifth or sixth day; but in general the pain becomes throbbing (pulsative), the redness diminishes, and one or more abscesses form, which when opened give exit to healthy pus which is occasionally mixed with flakes of mortified cellular tissue.

When the cellular tissue is more deeply affected, or when phlegmonous erysipelas occupies an entire limb, the disease sometimes commences with great rapidity, and in general the cellular tissue appears to be inflamed simultaneously with the skin, sometimes even before it. Here the pain is deep seated, the least motion of the limb causes the patient to utter loud cries, the skin is red, very tense, and painful on the least pressure; the pulse is frequent, hard, and concentrated; there is oftentimes delirium, intense thirst, dryness of the tongue, and copious sweats. The termination, unless very active treatment be employed, is hardly ever in resolution; the suppuration, which takes place from the fifth to the seventh day, and sometimes sooner, is accompanied with shivering: the redness of the skin diminishes as well as the pain; but the tumefaction increases; the pus sometimes continues for a very long time without any spontaneous opening taking place on the skin, but most frequently whether this opening may have occurred naturally, or may have been made by art, it runs out mixed with, oftentimes, very large flakes of gangrened cellular tissue. In these cases the duration of the disease is usually long; burrowing takes place beneath the skin, portions of this membrane are thrown off to greater or less extent, and frequently colliquative diarrhoea comes on, which terminates in the death of the patient, who is now exhausted by a slow fever and profuse suppuration. The symptoms of phlegmonous erysipelas may be still more severe, more especially when aponeurotic structures by opposing the swelling, produce real strangulation, as is observed in the feet and hands. The constitutional symptoms are then very violent; from the second to the third day purple spots form on the surface of the erysipelas; the skin loses its sensibility; it becomes covered with phlyctenæ over the spots, which extend rapidly; eschare supervene generally of small extent, more particularly when proper treatment has been employed: they become detached

gradually, and the cure takes place after profuse suppuration of greater or less duration. But when the erysipelas occupies a great extent, and this fatal termination occurs, the system soon feels its effects: symptoms are observed of severe gastro-intestinal irritation characterized by prostration of strength, dryness of the tongue, severe diarrhoea, great frequency of the pulse, &c. To these are sometimes added silent delirium, reveries, stupor, change in the features, precursory signs of death.

According to the region it occupies erysipelas presents some modifications deserving of notice.

Erysipelas of the face is the most frequent of all: it commences in general at the nose, at one or other cheek, on the eyelids, it then soon extends and attacks the entire face; the features in a little time can no longer be recognized; the tumefaction of the eyelids is often very great. There are at the same time constitutional symptoms more or less severe, such as frequency of the pulse, heat of skin, violent headache, want of sleep, and slight delirium during the night. These general symptoms are at times very well marked; but in some cases they scarcely exist. The exantheme is generally at its height on the fourth or fifth day, and the resolution is well marked on the eighth day.

Erysipelas of the hairy scalp often succeeds that of the face. In other cases it becomes developed after punctures, contusions, slight operations, &c. It is remarkable by the oedematous tumefaction and great sensibility of the inflamed skin: the redness of the part is not very bright; frequently there is merely observed a slight rosy tint. Termination in suppuration is very frequent in this variety, and the subcutaneous cellular tissue is frequently attacked with gangrene; but mortification of the hairy scalp itself very seldom occurs, by reason of the anatomical disposition of its vessels. Cerebral symptoms come on more frequently, and they are more to be dreaded in this variety than in the others.

Erysipelas of the mammae frequently presents in women all the characters of phlegmonous erysipelas. It may come on in them a little after their accouchment, particularly in those whose breasts are very large, and with peculiar characters: first an acute pain comes on, but without tumefaction: the skin merely presents a rose tint around the nipple; the redness extends irregularly outwards,

and small phlyctenæ of a herpetic character circumscribe its extent; but according as it goes on thus, the skin which was primarily affected becomes of a yellowish white colour; it loses its sensibility, and when at the end of two or three days, the erysipelas becomes limited, this membrane is then found to be mortified over the entire extent which separates the areola of the nipple from the point where the progress of the erysipelas was arrested. The skin thus gangrened, emits no scent; but it becomes detached gradually by suppuration, and then it exhales a very fetid odour. A broad ulcerated surface is exposed, and cicatrization takes place very slowly. The two breasts may be affected with the same disease; but whatever be the extent of the gangrene, the nipples as well as the areolæ surrounding them, remain entirely intact.

Erysipelas of the umbilical region is frequently observed in new born infants, in hospitals, and foundling houses. It is attributed to improper traction of the chord, and more especially to the vitiated air which children breathe in those establishments; it sometimes extends to the hypogastrium, and to the genital parts, which may become gangrenous; death is then the almost inevitable result.

Erysipelas of the limbs is sometimes of small extent; at other times an entire limb is attacked, and in these cases the termination often takes place in suppuration in a circumscribed point, whilst resolution takes place every where else.

The most formidable complications of erysipelas, are no doubt cerebral and gastro-intestinal inflammations, which may become developed in great severity, and may soon end in the death of the patient. It ordinarily happens that in these cases the erysipelas disappears abruptly at the same time that the symptoms of the disease become developed; but in some cases it continues. Swelling of the parotids is rather a frequent complication of erysipelas of the face.

Resolution, metastasis (delitescence), suppuration, gangrene, and death are the terminations of erysipelas: the first is fortunately the most common; it is sometimes preceded by epistaxis, at least in erysipelas of the face.

Necropsy.—In cases of bad erysipelas, there are found not only traces of inflammation on the skin, but the subcutaneous cellular tissue is also very friable and infiltrated with pus.

Under some circumstances, particularly when death has come on very soon after

intense inflammation of the brain and its membranes, no appreciable pathological lesion is found.

In other cases, again, there are found lesions, either of the lungs or of the digestive passages, the existence of which was not even suspected.

Causes.—Erysipelas may attack all ages, both sexes, and appear in all seasons; but it most frequently attacks women and persons whose skin is very fine; it is generally observed in spring and autumn. Sometimes, in certain seasons, and at certain periods, it seems to prevail epidemically, and particularly in hospitals.

Certain external causes may occasion its development, by acting more or less directly on the skin, such as insolation, the action of cold, local irritants, punctures, a contused wound, a slight operation, &c. But oftentimes, even in these cases, it seems connected with some unknown disposition of the system.

Some cases again exercise a more or less marked influence on the appearance of erysipelas; namely, the habitual use of coarse food putrefied meats, spiced seasonings, fermented liquors, excess at table, watching, &c. In some cases, though very rarely, erysipelas appears under an *intermittent* form; it sometimes comes on *periodically*. Hoffman has noticed its return in amenorrhœa, at the time when the menses should appear. It sometimes returns in the same individual, at longer or shorter intervals.

Erysipelas frequently comes on when menstruation is commencing, at the critical period, and on the suppression of some habitual evacuation. Its appearance is often occasioned by strong mental emotions, painful disappointments, or violent gusts of passion; it sometimes accompanies, chiefly in old persons, gastric disturbances. But it is more frequently observed in persons labouring under chronic irritation of the alimentary canal, in those who live for a long time in prisons, in hospitals, and in places where the qualities of the air is deteriorated. Lastly, it appears very frequently in the course of acute gastro-intestinal affections, or in inflammations of the organs, and if very frequently its appearance augments the danger. There are some cases where it appears critical and salutary.

Diagnosis.—Erysipelas is accompanied with characters too well marked for any difficulty to be experienced in its diagnosis. A minute examination is sometimes necessary to detect erysipelas of the hairy scalp, particularly when it is accompanied

by a disease, the symptoms of which attract attention to it.

Prognosis.—Simple erysipelas of small extent is a disease not attended with any danger; but the same cannot be said of it when it covers a large extent of surface, or which is complicated with inflammation of the brain or of the alimentary canal. The variety described under the name of *erysipèle ambulante*, particularly when it continues for a certain time, indicates a state of the system which should excite considerable alarm.

The prognosis of erysipelas, which is developed in persons labouring under anasarca, as that also attacking persons who dwell in hospitals, prisons, &c., is usually of a serious character.

Erysipelas which comes on in the course of pleurisy, pneumonia, gastritis, &c., is more or less dangerous according to the character of the constitutional symptoms.

The sudden and spontaneous disappearance of this exanthème, preceded or followed by bad symptoms, indicating inflammation of some vital organ, is always to be dreaded.

The prognosis of phlegmonous erysipelas is, in general, more unfavourable, and it becomes still more so according to its extent.

Again, it is a dangerous affection when the skin, which is the seat of inflammation, is attacked with gangrene, and when there become developed at the same time adynamic symptoms, more or less marked.

In some cases, on the contrary, the appearance of an erysipelas has appeared to be a salutary crisis, particularly in gout and rheumatism, &c.

But it is particularly in chronic diseases of the skin, that the natural, or excited development of an erysipelas may become useful. It then modifies, and with great advantage, certain obstinate chronic inflammations, and especially some scaly affections of long standing, lupus, &c.

Treatment.—When the erysipelas, whatever may have been its cause, is simple, and of small extent, and occasions no disturbance in the system, all that is necessary is to keep the patient under a strict regimen, to give him cooling drinks, and to keep the limb quiet and in the horizontal position, when it is a limb which is affected; the inflammation proceeds regularly, and scarcely requires any other additional treatment.

Goulard's lotion, in the cold state, produces very good effects in the erysipelas known by the name of *chilblain*.

When the exanthème is more extensive,

and that violent constitutional symptoms accompany it, as often happens in symptomatic erysipelas, we must have recourse to more active treatment, and in these cases bleeding, emetics, purgatives, and certain local applications, should be employed.

Bleeding is in general indispensable: it should be applied promptly in young plethoric subjects, and when the general reaction is very marked; the inflammatory fever which precedes the appearance of the erysipelas, imperatively calls for the employment of this means, when it is very high. Bleeding from the arm is better than from the foot, even in cases of erysipelas of the face, because we are more certain of obtaining the quantity of blood desired; a repetition also may be necessary, if the symptoms are urgent. If, when the pulse loses its strength, the erysipelas still continues intense, local bleedings will be more effectual, especially when the inflammation occupies the face or the hairy scalp. It will moreover frequently be of use to employ these local bleedings simultaneously with general bleeding, taking care to employ them at some distance from the seat of inflammation, and never on the inflamed surface itself.

Bleeding is to be repeated according to the continuance or further increase of the symptoms; there are cases however when, notwithstanding the apparent severity of the erysipelas, we should be somewhat reserved in the employment of these means. There are cases where the disease attacks subjects already debilitated, either by some severe sickness, or by the active treatment considered necessary, and in persons who have lived a long time in prisons, &c.

Emetics are sometimes useful when the digestive organs are exempt from inflammation, particularly when there is a bitter taste in the mouth, a yellowish coating on the tongue, &c. This was the practice of Scott, of Desault, and is, at the present day, frequently employed with advantage, particularly in old subjects.

Purgatives are also occasionally very salutary to remove the saburral state which may accompany an erysipelas of the face; the derivative effect which they produce on the intestinal canal may become very serviceable. In most cases it will be sufficient to have recourse to laxatives or mild purgatives.

Local applications are of the least use in the treatment of erysipelas; it will be particularly necessary to avoid the use of refrigerants, which sometimes produce very bad effects.

Fatty bodies, cataplasms, have no other effect except that of augmenting inflammation. Blisters should not be employed, except for the purpose of arresting the variety called erysipèle ambulante, or to bring back this exanthème to the part previously affected, when it has disappeared suddenly, and this disappearance coincides with symptoms more or less alarming.

Dr. J. Higginbottom, of London, has arrested erysipelas of the face by touching a small surface with nitrate of silver.

The same means have been employed with advantage, in order to circumscribe those attacks of erysipelas which have a tendency to spread. M. Veipeau has already noticed this method.

Phlegmonous erysipelas demands a very active treatment, which will require to be modified according to the extent or severity of the evil. General and local bleeding, often simultaneously, must be employed vigorously, and from the commencement; emollient local baths must be employed and continued for a long time, as well to favour the flow of blood, as to diminish the erythism of the affected parts. But when these means have not produced any amendment, or when they have not been employed, and the symptoms proceed rapidly, we must have recourse to incisions (debridements), not when gangrene has shewn itself, as has been stated, but long before, to endeavour to prevent it.

The extent of the incisions must vary according to the extent and seat of the disease. The object of their employment is to remove the tension of the aponeuro-expansions, and consequently the inflammatory strangulation. The incisions are necessary when the phlegmonous erysipelas terminates in suppuration, or to limit the gangrene.

Compression has been proposed as having sometimes been very serviceable in phlegmonous erysipelas; but when we reflect on the serious consequences which too often happen in fractures, where, on the application of a simple bandage, the limb becomes swollen; the use of this means appears, on the one hand, too dangerous to be adopted, and, on the other hand, as it cannot be employed except at the commencement, and as the advantages of an active antiphlogistic treatment at this period are indispensable. Many instances of success could be adduced in order to warrant us in sacrificing such valuable time to this mode of practice.

LECTURES ON SURGERY

BY JOHN HUNTER, F.R.S.

Delusive Symptoms respecting Sensation.

This delusion of the senses makes disease seem where it really is not, from the different seat of the symptoms and of the diseased part. Thus, diseases of the liver are referred to the shoulder, of the testicles to the back, of the hip to the knee, and even in some cases, as was before observed, they are referred to some other person. When the trunk of the nerve is injured, the pain is referred to the termination of it, as, after amputation of the leg, pain is felt in the toes. When pressure is made on a large nerve, the most acute sensation will be at some distance below the part pressed on.

A gentleman complained of a pain in the hip, running down the outside of the leg and foot. Supposing it rheumatism, I gave him James's powder, Dover's powder, and volatile tincture of guaiacum, but with no good effect. A liniment of opium to the leg and foot gave some relief. He at last perceived a tumour by the os ischii, just at the posterior edge of the glutens maximus. This tumour increased, and the person died. The tumour was found to fill a part of the pelvis, and had made its external appearance at the foramen magnum ischii, being filled with coagulated blood; but the pain in the limb seemed to have been produced by its pressing on a great branch of the nerve, but chiefly perhaps from the great ischiatic nerve being stretched very tight over the upper surface of the tumour. Here that happened which may often be observed; that is, the impression made on the trunk of the nerve gave a sensation as if it had been on the extremities of the nerve. The first action of a nerve is at its extremity, and the last in the brain; and this last in the brain refers the sensation receiving the first impression; and if, after the brain has become accustomed to refer any sensation to the extremities of the nerves, any impression be made on the trunk, the brain receives the impression in the same point where it was accustomed to receive the impressions made on the extremity of that nerve, and therefore the mind refers the sensation to the same spot, that is, the extremity of the nerve. This happens when the sense to which the sensation is referred does not exist, as a person, having had a

tated limb, will for a long time refer his sensations to the fingers or toes.

In diseases the general character of the patient should be known, which is essentially necessary before we can judge of every symptom; for besides what we can know by the symptoms of a disease, yet peculiarity of temperament, &c. will occasion great differences in the character of the disease. For our being informed by the first mode of intelligence, the patient's sensations, the patient must be in his right senses, otherwise he may be deluded, and delude us. But even where the patient is perfectly sensible, many symptoms may appear to the physician which the patient is not sensible of, as wild looks, quick pulse, &c. The brain may not be conscious of them, and a false conception of their feelings is then present; and this may be called half-delirium. A complete delirium is an action of the mind directed by no sensation whatever. But we do not know how to distinguish between these two deliriums, the former being an action of the mind from sensation, but which sensation is incapable of directing its influence to the senses, and refers it to other parts or other objects. These should be well understood in practice, as in half-delirium the patient will have the sensation, but will direct it to some one else, or to the wrong part, which if we know we may be able to afford them the relief they want. The history of everything relative to a disease should be known, as symptoms alone are often not enough to direct us; we should, therefore, get the history of it and of prior diseases, of peculiarity of constitution, manner of living, &c.

GENERAL PRINCIPLES OF INFLAMMATION.

The operation in the body called inflammation is one of the most common and most extensive in its effects, and requires our greatest attention. It is the cause of many effects, both salutary and diseased, producing abscesses, fistulas, diseased bones, &c., and in many diseases is the first step towards a cure; so that it becomes a first principle in surgery.

Inflammation would appear to be produced by an increased action of the vessels, but it is most probably in the smallest vessels, and may be confined almost to a particular vessel, but the smallest vessels are not the particular action of the mind, but in the common way of ascertaining

we being more able to judge of the effects than of the immediate cause.

Inflammation may be considered as a genus, of which there are many species. It may be divided into healthy and unhealthy. The healthy is that which will always take place in a healthy constitution or part, and is rather to be considered as a restorative process than a disease. Unhealthy inflammation is that which takes place in an unhealthy constitution or part, and will vary according to the kind of unhealthiness of that constitution or part.

Inflammation is either simple or compound; simple, when there is only one mode of action in the part inflamed, as in its first stage; compound when there are two or more modes of action. The compound produces three great effects, namely, adhesion, suppuration, and ulceration, which I shall call adhesive, suppurative, and ulcerative inflammation. The last is only an effect of inflammation, for the process takes place in a different set of vessels.

I shall place the adhesive first in order, though it is not always so, for with respect to priority of these effects of inflammation, it depends principally on the nature of the parts, with the degree of violence of the inflammation. To explain this more fully, I shall consider inflammation as it effects, 1st, The cellular membrane in general, and the circumscribed cavities; 2nd, All the outlets of the body, i. e., the excretory outlets and ducts of glands, as the mouth, nose, tunica conjunctiva, &c., which have been called mucous membranes, and which I shall treat of in their proper order.

When inflammation takes place in the first order of parts, it is commonly the adhesive: but it will be according to circumstances whether the suppurative or ulcerative follows first, and probably according to the degree of inflammation. But it sometimes happens that the suppurative takes place almost immediately, probably from two causes, either from the inflammation exciting the suppurative almost immediately after the adhesive, or from the inflammation having little or nothing of the adhesive in it. I suspect that the erysipelatous has little of the adhesive in its nature, no adhesion taking place before suppuration, whilst in phlegmonous inflammation of the cellular membrane it does; so that the erysipelatous might be called œdematous inflammation. When inflammation occurs with violence on the surface of the skin, the

ulcerative process takes precedence of the suppurative, although in the cellular membrane the reverse of this is the case. In the second order of parts the suppurative takes place first, and the adhesive does not take place, unless the inflammation is carried to a great height.

When the inflammation is in the first order of parts, the suppuration and ulceration are so many actions superadded to the first, or adhesive, and arising out of the effects produced by that which now becomes new causes, especially of the ulcerative, which is an action of the absorbents. All these actions arise from the first irritation or cause.

The adhesive or suppurative, either in the first or second order of parts with their varieties, may have a fourth character superadded, such, for example, as the scrofulous or venereal disposition, or other specific disease.

These three modes of action, when carried on perfectly, are the effects of a good constitution, and constitute what I would be understood to mean by common inflammation.

The union of cavities in an animal body is formed by a uniting medium, which appears to be the coagulable lymph, which, by the inflammatory disposition of the vessels, is separated from other parts of the blood and thrown out on these surfaces. That this is the case appears from the following observations. In all large cavities where we can make our observations with certainty, we find when they have been inflamed that a substance similar to the coagulable lymph when separated from the serum and red particles, is diffused all over the sides or through the cavity. When we cut into an inflamed part after death, we find it firm and solid, like the section of a lemon, or some œdematous tumour, where we know extravasation has taken place; and this appearance arises from the cells of the cellular membrane being loaded with extravasated coagulable lymph.

This mode of separation of coagulable lymph is not peculiar to this species of inflammation; it is separated on many other occasions to form tumours, where inflammation does not seem to be the leading cause.

It is probable that the coagulable lymph undergoes some change in its passage through the inflamed vessels which obliges it to coagulate sooner than it otherwise would, for in those cases of inflamed arms, after bleeding, we find that the cavities of the veins are in many

places furred over, and in others united by coagulable lymph, which must have been thrown out by the vasa vasorum, and coagulated immediately. Hence it is reasonable to suppose that in this separation the lymph must have undergone some change, arising from the vessels, and that it is not simply such coagulable lymph as is circulating in the blood, else it would be carried off by the circulating blood passing through the vein. This change I suppose to arise from sympathy with the inflamed vein. The lymph seems, however, to retain the living principle, and probably in a greater degree than under common circumstances, and is, therefore, better fitted to become a living solid. It does not seem, however, absolutely necessary that coagulable lymph should first undergo this change in the extravasating vessels, for, as I have before said, blood extravasated from ruptured vessels is perhaps equally efficacious in this respect.

In order for spontaneous inflammations to produce suppuration, they must be much more violent than those inflammations (suppuration being equally necessary,) arising in consequence of an operation or accident; and those inflammations from either operations or accidents, if they have not produced death in the part operated on, are more violent and of greater extent than those in which death of a part has been produced. Thus, the inflammation of a boil or bubo is more violent, and commonly more extensive, than that in consequence of a cut, or even amputation of the leg; and the inflammation arising from these latter will be more violent than that from a gunshot wound or the application of caustic. It may not be easy to account for all these differences: however, it is possible that in spontaneous inflammations the inflammation is more necessary for the ultimate effect than the suppuration; as in gout, the inflammation is the mode of carrying off the action of the disease. It is curious to remark, that in gout, nature seems to produce all the purposes and effects intended by inflammation, but unaccompanied by either adhesion, suppuration, or ulceration; and although the inflammation runs much higher here than in many other cases, and although it is attended with all the common appearances, yet no adhesions are formed here; for the lymph is taken up, and chalk (urate of soda) is deposited in its place. In spontaneous inflammation, parts are either naturally more susceptible of the inflammation, or

become so by disease. When inflammation is produced by the stimulus of the death of a part, or of effused blood, the inflammation is commonly slow; but that from a bruise is often quick and violent, but then the injury has not produced death. If caustics do not act with vigour, they will irritate and inflame much sooner than if they had immediately killed the part; but irritating applications must be continued some time to produce inflammation. After operations where inflammation must take place for the union of the wounds, suppuration is more necessary than inflammation, and we find it is soon produced.

The ulcerative inflammation is that which takes place in consequence of suppuration, therefore is not so much the original inflammation as the consequence. It is that inflammation which disposes parts to absorb themselves, and which brings matter or any extraneous substance to the surface to be discharged, the absorbents removing all the parts lying between the matter and the surface. This process has been erroneously ascribed to the melting down or dissolution of living solids with the pus.

From the foregoing general account of inflammation, it may be said to arise in all cases from injury done to the solida, where either the natural conformation of the parts on which natural actions depend is so destroyed that they are not able to support themselves in that state, or from the natural actions or functions of a part being materially obstructed, the texture not being primarily affected. The first state arises from causes that are visible or external, such as the application of any irritating matter, as a blister, heat, or even cold, which acts as a sedative when applied only in a certain quantity; but when in too great a quantity, the parts, finding that they are losing their action, are roused to action beyond that which is natural, in order to destroy the irritating cause. Inflammation may also be produced by causes not known or suspected, or from a constitutional disposition being determined to some part, producing local effects. I need hardly mention that fever is thus often a cause of local inflammation.

Inflammations from the constitution are of two kinds: one may be called accidental, as those arising in common fever; the other are determinate, depending upon the species of fever which may be called specific, as small-pox, &c.

These inflammations are thought to be

critical, but I very much doubt the truth of this opinion. The smallpox and chickenpox are the only diseases that can be brought in proof of it, with perhaps the inflammation of the measles; but even these pustules or abscesses are perhaps not necessary, as critical abscesses, to carry off the fever, for specific fevers cannot exist beyond a certain time, though no eruption appears; which time depends on the nature of the poison, and the constitution. And in these fevers we have large abscesses as often formed as after any other; and certainly I cannot suppose those abscesses to be critical, for they possess nothing of the specific nature of the preceding disease, and must therefore be common; or, where the constitution possesses a susceptibility for scrofula, they may be scrofulous, but not critical; and as the preceding disease has already been followed by pustules or abscesses, which, if they deserved to be termed so, certainly ought to be termed critical, we shall find that these inflammations and abscesses depend on the state of the constitution and part at that time, and are an effect of simple fever abstracted from every specific peculiarity. Fever is at all times a disturbed action, which may have a specific action joined with it or not. The inflammatory fever is perhaps, the most simple fever; and the putrid fever is, perhaps, only the same fever occurring in a constitution predisposed to its peculiar actions. This opinion may be illustrated by what occurs in the smallpox: two different people having this fever from the same infection, the effect in one will be benign smallpox, with only simple inflammatory fever; in the other it will be erysipelatous or confluent smallpox, with a tendency to putridity or gangrene. This difference cannot depend on the specific poison, as this can have but one mode of irritating. Now, since every fever is capable of producing inflammation and abscess, and as I have shown that in specific diseases they have no right to be termed critical, they certainly cannot be supposed critical in common fever.

Inflammation may arise from one of four causes, which may be called remote: 1st. From accidental force applied to a part; 2d. From some irritation, which does not destroy the texture of a part, but simply the natural actions, as friction, blisters, heat, cold, and often fevers of various kinds; 3d. From some particular disposition in the part itself, as boils arising spontaneously; 4th. From the

general state of the constitution affecting some particular part, as gout falling on the toe, or irritation of fever on the lungs, liver, or any other part, producing adhesions or abscesses; but such, I suspect, are of the scrofulous kind, and not in the least critical, and therefore belonging to the second cause. To these, I think, we may add specific causes, as scrofulous, venereal, &c., as a 5th; and the stimulus of defect or imperfection of parts, especially cavities, as a 6th.

Obstruction of the blood's motion in the small vessels has been long supposed to be a great cause of inflammation, but is, I believe, now pretty generally rejected. This was certainly too confined an idea: it reduced all inflammations to one species. The only distinctions of inflammations must have arisen from the nature of the constitution; but this doctrine never could account for the peculiar action of any specific disease or poison. It was also too mechanical. If they had said that any obstruction to the natural actions of the parts which could stop the blood's motion in the part became the cause of inflammation. In such a case the stagnated blood would cause irritation of the vessels, and suppuration would be employed to get rid of it. The immediate operation of these inflammations cannot be called disease, though their remote causes may, as smallpox, &c.; for they may arise from the part being only disturbed, and hardly exceeding the idea we have annexed to that of being disturbed. It is the cause producing inflammation, then, which is the disease, and not the inflammation, for all inflammations that can be called diseases have specific causes; and, indeed, even these can be hardly called diseases, for in smallpox, where the inflammation goes on well, it is merely the action of health; if diseased, it would be erysipelatous, &c. Sometimes, by amputating a leg, more than simple disturbed action is produced, for it is a great loss to the constitution; but yet when the constitution is in a healthy state, we generally find a healthy inflammation and digestion of the wound take place: it will not go into an inflammation which is unhealthy. Specific inflammation as well as simple inflammation partake of the nature of the constitution. Some constitutions are more disposed to certain specific actions than others, and will fall into that specific kind of inflammation, as the erysipelatous, the scrofulous, &c.; and every aggravation is an aggravation of the specific nature of the

inflammation; thus it happens in scrofula, cancer, &c. But some specific irritations bring all constitutions to their own nature, as the plague, jail-fever, &c. Here it is not a specific joined with a simple inflammation, but a thorough change of constitution, and the patients generally die, all suffering alike. The inflammation arising from these causes may be either the adhesive or the suppurative. From all which we may conclude that irritations either produce inflammation according to the disposition of the constitution or of their own nature, of which last is the plague.

The specific diseases will change, according as the constitution changes; for instance, after receiving the smallpox, if the constitution, then healthy, should by any means become disposed to show putrid symptoms, the smallpox will have the appearance; but if the constitution is altered from this tendency, the eruption will also alter. Now the knowledge of this fact is very useful in the treatment of specific diseases: for example, if with a venereal chancre the constitution be erysipelatous, we may have an erysipelatous inflammation in addition to the chancre, which will spread over the whole penis. Now, in this case, we must make use of mercury against the one, and of bark against the other of these specific diseases, until we bring it to the simple ulcerative inflammation. Again, in the smallpox, when simple, the pustules retain their specific distances, but if an erysipelatous inflammation be joined to it, it becomes of the confluent kind. In the irritable constitution we find from continuous sympathy the inflammation will extend itself very far; but in general we find that considerable inflammations confine themselves very much.

Some parts are more susceptible of one kind of inflammation than of others, some admitting of only one kind, some two, and some all three, which difference appears to be according to the situation in the body of the inflamed parts, and also according to the nature of the parts inflamed. The deeper-seated parts, especially the vital, admit very readily of the adhesive inflammation, as is proved by dissections, for we hardly ever open a human subject that has not had considerable adhesions in the circumscribed cavities; but they do not so readily pass into the suppurative, which is fortunate, otherwise internal inflammation would oftener kill. But if the inflammation comes on at once with great violence, it would ap-

pear to pass almost at once over the adhesive, and to take up the suppurative action, and in this case we may sometimes have the erysipelatous added.

The external parts of the body are more susceptible of the suppurative inflammation than the internal, but they always begin with the adhesive. This greater susceptibility of the superficial parts to suppuration is shown in the passage of pins, bullets, and other extraneous bodies to the surface: if deep-seated, they will remain a long time inactive, inclosed in a cyst, and produce no inconvenience until they work their way to the skin, when suppuration will be produced. It is very remarkable of the cattle fixed in the bleaching fields, and are always found after death to have a number of pins in them. (The stomach of a bull was shown, in which several pins were sticking, and which were not known to have caused any inconvenience.) Perhaps this does not altogether depend on the situation of the part, but also on the degree of irritating power possessed by the extraneous substance: thus, metals and glass seem to produce such a disposition in the part, that it becomes satisfied with the adhesive inflammation. A gentleman had a piece of glass in his hand for many weeks, which produced no pain, except on pressure. This insensibility of deep-seated parts to extraneous substances, depends on a sac being formed round these substances, possessing a peculiar degree of insensibility. Nature acts here with her usual care, preferring the least evil by securing the extraneous substance in a part possessing peculiar insensibility, rather than calling up the vital powers to produce suppuration, which must be considerable to reach the surface, and might expose parts which would be attended with considerable danger; but when they become external, then she chooses the other, to get rid of them as soon as possible.

In my division of parts, as regards inflammation, into two orders, I have made a distinction between the cellular membrane and circumscribed cavities on the one hand, and the ducts, canals, and outlets which are lined with what has been called a mucous membrane on the other. In the first order of parts, inflammation proceeds in this order; adhesive, suppurative, ulcerative: but in the second order of parts, the order of inflammation seems to be inverted as regards the two first, as may be seen in internal canals. In these, if the inflammation is but slight,

the suppurative takes place almost immediately, not being retarded by the adhesive going before: as we see in gonorrhœa, catarrh, &c. It has been said that these discharges are not purulent, but in my opinion they certainly are; the purulent matter being only a change in the natural secretion, and its thickness or thinness depending on the degree of the inflammation. If the erysipelatous inflammation should come on in these parts, then the movement takes place from the suppurative to the ulcerative. In the mucous membrane ulceration will take place, probably from the violence of the inflammation having produced coagulable lymph, which acts as a stimulus, and the parts having been weakened, are unable to support themselves: this is sometimes the case in the mouth, from salivation; in the tongue, in scurvy &c.; in the intestines in dysentery, &c. Mr. Hunter endeavoured to produce adhesive inflammation in the vagina of an ass. He first, by moderate stimulus, could only produce suppuration, but by a very active stimulus, as a solution of corrosive sublimate, he produced the adhesive, causing coagulable lymph to be effused, which afterwards became membranous and inseparable, as was seen in the preparation of the parts which he exhibited.

THE ANATOMIST.

ORGANS OF THE SENSES.

THE ORGAN OF TOUCH.

The skin is composed of the cuticle, or epidermis, the rete mucosum, and the corion, or cutis vera.

The cuticle is a transparent inorganic layer of membrane, extending over the corion. Its thickness varies, being thinnest in those parts least exposed to pressure and friction, and thickest in the soles and palms.

The rete mucosum is a thin membrane attached to the outer surface of the corion, highly vascular, and gives the colour to the skin, being black in the negro, and white brown or yellow in the European.

The corion is a dense strong membrane, consisting of fibres, interwoven with each other, which are more firmly compacted the nearer they are to its outer surface. Its internal surface is cellular, its external very vascular, and presenting numerous small conical papillæ; at the extremities

of the fingers these papillæ are best developed, are furnished with minute nervous filaments, and covered with very thin cuticle; thus affording a delicacy of organization necessary for the greater perfection of the sense of touch.

THE ORGAN OF SMELL.

The nose is bounded superiorly by the nasal, frontal, ethmoid, and sphenoid bones; inferiorly by the palatine plates of the superior maxillary and palate bones; externally on either side by the superior maxillary, lachrymal, inferior spongy, ethmoid and palate bones, and by the internal pterygoid plates of the sphenoid bone. It is divided into the *two nares* by the *septum nasi*, which is formed by the azygos process of the sphenoid bone, the nasal plate of the ethmoid bone, the vomer and the mesial spines of the superior maxillary and palate bones. Besides the bony boundaries, the nose presents, anteriorly, five cartilages, which form the *anterior nares*, or the nostrils. The middle vertical cartilage is of a triangular form, and rests in the fissure of the vomer, inferiorly is attached to the vertical plate of the ethmoid bone above, and presents anteriorly a subcutaneous, free, thick edge, and thus completes the *septum nasi*. The lateral cartilages which form the wings of the nose, are also triangular, are attached to the superior maxillary and nasal bones, and in the median line to the vertical cartilage. The inferior lateral fibro-cartilages, are attached to the three cartilages just described, are thick and semi-circular, forming, with the vertical cartilage, the anterior-inferior oval openings of the nostrils.

The posterior nares are of an oval shape, and open into the upper part of the pharynx; they are separated from each other by the posterior free edge of the vomer, are bounded superiorly by the body of the sphenoid bone, inferiorly by the palate bones and externally by the internal pterygoid plates of the sphenoid bone. The external lateral wall of each naris, from the arrangement of the spongy bones, form three fossæ, called *meatuses*, with which several orifices communicate.

In the inferior meatus, at the junction of its anterior with its middle third, is the opening of the *nasal duct*, and posteriorly, on a level with the inferior spongy bone, is the opening of the Eustachian tube. In the middle meatus is the slit-like opening of the *antrum maxillare*, anterior to which is the groove called *infundibulum*, which leads from the front-

tal sinus, and into which open the anterior ethmoidal cells.

Into the superior meatus, the posterior ethmoidal cells and the sphenoidal sinus open. The interior of the nose is lined with the schneiderian membrane, which is highly vascular and sensible, and consists of two layers, a fibrous layer, which is the periosteum, or the perichondrium of the nasal cavities, and a mucous membrane. The nerves which supply the nasal cavities are the olfactory, the internal nasal of the ophthalmic, and branches derived from Meckel's ganglion.

THE ORGAN OF TASTE.

The tongue presents several papillæ covered by mucous membrane. It is of a triangular form, is connected by its base to the os hyoides, by folds of mucous membrane to the epiglottis and palate, and by muscles to the lower jaw. It is highly vascular, and receives six nerves, three on either side, viz., the gustatory branch of the fifth for taste, the ninth, or lingual, for motion, and the glosso-pharyngeal to connect it in sympathy with the pharynx.

THE ORGANS OF VISION.

The eyes are distinguished into the globes of the eyes and their appendages. The eye-ball is composed of membranes and fluids, called humours.

The sclerotic coat, occupying about four-fifths of the globe, is of a strong fibrous structure, is thicker behind and anteriorly than in its centre. Its outer surface is in contact with the adipose tissue of the orbit, the tendinous expansions of the orbital muscles, and anteriorly with the conjunctiva, its inner surface being lined by the choroid coat. It presents posterior a small aperture for the transmission of the optic nerves, and an anterior large one, about six or seven lines in diameter, for the cornea.

The cornea, which forms the anterior fifth of the globe, is smooth and transparent. It consists of three layers, viz., the conjunctival layer externally, the elastic cornea internally, and, between both, the proper cornea, which is composed of laminae, connected together by fine cellular tissue.

The choroid coat is a thin vascular membrane, situated between the sclerotic coat and the retina; it extends from the entrance of the optic nerve to the ciliary ligament, to which it is firmly connected; it then is directed inwards, and forms the folds called ciliary processes. Its internal

surface is covered by a dark brownish secretion, called *nigrum pigmentum*, its outer surface being connected to the sclerotic coat by fine cellular tissue, and by the ciliary vessels and nerves; on this surface the veins observe an arched arrangement, and are called *vasa vorticosæ*.

The ciliary ligament is about a line and a half in breadth, of a greyish white cellular structure, and corresponds to the circle of junction of the cornea and sclerotic coat externally, and the choroid and iris internally.

The ciliary processes vary in number from sixty to seventy, and are productions or continuations of the choroid coat; each ciliary process is of a triangular figure, the anterior edge being attached to the ciliary ligament, the posterior to the hyaloid membrane, and the internal free projecting into the posterior chamber of the aqueous humour, towards the lens but not attached to this body.

The Iris is a circular membrane placed in a transverse vertical position, attached by its larger circumference to the ciliary ligament, floating in the aqueous humour, and presenting a circular opening in its centre called the *pupil*. It divides the space between the anterior surface of the capsule of the lens, and the posterior surface of the cornea, unequally into what are termed the *chambers of the aqueous humour*, the anterior chamber being much the largest; both chambers, however, communicate through the pupil. The anterior surface of the iris presents a radiated appearance, and varies in colour in different individuals; the posterior surface is covered by *nigrum pigmentum*, and has received the name of *uvea*. The iris is supplied by the ciliary nerves and vessels.

The retina placed between the choroid coat and vitreous humour, consists of three layers, an external or *serous layer*, called from its discoverer *membrane Jacobi*, an internal or vascular layer, and between both the nervous layer. About two lines on the temporal side of the entrance of the optic nerve the retina presents a small hole surrounded by a yellow margin, called the *foramen of Sammering*, round which the retina is thrown into a fold.

The aqueous humour is contained in the anterior and posterior chambers of the eye, is perfectly transparent, and is from four to five grains in quantity.

The vitreous humour occupies about three posterior fourths of the eye, it is contained in the *hyaloid membrane*, which not only envelopes it, but sends numerous

partitions from its inner surface to form cells in which the transparent fluid is deposited. The vitreous humour thus contained in its capsule is convex posteriorly and on its lateral circumference, but presents anteriorly a concavity for the reception of the crystalline lens; around the circumference of this cavity the vitreous humour presents a striated appearance, caused by the marks of the ciliary processes, to which the term *corona ciliaris* is applied.

The *crystalline lens*, enclosed in its capsule and placed in the anterior depression of the vitreous humour, is a transparent body, presenting an anterior and a posterior convex surface, the latter being more prominent, and corresponding to the vitreous humour. Its external surface is soft and pulpy, gradually increasing in density towards its centre.

The *capsule* of this body, like the lens itself, is transparent, and from its thickness, strength, and elasticity is considered by Dr. Jacob as being cartilaginous.

The lens and its capsule derive their nutriment from the vessels of the hyaloid membrane.

Liquor Morgani is a fluid which is found some hours after death, between the lens and its capsule. It is the effect of transudation.

Canal of Petit.—The lens is retained in its situation by the hyaloid membrane, which, splitting into two laminae at its circumference, pass one anterior the other posterior to its capsule; a triangular canal is thus formed, and is intersected by minute septa; this is the canal of Petit, and may be demonstrated by distending it with the air, when it will present a vesicular appearance.

THE APPENDAGES OF THE EYE.

The *lacrimal gland*, placed in the upper and outer part of the orbit, behind the external angular process of the os frontis, and about the size of a small almond, is of a greyish colour, consists of numerous granules, united by an imperfect capsule, and pours forth its secretion of tears by means of five or six minute ducts, which open behind the upper eyelid, in the angle formed by the reflection of the conjunctiva.

Tunica Conjunctiva, a mucous membrane which lines the interior of each eyelid and is reflected on the anterior part of the globe of the eye. At the inner angle of the eye it forms a small fold called *plica semilunaris* covers the *caruncula lacrymalis*, and having lined

the lacrimal sac and duct becomes continuous with the mucous membrane of the nose.

This membrane where it passes over the cornea is perfectly transparent.

Caruncula lacrymalis, a small vascular body composed of mucous glands and cellular tissue situated in the nasal angle of the eye and covered by the *membrana conjunctiva*.

The *palpebræ* or *eyelids*, semicircular in form are composed of skin externally, which is very fine, the *tunica conjunctiva* internally, and between both the orbicularis palpebrarum muscle, the tarsal cartilages and their ligaments, and the Meibomian glands, together with blood vessels, nerves, and absorbents.

The superior eyelid besides being the largest has also peculiar to it, the levator palpebræ superioris muscle.

The *tarsal cartilages* are thin cartilaginous plates of a semicircular form, the superior being the largest; to their convex margins are attached the *palpebral ligaments* which are continuations of the orbital periosteum.

The *Meibomian glands* of a yellow colour are very numerous, particularly in the upper eyelid, and are arranged in vertical rows.

The opposed edges of the eyelids are thick and are bevelled off obliquely towards the eye, so that when closed they only touch at their anterior edges; thus leaving a triangular canal, the base of which is formed by the *tunica conjunctiva*, along which the tears are conducted to the *puncta lacrymalia*.

The *cilii* or *eyelashes*, attached by their roots to the opposed margins of the eyelids observe a curved arrangement, their convexities looking towards each other.

The *puncta lacrymalia* are the two minute orifices of the lacrimal canals, placed within two or three lines of the nasal terminations of the eyelids and upon their opposed edges.

The *lacrimal canals*, the superior of which is longer and curved, the inferior being nearly straight, lead from the *puncta lacrymalia* to the lacrimal sac.

The *lacrimal sac*, placed in the fossa, formed by the lacrimal and superior maxillary bones, is of an oval form, receives the lacrimal secretion by the *puncta lacrymalia* and transmits it to the nasal duct with which it is connected inferiorly.

The *nasal duct*, enclosed in a bony canal formed by the lacrimal, superior

maxillary, and inferior spongy bones, passes obliquely downwards, backwards, and outwards, and terminates in the inferior meatus of the nose.

THE ORGAN OF HEARING.

This organ consists of the external ear including the auricle and meatus auditorius externus; the middle ear, including the cavity of the tympanum and its appendages, and the internal ear or labyrinth, including the vestibule, semicircular canals and cochlea.

The *external ear* consists of a fibro-cartilaginous plate covered by skin and so moulded as to form different elevations and depressions, which have been described with more minuteness than they deserve.

The *helix* is the semicircular eminence which forms the outline of the external ear.

The *antihelix* commences superiorly by two roots, which enclose a fossa, (*fossa navicularis*) and is situated inferior to the helix.

The *tragus* is an eminence placed anterior and inferior to the meatus externus.

The *antriragus* is a smaller eminence posterior to the meatus externus.

The *lobule* is a pendulous body placed underneath the antitragus.

The *concha* a deep conoidal cavity which leads to the meatus externus and to which the several depressions, formed by the eminences just described, lead.

The *meatus externus* is a curved canal which leads from the concha to the membrana tympani; it is lined by skin beneath, which are placed small glands (*glandulae ceruminosae*), which secrete the ear-wax (cerumen). The inner half of this canal is surrounded by bone.

The *membrana tympani*, separating the external from the middle ear, is of an oval form and consists of three layers, viz., the external or cuticular, the internal or mucous, and between both a fibrous layer, which some have supposed to be muscular. To its inner aspect is attached the crus of the malleus which, by drawing it towards the middle ear gives it a concave aspect externally.

The *middle ear* consists of the cavity of the tympanum and the small bones of the ear and their muscles.

The *cavity of the tympanum* is an irregular cylindrical space, closed externally by the membrana tympani, and bounded posteriorly by a bony partition which separates it from the labyrinth. It presents the following eminences and for-

amina, viz: the *promontory*, a convex eminence situated on its internal side and which marks the situation of the vestibule; the *foramen ovale*, placed above the promontory and to which the base of the stapes is affixed; the *foramen rotundum*, below the promontory, closed by a membrane (*lesser tympanum*), which separates the scala tympani of the cochlea from the cavity of the tympanum; the *opening of the mastoid cells*, situated posteriorly and superiorly; the *pyramid*, a bony projection placed below the opening of the mastoid cells, hollow within and containing the stapedius muscle; a *small foramen* below the pyramid for the transmission of the chorda tympani nerve; anteriorly the openings of the two bony canals, the superior of which lodges the tensor tympani muscle, the inferior forming the bony part of the eustachian tube; inferiorly is the opening of the Glasserian fissure, and superiorly are several small foramina for blood vessels.

The *bones of the ear* are three in number, very small and contained within the cavity of the tympanum.

The *malleus* is divided into the head which is smooth and articulates with the incus; the neck which is small and connects the head to the shaft; the *handle or shaft* which descends from the neck and is attached to the membrana tympani, and the *processus gracilis* which passes from the neck to the Glasserian fissure.

The *Incus* is divided into its body, which presents a cap-like cavity for the head of the malleus; a superior crus, which is short and lines the mastoid cells, and a long crus, to the extremity of which is attached a small process of bone, considered by some as a distinct bone and called *os orbiculare*.

The *Stapes* presents a small head which is attached to the orbicular process, a short neck, two curved crura, which terminate in the base, the base itself being of an oval shape and connected to the foramen ovale.

The *internal ear or labyrinth*.

The *vestibule*, placed behind the cochlea and before the semicircular canals, is a small oval cavity lined by a membrane common to the labyrinth, contains a watery fluid, and presents the following openings, viz.: The foramen ovale, the five orifices of the semicircular canals, the orifice of the scala vestibuli of the cochlea, and the orifice of the aqueduct of the vestibule.

The *semicircular canals*, placed behind the vestibule are three in number, two

vertical and one horizontal; of the former, one is superior and the other posterior. The openings of these canals are only five in number, in consequence of one opening of the vertical canals being common to both.

The *Cochlea*, of a conical form, the base towards the internal meatus, the apex towards the carotid canal is composed of a bony tube which makes two turns and a half round a central pillar called the *modiolus*. This tube is divided longitudinally by a thin plate, half bony half membranous and called *lamina spiralis*, into two independent cavities: the two tubes thus formed are called the *scala* of the cochlea, they both unite at the apex in a cavity called *infundibulum*, and at the base of the cochlea they separate, one called *scala vestibuli*, the other called *scala tympani*, which opens into the tympanum by the foramen rotundum. From the *scala tympani* proceeds a narrow bony canal called the *aqueduct of the cochlea*, which terminates in a slit-like opening in the petrous bone, a little inferior to the meatus auditorius internus.

The *auditory nerve* gains the internal ear by the minute foramina at the base of the meatus auditorius internus, and is expanded in the form of soft pulpy filaments in the cochlea and vestibule.

THE ABSORBENT SYSTEM

comprehends, 1st. the vessels which convey the lymph and chyle into the veins, and 2ndly. the enlargements which occur in their course called glands or ganglia.

The *Lacteal* or *Chyliferous vessels* commence on the mucous surface of the intestines, pass through the mesenteric glands backwards towards the spine, where they terminate in the thoracic duct.

The *lymphatic vessels* are found in most situations of the body, and generally observe a deep and superficial arrangement.

Lymphatics of the lower extremities. The superficial set accompany the external and internal saphena veins: they communicate freely in their course with the deep lymphatic trunks which accompany the deep vessels. Those which accompany the external saphena vein enter the glands in the popliteal space, whilst those accompanying the internal saphena vein ascend to the groin and pass through the inguinal glands, having formed numerous connections with the superficial

lymphatics of the abdomen, the perineum, and the genitals. The deep lymphatics of the hip and perineum are conducted by the branches of the internal iliac vessels into the pelvis and pass through the pelvic glands. From the inguinal and pelvic glands the lymphatics pass along the primitive iliac vessels to the receptaculum chyli.

The *Thoracic Duct*. This canal commences by a dilatation called *receptaculum chyli*, placed on the body of 2nd. or 3rd dorsal vertebra, passing between the crura of the diaphragm it gains the posterior mediastinum, where it lies between the aorta and the vena azygos; at the fifth dorsal vertebra it crosses the spine obliquely to the left side, passing behind the œsophagus and arch of the aorta, and placed behind the left pleura and between the left carotid and left subclavian arteries, it is conducted by the œsophagus to the left side of the neck as high as the sixth cervical vertebra, where, making a slight curve downwards and outwards, it opens close to the angle formed by the left subclavian and jugular veins.

Lymphatics of the upper extremities.

—The superficial set accompany the superficial veins, and pass through two or three glands situated at the inner condyle; having joined the deep lymphatics which accompany the *venæ comites*, they proceed onwards to the axilla, and pass through the axillary glands; following the course of the axillary vein, they pass beneath the clavicle, join the lymphatics of the neck, and terminate in the thoracic duct. The lymphatics of the right upper extremity and right side of the neck unite to form the *right* or *lesser thoracic duct*, which opens into the right vena innominata.

The lymphatics of the trunk consist of a deep and superficial set; in the chest the former are seated between the muscles and pleura, in the abdomen between the muscles and peritoneum, the superficial being subcutaneous. The viscera contained in the chest and abdomen also have a superficial and deep layer of lymphatics, the deep being distributed to the peculiar tissue of each organ, the superficial running beneath the membranous envelope.

Lymphatics have been denied to the brain and spinal chord, and to the ear, eye, and placenta.

LINNÆAN SOCIETY.

From a forthcoming "History of the Learned Societies of the Metropolis,"

By A. BOOTH, F.B.S., &c.

The impulse given to the prosecution of science, and the steps which were taken on the Continent, in the advancement more particularly of natural history, towards the termination of the eighteenth century, gave a powerful impulse to English philosophers and naturalists. Hitherto the transactions of the Royal Society had been the only archive for the deposit of the results of their progress, or the arena of their discussion; and its proceedings were so very extensive that the limits of research in any capacity were of necessity extremely narrow. From the beginning, that learned body had bestowed great attention upon the physiological part of natural history. Mr. Willoughby, the distinguished English naturalist, was one of the original fellows; his friend Ray, the father of English botany, was admitted in the year 1667; Dr. Lister, the great conchologist, was very early associated with it, as well as that admirable vegetable physiologist, Dr. Grew. Nor was France behind hand with England in attention to the sciences, and particularly of natural history. Henry IV. had long ago endeavoured to promote literature and useful knowledge throughout his dominions; and, amongst other institutions, the botanic gardens at Paris and Montpellier were owing to his munificence; but his untimely death, and the subsequent disturbances, for a while put a stop to the cultivation of the arts of peace. In the reign of Louis XIV., for the purpose of promoting botany and enriching the royal garden, the illustrious Tournefort was sent to the Levant; and the accurate and indefatigable Plumier made three voyages to America, and died as he was about undertaking a fourth. An Academy of Sciences was instituted at Paris in 1666, and another some years after at Montpellier. Many similar institutions were set on foot throughout other parts of Europe, of which was the Imperial Academy, *Naturæ Curiosorum*, begun in 1652. A number of botanic gardens were also established in Germany, and the gardens of Holland were overflowing with riches from the most distant parts of the globe. The Amsterdam garden, under the care of the Comelins, was now

one of the first in Europe; and that of Leyden was rendered celebrated by the catalogue published by Herman. Holland had likewise the glory of producing at this time that most sumptuous and excellent work, the *Hortus Malabaricus*, by which a new world was, in a manner, laid open to the botanists of Europe; and from which they learned with surprise that the knowledge of plants had made almost as much progress in the remote regions of Asia, as in their own part of the world. The study of nature, however, was no where making so uniform and steady progress as in Sweden, for at Upsal, under the auspices of the great Rudbeck, was laid the foundation of an unrivalled school of natural history, which was destined afterwards to give laws to the rest of the world.

During this period several distinguished botanists and naturalists brought forward several systems, upon many of which warm controversy ensued. The first who revived the idea of a classical arrangement of plants, since the time of Cæsalpinus, was Morrison, after whom succeeded Ray, Tournefort, and Rivinius. To these succeeded Vaillant, who is the first who was well acquainted with the sexes of plants; Boerhaave, whose system had great merit in being founded more or less on all the parts of fructification; Christopher Knaut, whose method was an alteration of that of Ray, without any improvement, and Professor Magnol, of Montpellier. Nor was this era of botany a systematic one, as Linnæus asserted that, at the termination of the seventeenth century, within the space of twenty years, twice as many plants were discovered as had been made known by the joint labours of all preceding botanists. Besides those which were collected by Tournefort, Plumier, and Ray, a noble collection was brought from Jamaica, by Dr. Sloane afterwards Sir Hans Sloane. Mr. Sherard, consul at Smyrna, who cultivated botany with princely munificence, and the ardour and discernment of a true philosopher was the means of making known a very great number of plants; and his vast herbarium and library were deposited in the University of Oxford. The indefatigable Plukenet procured and published an immense number from all parts of the world; Petiver was no less persevering in making collections; the acquisitions of Dr. Herman in Ceylon were very considerable; and the rich treasures of Amboyna were made known by the laborious Rumphius, whose ardour was not to be damped even

by the greatest misfortune that can befall a naturalist—the loss of sight.

While botany was making this great progress, entomology began to be cultivated with an assiduity which was amply repaid by the curious and astonishing facts it brought to light, the notion of equivocal generation having been refuted by Harvey, Redi, and Malpighi, the propagation and metamorphoses of insects became an interesting objects of inquiry with several able men; among the first of whom were Goedart and Swammerdam. Madame Marian also wrote a work on the insects of Surinam, one of the most splendid in natural history. Other admirers of nature turned their attention to shells and marine productions; a few authors, as Aldrovandus, Columna, Imperati, &c., had written on shells about the beginning of this century, but at the end Bonnani and Lister were particularly distinguished as writers on conchology. Mineralogy yet made little progress, for even now Tournefort maintained the vegetation of stones, and Lister asserted that extraneous fossils were only *lusus naturæ*, and never were the real shells they represented.

The removal of Dillenius to England, who published an excellent edition of Ray's *Synopsis Stirpium Britannicarum*, in 1724; the assistance and encouragement given to the science by those distinguished brothers, William and James Sherard, as well as by Sir Hans Sloane, seemed to promise the establishment of the botanic sceptre in this country. The Physic Garden, at Chelsea, was in a very flourishing state under the care of the celebrated Miller; and that of Mr. Sherard, at Eltham, contained one of the choicest collections in Europe. Botanists were, however, almost at a stand without arrangement, as all the different systems which had been proposed were found very insufficient for the purposes of practical botany; the science was again in danger of relapsing into confusion, and botanists were almost overwhelmed with the riches which daily flowed in upon them. In this state of things a new turn was given to the science of botany, and indeed to all natural history, by the publication of the *Systema Naturæ* and *Fundamenta Botanica*, of Linnæus, in 1735, nor were the learned world determined how they should receive these extraordinary productions, when, in 1737, the same author fixed the attention of all Europe by his *Critica Botanica*, *Genera Plantarum*, *Hortus Cliffortianus*, *Flora Lapponica*, No. 21.

and *Methodus Sexualis*, five works of great merit, all the produce of one year. Returning in 1739 to Sweden, his native country, he laid the foundation of the Academy of Sciences at Stockholm, of which he was the first president; and his medical and botanical lectures at Upsal soon attracted a number of students from all parts of the world, and exalted that university to a degree of fame previously unknown. His *Fauna Suecica* appeared in 1746, and his *Materia Medica* in 1749; in 1751 appeared the *Philosophia Botanica*; and two years afterwards, the first edition of his *Species Plantarum*. This may be reckoned the most flourishing period of natural history, when disputes about methods and systems being for the most part laid aside, every admirer of nature's works was employed in practical observations and discoveries; while Linnæus, whom nothing escaped, and to whose decision all doubts and difficulties were referred, supervised and methodised the whole. His improvements, in particular, had so much facilitated the study of botany, that it was no longer an abstruse science confined to the schools, but became an agreeable amusement to persons of leisure in all ranks and situations.

At this period in England, great progress had been made in Horticulture, particularly by the celebrated Miller's instrumentality. Bartram was sent to America for the purpose of supplying our gardens with plants; and we are much indebted to him, as well as to Houston, who discovered many rare vegetables in South America and the West Indies. In Holland botany was ably supported by the labours of the two professors, Van Royen, at Leyden, and the assiduous Burman, professor at Amsterdam. In Germany, Professor Ludwig, of Leipsic, was in great reputation, and he showed himself an able physiologist and accurate observer, but no where were the Linnæan improvements more slowly received than in France, except in the south, where they had many admirers. At Berlin, botany and Linnæus had long a noble support in Professor Gleditsch, who first principally distinguished himself by answering the criticism of a contemporary upon the Linnæan system. In addition to the tour of Linnæus to Lapland, of Buxbaum to the Levant, and of Gmelin to Siberia, where they were sent by the Petersburg Academy, several expeditions for researches in Natural History, were undertaken by the disciples and pupils of the

former. In 1745, Ternstroem, one of his first, undertook a voyage from Cochin, but died at Poulicandor; Katsn, who visited North America in 1747, by his botanical discoveries very much enriched the *Species Plantarum* of his great master; Hasselquist visited Egypt and the Holy Land in 1749; Osbeck went to the East Indies in 1750; and Loetzing, a favourite disciple of Linnæus, and an excellent botanist, undertook the examination of Spain in 1751, where he found many new and rare plants; but having left for South America, he was there cut off at the early age of twenty-seven. Amongst others, Martin and Solander visited Lapland, Bergius and Talk went to Gothland, Solander to Surinam and St. Eustatia, in 1775; Martin visited Spitzbergen in 1771, and Toren went twice to the East Indies; all of whom contributed very much to the general stock of natural knowledge. Whilst botany was thus progressing, the age of Linnæus was no less brilliant in zoology. In our own country was the ingenious, accurate, and patient Ellis, whose discoveries relating to corallines formed one of the most interesting events in the history of the last century. Many of the most systematic botanists, as Scopoli, Hudson, and Alioni, turned their attention to the study of entomology which also boasted of Geoffrey, De Geer, and Reaumur. A still less attention was paid to the works of Linnæus in France, than even to those on botany, which was principally attributed to the success of his great opponent, the Count Buffon, whose splendid publications and captivating style of writing, so well calculated to dazzle the multitude, and to charm the people among whom he lived, engrossed all the attention of his countrymen, and have been admired throughout Europe. The French possessed a more systematic writer than the latter in Brisson; and England produced a genius at least equal to the latter in Pennant; whilst Bonnet, of Geneva, was equally distinguished. In 1771, Linnæus, whose powers were beginning to decline, published the *Manitissa Altera*, which may be considered his botanical testament soon after which he died.

HEAT—COLD—CLIMATE—AIR.

The known powers of nature may be reduced to two primitive forces, *attraction* and *repulsion*. The first is the cause

of *gravity*; in other words, it is by the attraction that exists between the mass of the earth and all bodies near its surface, that everything has a natural tendency downward; that, in fact, all matters naturally fall to the ground, &c. The second principle is the cause of *elasticity*, and this, by counteracting the effects of attraction, prevents the matter of the universe from becoming a solid mass.

Ancient authors believed, and it is still popularly understood, that there are only four distinct species of elementary or original matter, namely, fire, air, water, and earth. Modern science has however discovered that none of these are to be considered as *elements*, or *primary substances*; while, on the other hand, it has increased the number of elementary *principles* to fifty-two. But as the popular arrangement is sufficient for our present purpose, we will not depart from it.

There is reason to believe that fire, heat, or caloric, is the only *permanently elastic substance* in nature. When it penetrates the pores of any body, it uniformly causes the expansion of such body. A bar of iron is lengthened by being heated, metals and other substances are melted by heat, and by heat water is converted into vapour. There is therefore ample ground for believing that all fluidity is the effect heat. The natural state of water is ice; and air itself, where there are any means of producing a sufficient degree of cold, might probably be reduced to a solid mass.

As all fluidity has heat for its cause, so we find that a much greater degree of heat is requisite to keep one substance in a fluid state than another. Iron, for instance, requires more heat to keep it in fusion than gold; gold much more than tin; but much less suffices to keep wax, much less to keep water, much less spirit of wine, and at last exceedingly less for mercury (qui ksilver), since that metal only becomes solid at 187 degrees below the point at which water freezes; mercury, therefore, would be the most fluid of all bodies, if air were not still more so. Now, what does this fluidity, greater in air than any other matter, indicate? It appears to indicate the least degree of adherence that can be conceived between the parts of which it is composed, supposing them to be of such a figure as only to touch each other at one point. The greater or less degree of fluidity does not, however, indicate that the parts of the fluid are more or less weighty, but only that their adherence is so much the

less, their union is so much the less intimate, and their separation so much the easier. If a thousand degrees of heat are required to keep water in a fluid state, it might perhaps require but one to preserve the fluidity of the air.

It is yet doubtful whether light consists of the same matter with the elementary fire or not. The great source of light is found to be the sun, from which it is projected to the earth in the space of about eight minutes; and as the sun is computed to be distant ninety-five millions of miles, light must of consequence travel at the rate of about two hundred thousand miles in one second of time.

Light may be reflected as well as projected. The light which we receive from the moon is only reflected from a mirror. The light of the sun is three hundred thousand times stronger than the light of the moon.

The air we inhale is composed of 21 parts of oxygen to 79 of nitrogen gas, which are mixed with vapour and small quantities of other gases.

The effects of heat in producing a noxious quality in the air, are well known. The torrid regions under the line are always unwholesome. At Senegal, the natives consider forty as an advanced time of life, and generally die of old age at fifty. At Carthage, where the heat of the hottest day ever known in Europe is continual . . . where, during the winter season, these dreadful heats are united with a continual succession of thunder, rain, and tempests . . . the wan and livid complexions of the inhabitants might make strangers suspect that they were just recovered from some dreadful distemper. The habits of the natives are influenced by the same causes as their colour, and all their motions are relaxed and languid; the heat of the climate even affects their speech, which is soft and slow, and their words generally broken. Travellers from Europe retain their strength and colour, possibly for three or four months, but afterwards suffer such decays in both, that they are no longer to be distinguished by their complexion from the inhabitants. Here, however, this languid and spiritless existence is frequently drawled on sometimes even to eighty. Young persons are generally most affected by the heat of the climate, which spares the more aged; but all, upon their arrival on the coasts, are subject to the same train of fatal disorders. In the memorable expedition to Carthage, more than three parts of our

army were destroyed by the climate, and those that returned from that fatal service, found their former vigour irretrievably gone. Of the expedition to the Havannah, not a fifth part of the army were left survivors of their victory; climate is an enemy that even heroes cannot conquer.

The distempers that proceed from those climates are many: that, for instance, called the *Chapotonadas*, carries off a multitude of the people, and extremely thins the crews of European ships, whom gain tempts into those regions. The nature of this distemper is but little known, being caused in some persons by cold, in others by indigestion. But its effects are generally fatal in three or four days: upon its seizing the patient it brings on what is there called the black vomit, after which few are ever found to recover.

A different set of calamities prevail in some climates where the air is condensed by cold. In such places the train of distempers known to arise from obstructed perspiration, are very common—eruptions, boils, scurvy, and loathsome leprosy, that covers the body with a scurf and ulcers. These disorders are also infectious, and not only banish the patient from society, but generally accompany him to the grave. The men of those climates seldom attain to the age of fifty; but the women, who lead less laborious lives, live longer.

One fact our senses teach us, namely, that although the air is too fine for our sight, it is very obvious to the touch. Although we cannot see the wind contained in a bladder, we can very readily feel its resistance; and though the hurricane be colourless, we know that it does not want force. We have equal experience of the spring, or elasticity of the air; a bladder filled with air, when pressed, returns again, upon the pressure being taken away.

So far the slightest experience teaches us; but, by carrying experiment a little further, we learn that air also is *heavy*; a glass vessel, emptied of air, and accurately weighed, will be found lighter than when weighed with the air in it. Upon computing the superior weight of the full vessel, a cubic foot of air is found to weigh 527 grains, while the same quantity of hydrogen gas weighs no more than 40 grain. This familiarly illustrated in balloons, the ascent of which is at the present time so common in this country. The balloon ascends because the gas with which it is filled is lighter than the quan-

ity of atmospheric air which would fill the same space as the balloon itself, and the ascending power of the balloon, and consequently the weight it will carry, is in proportion to the actual difference between the weight of the gas and the weight of the air. When it is required that the balloon shall descend, some of the gas is let out of the balloon through a valve, just as water might be let out of a barrel. The gas that remains in the balloon is still lighter than the air, measure for measure, but the proportions between the gas originally contained in the balloon and the weight the balloon carries, are destroyed; the balloon with its burden becomes heavier than the air it displaces, and, consequently, the balloon descends.

We learn, therefore, that the earth, and all things upon its surface, are in every direction covered with a ponderous fluid, which, rising very high over our heads, must be proportionally heavy. For instance, as in the sea a man at the depth of twenty feet sustains a greater weight of water than a man at the depth of but ten feet, so will a man at the bottom of a valley have a greater weight of air over him than a man on the top of a mountain.

If by any means we contrive to take away the pressure of the air from any one part of our bodies, we are soon made sensible of the weight upon the other parts. Thus, if we place the hand upon the mouth of a vessel whence the air has been expelled, we feel as if the hand were violently sucked inwards; this is nothing more than the air upon the back of the hand that forces it into the empty space below.

As by this experiment we perceive that the air presses with great weight upon everything on the surface of the earth, so by other experiments we learn the exact weight with which it presses. First, if the air in a vessel be exhausted, and the vessel set with the mouth downwards in water, the water will rise up into the empty space, and fill the inverted glass—for the external air will, in this case, press up the water, where there is no weight to resist, just as one part of a bed being pressed makes the other parts that have no weight upon them rise. In this case, as we said, the water being pressed without, will rise in the glass, and would continue to rise to a height of thirty-two feet. Hence we learn, that the weight of the air which presses up the water is equal to a pillar, or column, of water, thirty-two feet high, for it is able to raise such a

column, and no more. In other words, the surface of the earth is everywhere covered with a weight of air, which is equivalent to a covering of thirty-two feet deep of water, or to a weight of twenty-nine inches and a half of quicksilver, which is just as heavy as the former.

It is found, by computation, that to raise water thirty-two feet requires a weight of fifteen pounds upon every square inch. Now, if we are fond of computations, we have only to calculate how many square inches are in the surface of an ordinary human body, and allowing every inch to sustain fifteen pounds, we may amaze ourselves at the weight of air we sustain. It has been computed that the ordinary pressure of the air on a man amounts to within little short of forty thousand pounds!

The elasticity of the air is one of its most amazing properties, and to which it should seem nothing can set bounds. A body of air, that may be contained in a nut-shell, may be dilated by heat into a sphere of unknown dimensions. On the contrary, the air contained in a house may be comprehensible into a cavity not larger than the eye of a needle. In short, no bounds can be set to its confinement or expansion, at least experiment has hitherto found all attempts indefinite. In every situation air retains its elasticity, and the more closely compressed, the more strongly does it resist the pressure. If, in addition to increasing the elasticity by compression, it be increased by heat, the force of both soon becomes irresistible; and it has been well said, that air, thus confined and expanding, is sufficient for the explosion of a world.

NITRATE OF SILVER IN GONORRHŒA.

“Philip Bennett Lucas recommends the *Argentum nitricum* in gonorrhœa. Even during the first stage he injects a solution of ten grains in an ounce of rose-water. The first injection causes commonly at the instant violent pain, which lasts for twenty minutes, and is also felt on voiding urine. Soon after, the secretion becomes thicker and more scanty, and after a second injection disappears entirely. For the most part two injections suffice; sometimes, however, they must be renewed. In gleet this plan is useless. The syringes ought to be made of ivory or bone. The surgeon must perform the injection himself, and not confide them to the patient!”—*Dierbach's Neusten Entdeckungen in der Materia Medica*, p. 539. 1837.

The London Medical

AND

Surgical Journal.*Saturday, August 26th, 1837.***NECESSITY OF PUBLIC EXAMINATIONS—THE LONDON COLLEGE OF SURGEONS—THE METROPOLITAN UNIVERSITY.**

The London Medical and Surgical Journal was the first amongst its contemporaries, seriously and emphatically, to urge on the consideration of the medical senate of the NEW METROPOLITAN UNIVERSITY, the expediency of adopting public examinations as the only true and honest means of ascertaining the proficiency of candidates desirous of obtaining its *diploma*, and as the only method of silencing complaints, which the most illiterate student and the best informed had equally in their power to make against their examiners, in the event of rejection.

We also pointed out that to the student himself a public examination would be even a greater boon than to his examiners, inasmuch as his feelings dared not be tampered with, and that in the event of timidity for a time taking possession of him, full allowances would be made for such; a reasonable period would be allowed him to familiarize himself to his novel situation; and the terrors and injustice of the closed-doors system, so often made available for the most nefarious ends, would sink into insignificance when deprived of the mystery which it is the object of the Examiners of the far-famed associations of Lincoln's Inn Fields and Blackfriars, for purposes too apparent, to envelope it.

Scarcely had our observations, on this infamous hole-and-corner method of con-

ducting examinations, met the public eye than we received numerous communications on the subject; some from individuals who had experienced gross injustice at the hands of the examiners—some who considered the question in a calmer mood—and, in particular, a communication from a member and a participator in the spoils of one of the associations we have alluded to. These letters, however, we refrained from publishing, not having permission from their authors to affix their names to them; and that of our valued correspondent —, —, we made use of effectively, without however compromising his high character and position in the slightest degree.

If further evidence were necessary to show the innate baseness of the Council of the College of Surgeons, and the tenacity with which they adhere to a system of examination discountenanced by every honourable mind, we have only to refer to their late edict, wherein that despicable junto had the daring effrontery to command that any member of the college who was desirous of giving lectures on medical science, should be driven to the humiliation of presenting himself to undergo an examination in order that he might prove to THEM—a *self-elected despicable body of monopolists*—his competency as a teacher. A proof of the *propriety* and *delicacy* of this odious edict has lately been strongly exemplified in the case of an eminent individual, who, though not far advanced in “the prime of youth,” yet is possessed of sufficient professional reputation to have been selected as eminently qualified to fulfil the important medical duties of more than one of our metropolitan charitable institutions, and a man who has already largely contributed to medical literature.

The profession will rejoice to learn, and it redounds much to the credit of the

individual, that he has rejected with a proper contempt, the test by which it was proposed to ascertain his capabilities as a teacher; and we have an honest pride in stating that the new professor, notwithstanding the impediments thus cast in his path to professional fame and honour, intends to give the students of medicine in the Northern division of London an opportunity of availing themselves of his instruction.

PROFESSORSHIP OF ANATOMY IN THE UNIVERSITY OF DUBLIN.

We are informed on authority, upon which we can rely, that Dr. Harrison of Dublin is the most likely candidate to fill the chair of anatomy, vacated by Dr. Macartney. If the late Professor Quain would subscribe to the Thirty-nine Articles, and take the oath abjuration, and become a brother of the purple and orange lodges he would be appointed; but such is the intolerance of the silent sister, that were Herophilus, Erasistratus, and John Hunter candidates, they would be excluded on any other terms.—Such is the march of intellect in the far famed Trinity College Dublin.

Tempora mutantur et nos *non* mutemur cum illis.

UNIVERSITY COLLEGE HOSPITAL

LATE

NORTH LONDON.

[The following is Mr. Liston's account of his fatal case of lithotrity, as published in the *Lancet* of last week, and to which we alluded in our last. We shall offer no comment on it at present, but leave our reporters to notice it as they think proper.]

Lithotrity—Mismanagement with a Catheter—Death.

William Knox, aged sixty-one, was admitted on the 24th of June. About two years and a half ago he met with an accident, whilst on horseback, striking himself on the pommel of the saddle, for which he was cupped and leeches at the time, and was confined to his bed for a month; during this period he first experienced pain in making water, and when he took exercise he had small discharges of blood. About twelve months afterwards he passed a small stone, of about the size of a pea, from which he felt much relief. At present he complains of extreme pain at the end of the penis, extending up to the kidneys and down the thighs. He passes urine every half hour, mixed with clotted blood, sometimes stopping, then flowing again.

June 24. Mr. Liston sounded him, and found two stones in the bladder, and ordered him to drink freely of barley-water, and to have his bowels opened with castor-oil.

26. The lithotrite was introduced, and one of the stones easily crushed. The patient did not appear to suffer much pain from the process, and lost a very small quantity of blood.

Eight o'clock. The patient laboured under suppression of urine, which was mistaken for retention, by the house-surgeon then in office, whose plan of proceeding is described in the remarks made by Mr. Liston, in lecturing on the case, and reported farther on.

27. The urine very scanty; great pain in the left side, in the region of the bladder; swelling of the abdomen; bowels much confined. A dose of castor oil was given, but immediately vomited up. An enema, and a minim of croton oil, failing to take effect, the enema was repeated, and half a minim of croton oil, with two grains of calomel, was given every three hours. Pulse 90, natural.

28. Swelling of the abdomen, and tympanitic sound greatly increased; bowels still confined: extreme pain over the left side of the bladder; urine still very small in quantity, and bloody. Two drachms of carbonate of magnesia in two ounces of water, directly. Thirty-six leeches to the left side, in the region of the bladder; fomentations afterwards. Two grains of calomel and half a grain of opium every four hours. A mixture, composed of three minims of hydrocyanic acid, in four ounces of water, a table-

spoonful every third hour. Pulse, 100, and weak; tongue dry, and furred.

Three o'clock, P.M. Had a copious watery evacuation, well tinged with bile, and the purging continued every hour during the night.

29. Feels much relieved; pain greatly diminished; purging ceased at eight o'clock. Omit the hydrocyanic acid; to have some traccanth, and liquor potassæ.

Three o'clock, P.M. Omit the calomel and opium. Six grains of hydrag. cum creta, with half a grain of opium, every three hours. Pulse 120, small; countenance anxious; extremities cold, with clammy perspiration.

Nine o'clock. Still sinking; a small quantity of gin ordered. No inclination to sleep; urine slightly increased in quantity, but still bloody; bowels confined.

30. Gradually got weaker, and died at twelve, P.M.

In lecturing on this case, Mr. Liston observed, that when he performed the operation he was ignorant of some circumstance which had since come to his knowledge. The individual who had officiated as house-surgeon, *pro tempore*, had also omitted to state some circumstances regarding the after-treatment, which materially affected the issue of the case, and which he (Mr. Liston) was now painfully compelled to mention. When he first sounded the patient he easily detected two stones, neither of which was large, and the case seemed to be favourable for lithotomy, no circumstances appearing to counter-indicate the operation, the patient himself being anxious for its performance. The urine was tested, and was found to be but slightly albuminous. They had seen at the operation that after injecting the bladder he had experienced little difficulty in introducing the lithotrite. There was a slight stoppage at the triangular ligament, but this was readily overcome by the partial withdrawal of the instrument, and passing the point lower. One of the stones was easily seized and broken up, the patient suffering little, and losing scarcely any blood. Indeed, very little force was used or required. The patient suffered so little that the scoop was introduced twice, and several portions of the stone were seized, pulverized, and removed. So completely was it broken, that the nucleus was extracted on the second introduction of the scoop. After the operation the patient, who had complained very little of any part of the process, walked up stairs to

bed, unassisted. He, Mr. L., had since found that the patient had passed a very restless night previous to the operation; that he had made little urine, and was very feverish. In the reports of the case on the 27th, some very important circumstances had been omitted by the house-surgeon, who, it appears, having mistaken the suppression of urine for retention, endeavoured to introduce a catheter a long time without success. A gentleman who witnessed the proceeding thus describes it, in a letter, dated July 5th:—"I think he may have torn the urethra when I saw him; he had been some time trying to pass an instrument; there was plenty of blood; he fancied that the instrument was passed, and that he could feel it grating on some sand, but that I think that what he felt was caused by the eyes of the catheter rubbing over the sides of the torn urethra. I am certain he was not in the bladder when he fancied that he was." The catheter was again introduced, contrary to his (Mr. Liston's) orders. The parts were, after death, carefully dissected by Mr. Taylor. The urethra was severely lacerated in two parts, each admitting the point of a bougie; one passing from the membranous portion into the substance of the prostate, another from the apex of that gland, under its capsule. The bladder contained one entire stone, and many fragments of another. There was a cyst opening from the bladder, filled with puriform matter, the cellular tissue being broken down. One of the kidneys contained stones of various sizes; the other was proceeding to disorganization; the patient, therefore, could not have been cured. He (Mr. Liston) considered it proper to state these facts, both on his own account and on account of lithotomy itself, than the performance of which, as an operation, nothing could have proceeded more satisfactory. He was, however, misled respecting the state of the patient on the morning of the operation. The ill success of the case was mainly attributable to the lesions which he had named, so sure were untoward and unnecessary attempts to pass a catheter, when the bladder was empty, to tend to an unfortunate result in such a case, the bladder being, during the operation, as they saw, occupied by a sufficient quantity of fluid, and the whole process being conducted with the utmost care and gentleness. Mr. Liston further remarked, that the operation of lithotomy, if well understood, would, in many cases, if it

the subjects for its performance were properly chosen, do away with the necessity of cutting. Patients, under a prospect of so easy a means of relief, would apply early to the surgeon, and the cure would consequently be rendered so much the easier. The instruments had been so much simplified and improved of late years, that the operation was now by no means a formidable one, and was attended with none of those dangers to which it was liable when the complicated and inefficient apparatus was first brought into use.

ANOTHER PRIVATE AND EXTRAORDINARY OPERATION IN LITHOTRITY.

On Friday evening the 18th instant, at dusk, a ladder and scaffolding were appended to the medio-anterior aspect of the *late* NORTH LONDON HOSPITAL, and all preliminaries being arranged, the master stone-cutter of the charity proceeded to remove the obnoxious calcareous excrescences, which until then disfigured that region of the edifice.

Before the operation was determined upon, the opinions of the therapeutic and obstetric professors were conjointly taken. The only objection raised in the consultation was as to whether the time-serving excrescences of N.O.R.T.H. L.O.N.-D.O.N. H.O.S.P.I.T.A.L. could be better removed without injury to the OBJECT, by the *bone nippers*, the *lithotriptic machine*, or the ordinary *pile-engine*.

After a most painful and learned discussion by the *northern luminaries*, it was unanimously resolved that the ordinary gouge and mallet were the most efficient instruments for extirpating the IMPOSING characters of the disease, and for completely obliterating the TYPE of the dis-temper.

At half past nine o'clock P.M. the operation was commenced, and in one minute four seconds and three quarters, as ascertained by the college time-keeper, the entire was completed.

We regret to add that the result has been fatal!

Of an originally fair and sound constitution, the deceased promised a few years ago to live a long and useful life; but from being tampered with by designing intriguers, it soon fell a victim to the combined influences of avarice, humbug, duplicity, and arrogance.

The morbid parts removed, have been consigned to the care of the curator, who has expressed his ability to form from them an original and curious series of *plastic* preparations.

The following beautiful and pathetic epitaph has been sent to the stone cutter to be carved. Here lie the remains of North London Hospital.

Beneath this marble slab
Lie buried the remains,
Of Old North London Hospital
Fam'd for curing aches and pains.

Tread lightly gentle reader
O'er its skeleton of bones,
For in its day it witnessed
The cutting out of many stones.

Requiescat in pace!

EDINBURGH UNIVERSITY.

On Tuesday, the 1st of August, 105 gentlemen received the degree of doctor of medicine in this University, after having the previous day defended their theses. Of these, only one was written in Latin, a circumstance which a contemporary of yours some time ago thought fit to deplore, as evincing a sad falling off in classical knowledge. Now it was well known that formerly the theses were no more written in Latin by the candidates for the degree than they are now, the English copy being almost invariably translated into that language by individuals who received so many guineas for the trouble. Abolishing Latin composition, and Latin examinations, marks the advance of improvement in our University, as it was well known that the affected cloak of learning only served to cover the grossest ignorance, while it offered no incentive to the industrious or talented student, inasmuch as his Latin compositions were never read, and his Latin examination was a mere form. It has been an object lately with the senatus to improve the character of the theses, and with this view it was advertised that a gold medal would be given for the best production of this class. This plan appears to have been eminently successful; a large number of most excellent theses have been given in. On the graduation day Sir C. Bell, as Dean of the Faculty, announced that Dr. W. H. Madden had obtained the Medal for the best essay on cutaneous absorption. Dr. J. H. Bennett another for the best re-

port of surgical cases. Dr. J. R. Cormack, and Dr. A. S. Thomson, one each for their respective thesis. He stated that the two latter prizes had been awarded to those dissertations which contained the greatest amount of original information; but that the theses of the following gentlemen had likewise been selected by the professors as worthy of being so distinguished:—Dr. H. C. Barlow, Dr. J. H. Bennett, Dr. W. H. Madden, Dr. G. S. Newbigging, Dr. C. Chadwick, Dr. M. Satterthwaite, Dr. T. W. Curtis, Dr. Hunter, Dr. E. C. Seaton, Dr. J. O'Brien, M. Barry.

We understand that the prize essays were all extremely good; and as one of the conditions was to print, we anticipate that the profession generally will benefit by the mass of experiments and original observations which we understand to have been displayed in the respective dissertations. The medals, much to the disappointment of those present, were not forthcoming, a circumstance owing no doubt to the anxiety of the senatus that the die about to be made for the occasion, and the medals themselves, should be worthy of the successful competitors, and the alma mater to which they belong.

The following is a list of the gentlemen, 105 in number, who received the degree of Doctor of Medicine at the University of Edinburgh, Tuesday, August 1st, with the title of their theses:—

H. C. Barlow—On the causes and effects of disease, considered in reference to the moral constitution of man.
T. H. Burgess—On paralysis.
William Brown—On morphology.
W. H. Brownson—On the nature and treatment of gunshot wounds, and their consequences.
William Bayard—On Asiatic cholera.
Robert Butler—On apoplexy.
J. H. Bennet—On the physiology and pathology of the brain.
J. H. Branfoot—On the acquired perceptions of hearing.
J. O'B. M. Barry—On endocarditis.
James Barlas—On artificial pupil.
P. J. Barry—On rheumatism.
J. E. Cummins—On ophthalmia.
G. S. Carden—On tempora y insan
George Cossar—On inguinal hernia.
Joseph Cartmell—On pseudo-pathological appearances.
J. R. Cormack—On the air in the organs of circulation.
Francis Cooke—On pellagra.
J. W. Curtis—On the functions of the cæcum.

Michael Cormack—On asthma.
C. Chadwick—How far are secretion and nutrition dependent on nervous influence?
J. R. H. Couson—On nature, symptoms, and treatment of bronchitis.
A. W. Campbell—On acute pericarditis, particularly as connected with rheumatism.
Thomas Crawford—On paralysis.
Alex. Duncan—On hernia.
R. H. Davidson—On the organs and physiology of digestion.
Hugo Donaldson—On bronchitis.
S. P. C. Evans—On equivocal, comparative, and human generation.
James Edwards—On neuralgia.
John Fortune—On acute hepatitis.
J. W. Fullarton—On mortification.
George Frazer—On the connexion of nervous energy with muscular contractibility.
Thomas Gordon—On erysipelas.
F. W. Grant—On the nature, diagnosis, and treatment of aneurism; with a few remarks on the spontaneous suppression of hæmorrhage.
John Grant—What are the relative advantages of different trades and professions, as regards their compatibility with bodily health?
Alexander Greig—On asphyxia.
W. T. Geary—On the hydrated peroxide of iron as an antidote to arsenic.
G. D. Gordon—On acute dysentery.
John Houseman—On the morbid affections of old age.
A. Hunter—On the pathology and treatment of granular disease of the kidney.
S. Hunter—A practical treatise on ruptured urethra, produced by external violence.
George Hood—On aneurism and its treatment.
William Hilliard—Some general considerations on phlebitis.
Thomas Hayle—De necrosi.
William Hey Hodgson—On apoplexy.
E. Johnson—On the anatomy of the mammary gland.
J. Johnson—On the tongue, pulse, and urine, as indications of health and disease.
Jame Jopp—On angina pectoris.
H. Kinglake—On the physiology of digestion.
G. Kennion—A sketch of some of the principal diseases which are peculiar or incident to the puerperal state.
W. D. Kingdon—On scirrhus.
P. G. Kennedy—Observations on the

- general pathology of diseases of the eye, with remarks on the characters which are diagnostic of the idiopathic and symptomatic ophthalmia.
- Adam Lyszeński—On small-pox.
- S. D. Lees—On the pathology of the ear.
- T. H. Lowry—On tetanus.
- George Lund—On the use of the thyroid and thymus glands, and of the spleen and suprarenal capsules.
- George Aaron Martin—On scorbutus.
- W. H. Madden—On the connexion between the muscles and nervous system.
- L. M'lean—An account of the bilious remittent fever, more particularly as it occurs in the West Indies.
- Alexander Ross Morton—On dysentery.
- H. Montgomery—On the origin and mode of formation of tubercles in the lungs.
- W. O. Mackenzie—On the distinctive characters, classes, and treatment of those ulcers (including hospital gangrene) which have lately been prevalent in the British army and navy, on some foreign stations.
- George Parker May—On croup.
- James Mitchell—On scarlatina.
- John Morison—On apoplexy.
- J. L. Marsden—De kenothumia, or ennui.
- H. R. Melville—On the effects of climate and food on man.
- M. R. Mahony—Some observations on aneurism, and diseases of the heart; with case.
- G. S. Newbigging—On the effusion and organization of coagulable lymph.
- John O'Brien—On the hygiene of infants.
- J. C. Orgile—On the morbid effects occasionally induced by the operation of mercury.
- Eugene O'Neile—On vesicular emphysema.
- James H. Pring—On chorea.
- William Pringle—On phagedena gangrenosa.
- J. P. Phipps—On cold affusion in croup.
- Arthur Powell—On the causes of disease.
- Charles Ronayne—On cancer of the uterus.
- J. S. Reid—On variola.
- W. A. Reeves—On delirium tremens.
- E. C. Seaton—On the powers which move the blood.
- William Scott—Observations upon pseudo-inflammatory affections.
- R. Skerrett—On malignant or Asiatic cholera.
- M. Satterthwaite—On pathological chemistry.
- George Smyth—On ascites.
- J. P. Shuman—On the pathology of dropsy.
- John Spowart—On tetanus.
- William Stranger—On cynanche trachealis.
- J. H. Shirreff—What advantage do we derive from auscultation in detecting pregnancy?
- J. C. Sortain—On the function of the cœcum.
- Thomas Stratton—On chronic rheumatism.
- T. H. Shute—On fever, being an inquiry into its intimate nature and causes.
- James Satchell—On the signs of pregnancy.
- William Scott—On scarlatina.
- Thomas R. Scott—On wounds of the thorax.
- Henry Hunt Stubb—On influenza.
- F. N. Slight—On injuries of the head from external violence.
- H. H. Turnbull—On venous inflammation.
- A. S. Thomson—Observations on the influence of climate on the health and mortality of the inhabitants of the different regions of the globe.
- George F. Thomson—On croup.
- William Tatlock—On hydrocele.
- B. W. Wright—On the jungle fever of India.
- J. G. Wood—Under what circumstances is the operation of trephining to be had recourse to?
- J. Waters—On hypertrophy of the heart, and on that of the left ventricle in particular.
- J. W. Wallace—On hydrocele of the tunica vaginalis testis.
- James Balfour Wishart—On abortion.

SITTING OF THE FRENCH INSTITUTE OF THE 31st OF JULY.

MECHANICS.—*New method of preventing the explosion of steam engines.*—Monsieur Bache describes, in a letter to Monsieur Arago, an apparatus for prevention for the explosion of steam engines. This apparatus is composed of a metallic stem within a tube, which descends to the bottom of the boiler. The extremity of the stem is fixed in a ring by a little transverse bar of fusible metal. The other end of the stem is fixed to the extremity of a lever with a weight hanging to it, which is kept in suspension by the transverse bar. A bell or discharging cock is placed beneath this weight, so as

to put it in action by its fall. On the temperature in the boiler arriving at a certain height, the fusible transverse bar gives way, and the stem being no longer retained by it, is acted on by the weight, and either the bell rings or the safety-cock is opened. This method has been referred to the committee appointed some time since for the examination of this important question.

NAVIGATION.—*Soundings in the Sea at great depths*—Paper by Monsieur Champeaux la Boulaie.—Although it is of importance for the solution of many physical and astronomical problems to be able to determine everywhere the depth of the sea, yet navigators have hitherto paid very little attention to it. The only known way of determining the depth of the sea, consists in throwing into the water a leaden weight attached to a graduated cord that slips through the hand of the sounder; the diminution of the effort sustained by the hand indicates the moment at which the lead touches the bottom, and the quantity of cord run out expresses the depth, provided that the string be held vertical to the weight. This operation, to appearance very simple, is, nevertheless, complicated with so many difficulties, on the depth exceeding certain limits, that it is almost impossible to arrive at 1,800 or 2,000 metres, or French yards. Monsieur Champeaux la Boulaie analyses successively all the difficulties which present themselves in sounding to a great depth, and then seeks to determine the conditions most favourable to success. The following are the conclusions to which he has arrived:—

We cannot sound with success to very great depths, except in a smooth sea and in a dead calm. In a calm sea, and gentle wind, we shall arrive at the same result by sounding from on board a vessel, or steam-boat, which floats so as to remain immovable with regard to the surface of the water. In this position the plummet used must be very much elongated, cast in the form of the solid of least resistance, and attached to a line whose form (says the report from which we translate,) is that of the solid described by the revolution of a logarithmic round its asymptotic axis, the abscissa being diminished by a constant number.

The line is reeved through a very light pulley, of a yard in circumference, suspended to a very delicate dynamometer, furnished at its axis with an index. It is then wound round a well constructed reel as soon as the whole has assumed a

regular velocity, two observers write down, at equal intervals of time, the one the number of revolutions made by the pulley, and the other the indications of the needle of the dynamometer.

When the effort supported by the dynamometer, or the velocity of the reel, appear to the eye more or less suddenly diminished, the observations are repeated two or three times, and the lead is then withdrawn.

The moment that the tension of the line has suddenly diminished is almost exactly that at which the plummet has touched the bottom, and the number of revolutions of the pulley will give the depth in yards; if a curve be constructed, the abscisses of which represent the times, and ordinates the number of revolutions made during the preceding interval, the point at which this curve will experience a sudden inflection must lead to the same result. If, during the descent of the plummet, the line has continued to pull in a vertical direction it shows that there are no currents, or they do not vary as far as the depth attained, and the operation then presents the greatest chances of exactitude; nevertheless, the sounding would still good enough if the line varied but little from the vertical direction. But if the line shall have been much inclined, the observation will no longer serve to give the depth; but it will give curious notices of the force and direction of submarine currents.

The paper Monsieur Champeaux la Boulaie was referred to the examination of Messrs. Arago and Freycinet.

PALEONTOLOGY.—Monsieur Azema sends the fossil bones, to which he had before called the attention of the Academy, and which were found in the Commune of Sauveterre, a league south west of Lombès (Gers), near the left bank of the Save. These bones are referred to the examination of Monsieur de Blainville.

Alimentary Argilla.—The analysis, by Professor Cotting, of a species of argilla in the canton of Richmond, which is sought after by numbers of persons, and especially by infants, as an aliment.

This earth, whose colour varies from deep yellow to a whitish red, is met with in masses and strata, which present undulations; it is of a very fine grain, and soft, taking a polish from the nail, and attaching itself to the tongue. When damp it gives out an argillaceous smell, precipitates itself in powder in water, and does not form a ductile paste. 100 parts furnished 31 of silice, 12 of oxide of iron,

34 of alumina, 10 of magnesia, 12 of water, and 1 by loss.

It contains no remains of animal substances, but vegetable matter is to be met with in it in a state of putrefaction and lignite. It is found united with many other minerals in several elevated situations; the purest is found in the county of Richmond. Its taste is sweetish, resembling that of calcined magnesia. Persons worthy of credit, residing in the environs of this canton, assure us that there are frequent deaths among those persons who make too frequent use of it as food.

OTHER COMMUNICATIONS.—Messieurs Morisset, Durrand, and Clavaison, write that silk-worms can be fed on the leaves of the scorzonera, or viper's grass. In proof of what they advance, they send five balls of the worms nourished with the leaves of this plant. This is an experiment such as a schoolboy may make who feeds silk-worms in his writing-desk; but often-repeated attempts make us doubt of the experiment completely succeeding with only some thousands of worms. Besides, the leaf of the scorzonera is velvety, and the insect refuses to eat it until it has been previously brushed.—Monsieur Bertrami complains that in speaking of the Praries of North America, a correspondent of the Institute attributes this discovery, which belongs to him, as well as that of the sources of the Mississippi, to Monsieur Ruggles, the geologist, and Mr. Cooper, the novelist.—Doctor Guibert, forgetting that the butterflies can fly, and deposit their eggs on the branches of the vine without climbing up the stem, proposes to the proprietors of Argenteuil to wet the lower part of all the plants with train oil, mixed with one tenth part of spirits of turpentine.—Monsieur Caré informs us of the efficacy of a unique remedy for the cholera. This remedy, which he has communicated to the Neapolitan Ambassadors, consists of half a dram of eau de rabir, probably of eau de Rabel, or diluted sulphuric acid, in a quart of water, to be taken at three draughts. We have great doubts of the efficacy of this remedy, and no confidence whatever in the experience, judgment, or medical skill of ambassadors.

The original report, from which we have translated, is very carelessly drawn up, and in many places unintelligible and absurd. We have endeavoured to make the best of it, such as it is.

ON EXCISION OF THE SMALLER JOINTS.

By DR. GERNET, of Hamburg.

Among the many improvements in modern surgery, the substitution of excision of diseased joints and of carious portions of bone for amputation of the limb, is not the least important. A considerable number of years have now elapsed since this principle was first applied to the treatment of caries of the larger joints, and, in a late number of the Hamburg Journal, we find Dr. Gernet, assistant surgeon of the Hamburg Hospital, ably advocating its extension to the treatment of caries of several of the smaller joints. He reports seven cases, which were operated by Fricke, in the hospital. In four of these, the caries affected the bones of the hand, and, in the remaining three, those of the foot. Of the former number, the disease in three affected the metacarpel joint of the thumb, and was produced in one case by the point of an awl penetrating the joint; in the second, by the cut of an axe; and in the third, it was ascribed by the patient to a wire, which, some months previously, he had drawn tightly round the thumb; but the chief cause seemed to lie in the cachectic state of the constitution. In the fourth case, the caries affected the metacarpal joint of the middle finger, and, as in one of the former instances, was caused by the wound of an awl.

In those cases in which the foot was the seat of the disease, the caries affected, in the first, the joint between the first and second phalanx of the great toe, and could not be ascribed to any evident cause; in the second, no caries existed, but a large exostosis, which was attached to the head of the first phalanx of the great toe, greatly incommoded the patient. In the third case, the caries affected the metatarsal joint of the great toe.

In all of these cases, the operation was performed by removing the extremities of both bones; and this was judged the more advisable proceeding, even in the case of exostosis, where no lesion of the opposite articular surface existed. The ends of the bone were then approximated as nearly as could be done without much difficulty, or causing great uneasiness to the patient, and retained in this position by a peculiar apparatus. Union by the first intention was tried in two instances, but afterwards abandoned, and the wound

was stuffed with charpie. Torsion was employed to arrest the hemorrhage from the mouths of bleeding vessels; a practice which seems to be followed in all operations in the Hamburg hospital.

It has been advanced against the operation of excision of the smaller joints, that the time required for the cure, and the length and pain of the operation, were more than an equivalent for any advantage which could be derived from a shortened and ankylosed finger, and which perhaps would prove a worse than useless appendage to the patient. We shall therefore examine the results of the seven operations. Of the four cases in which the hand was affected, the success in three was complete. On an average, five and a half weeks were sufficient for the union of the wound and solidification of the bone; and all three were capable of returning to their work at the end of seven weeks. Two of them, in whom the metacarpal joint of the thumb had been affected, regained completely the use of the finger; and the other, the fourth case, was fast regaining the use of the finger when he left the hospital. In the third case, the wound healed slowly; but the patient was unable to use the thumb, and was dismissed at the end of three months, in rather an unsatisfactory state. Of the foot cases, the first was able to use the extremity at the end of five weeks; but, in the second, the cure was retarded by necrosis of a portion of bone till the end of the tenth week. Four weeks sufficed to effect the cure in the third.

In the first set of cases, the operation, including the time occupied in dressing the wound, lasted from fifteen to twenty-six minutes, the two extremes. In the second, ten, or at most fifteen, minutes were required. In no case were bad consequences, which could be ascribed to the nature of the operation, observed to follow. *Zeitschrift für die gesammte Medicin.* Band. iii, heft 4. 1836.

IMPORTANT TO ENGLISH MEDICAL MEN.

A very important decision has been given by the Court of Arras, in favour of English medical men wishing to establish themselves in France for the purpose of carrying on their profession. It was reported some time back in the London journals, that an order had been issued by the faculty of medicine in Paris, prohibiting English medical men

practising at Boulogne, St. Omer, Calais, Dunkerque, and other parts of France, inhabited by English tourists, which decision gave rise to a trial by Dr. Campbell and other medical men residing at Boulogne, and an appeal was made to the Court of Assizes of St. Omer and Arras, when the court, after a long discussion on the subject, decided, "That any English medical man who has passed the College of Surgeons in London, Edinburgh, or Dublin, and can produce his diploma as a guarantee that he is duly qualified, shall be allowed to practise his profession in France amongst his compatriots, by submitting to the usual regulations specified by the Faculty of Medicine towards foreigners;" which decision has been confirmed by the Court of Assize of Paris and the Faculty of Medicine.

REVIEWS.

The Fallacy of the Art of Physic as taught in the Schools; with the development of New and Important Principles of Practice. By SAMUEL DICKSON, M. D. Edinburgh: Adam and Charles Black: London, Longman, Rees and Co. 1836.

The paucity of new medical works for the last five or six months, the relaxing effects of the present season both on mind and body, and our anxious desire to afford some amusement to our readers after the toils and labours of a long winter's campaign, will, we trust, serve at least as some apology for our presenting them with a few extracts from the funny production above noticed. The work is dedicated to the Medical Officers of the Army, who are complimented by the author (himself a Medical Officer), as being "alike free from the intolerance of prejudice, and that petty spirit of self interest which so often, in civil life, militate against improvement; their liberal manners and cultivated minds having ever ensured to novelty a hearing, and to merit a proper appreciation." Whilst we are ready to admit this exemption from prejudice on the part of the Medical Officers of the army as generally true, a glance at our authors work obliges us to deny the universality of such exemption, inasmuch as we scarcely remember to have any where witnessed more blind prejudice against established principles and high authority, and that authority sanctioned by something more than mere time, in

any production than in this of Dr. Dickson's.

The Doctor commences his work by bewailing and bemoaning the sad and dire effects of the conflicting opinions of the Medical Profession on disease, and on the melancholy fact, that it is much more rare to find its members in unison than at variance in their ideas of the same disorder. "Two physicians," he says, "meet in consultation upon a case. Agreeing in their definition, they are at issue on the treatment; recommending remedies so opposite, the astonished is unable to comprehend a reason for such difference of practice." "In another—while both may coincide in opinion as to the remedy, they will dispute about the name, &c." Where, in the name of goodness, has the doctor been practising, that he has found cause for such complaint, about the discrepancy of medical men on the names and treatment of diseases? That such grounds of complaint may have existed some time back we are free to confess; but surely among regularly educated physicians of the present day, no such contradictory views, respecting either the nomenclature, or treatment of disease can be found. "There was a time," the Dr. says, "when we could have sympathised with the disputants." Kind hearted soul! Aye, Dr. and there is a time, and that time is the present, when we could sympathise with such downright innocence or total unacquaintance with the advanced state of pathology of the present day, were not such ignorance accompanied with another quality, which is indeed its inseparable attendant, and which is, to say the least, undeserving of sympathy. The Dr. premises to show, that, instead of many maladies, man, *properly speaking*, is "the victim only of one, and that this one, in the first instance, has no relation to organic change as a cause." Gentle reader! what think you is this *one* malady? neither more nor less than FEVER—REMITTENT OR INTERMITTENT, which, according to the sagacious author, "comprehends every shape and shade which disorder can assume." We believe the grand feature of Hahnemann's doctrine of Homœopathy is, that all diseases may be referred to one—and that one is *the itch!* These medical Newlights are certainly queer fellows! "The bigoted and selfish will repudiate a doctrine alike repugnant to their prejudices and interests," says the doctor. Yes, doctor, and the intelligent and experienced will repudiate your doctrine,

which is alike repugnant to common sense and every day observation. Only think of the author's modesty when he tells us, that "Hippocrates had at least a glimpse of this truth, namely, of the unity of disease. It was reserved for the doctor to see this truth in all its splendour, and in all its beauty.

The following is the author's description of HEALTH:—

"The body in this state maintains an equable and medium temperature throughout; the voluntary, and other muscles, obey with *alacrity* (the devil they do) the several necessities that call them into action. The mind neither sinks nor rises but upon great emergencies (such emergencies, we suppose, as that which stirred up the doctor to write the book now under consideration); the respiration easy, and continuous, requires no hurried effort—no lengthened sigh. The heart is equal in its beats, and not easily disturbed; the appetite moderate and uniform. (We must say that if this "continuity of respiration," and this "equality of the heart's beats," be essential to health, it were high time for us to be looking out for a doctor, for in consequence of all we have laughed from perusing the author's book, we have got a dreadful hiccup—but to proceed.) At the appointed time and occasion, the various secreting organs perform their office. (If the doctor includes the *excreting* organs in this list, we could satisfy him to a demonstration what dire mischief his book may produce, by disturbing and interfering with the *regularly appointed* time and occasion for these organs performing their respective functions, *verb. sat.*) The structures of the body, so far as bulk is concerned, remain unchanged, their possessor being neither cumbered with obesity nor wasted to a shadow. (What an ass Horace was, when he enumerated among the blessings of life, "Omnia præter ingenium pingua." The *excepted* part of Horace's prayer appears to have been preferred by some people, or at least to have fallen to their lot.) "His sensorium is neither painfully acute nor morbidly apathetic—(there's physiology and metaphysics with a vengeance)—his sleep is tranquil and dreamless,"—If it be necessary to health to have our waking hours "dreamless," the doctor's health must, we fear, have been in a bad way whilst he was writing his book.

Next comes the doctor's definition of *Disease*, which is described as "an *increase or diminution* of the proper functions of health."

"The temperature of the body being in the first place deranged, the patient complains of partial or general heat or cold; his muscles, under the control of their respective influences, become tremulous, spasmodic;—or wearied, palsied, the functions of particular muscles cease. The breathing is hurried on slight exertion, or it is maintained slowly and at intervals, and with a long occasional inspiration, that scarcely makes up for interrupted pulmonary action. The heart is quick, palpitating, or languid and remittent in its beats; the appetite craving, capricious, or lost. The secretions are either hurried and increased in quantity, or sluggish and suppressed; the body wastes, or becomes in part, or whole, preternaturally tumid and bloated. Alive to the slightest stimulus, the patient is easily impassioned or depressed; his mind, comprehending in its various relations every shade of unreasonable sadness or gaiety, prodigality or cupidity, vacillation or pertinacity, suspicious caution, or too confident security;—with every colour of imagination from highly intellectual conception, to the dream-like vagaries of hallucination. His sensations are perceptibly diminished or increased. Light and sound, for instance, confuse and distract him. Like the soft Sybarite, a rose-leaf ruffles him. With the smallest increase of temperature he becomes hot and uncomfortable, and feels chilled and shivery in the lightest breeze; or, as you sometimes behold you in extreme age or idiocy, equally insensible to excess of light, sound, heat, or cold. His sleep is broken, crowded with dreams, and easily interrupted, or so perfectly lethargic it is difficult to rouse him."

The doctor seems to have prepared himself for writing on pathology, by studying the novels and romances of the 17th and 18th centuries. Where else are we to suppose he could have found such tender and touching terms as the "soft sybarite, ruffled by the rose-leaf," and those other "dream-like vagaries of hallucination?" What a tranquillising and soothing effect the perusal of the above description of the sick man must have on us this hot weather, where he is represented as "chilled and shivery in the lightest breeze,"—that one line has actually served us instead of a glass of iced cream.

Nor does the author allow those coarse minded fellows, the morbid-anatomists, to escape scot free—men, who "hoping to find the origin of every disorder made

manifest by the scalpel, are ever mistaking effects for causes. Loth to believe that *death* can take place without even a palpable change of structure, these direct their attention to the minutiae of the dead, and finding in their search some petty enlargement, some trifling engorgement, or, it may be, some formidable tumour or abscess, hastily set this down as the first *cause* of a disease, of which it was only a *development*."

What a large stock of ignorance of the proper end of pathological anatomy, must have fallen to the lot of that man who could write such trash!

The dietetic gentry next come in for their share,—men "who, with the quantity or quality of our food or air, associate every disorder." Among these poor Mr. Abernethy gets a knock, "who invariably pointed to the stomach and bowels as the cause of every disturbance," forgetting that a passion or blow could alter the secretions of both.

In cycloping disease the author seems determined to keep at the safe side of the bush; for he would term every disorder, "*LOSS OF HEALTH*." However, in order to satisfy the reader, who may not rest without a medical name, he will call it "*Fever, aye, and Remittent*." And the sapient reason for this latter nomenclature we shall give in the author's own words:—"For," says he, "there is no state, morbid or otherwise, which can be said to be constantly and unremittently present in the human body. What is *life*, but a series of alterations? In health, man rests from his labour: he sleeps; he wakes to sleep again; his lungs now inspiring air, now expelling it; his heart successively dilating and contracting; his blood brightening in one set of vessels only again to darken in another; his food and drink nutritious one hour, to become excrementitious the next; in a word, all his appetites and necessities periodically alternating with each other. Nay, is not the sum total of our common lot a succession of petty joys and sorrows, hopes and fears? The very process by which we first come into the world, *parturition*, is a succession of pains and remissions."

There is a reason, gentle reader, for calling every disease to which flesh is heir, by the term *remittent fever*.

The author, after endeavouring to prove the unity of disease, by showing that they are all "variations of fever and nothing more," general or partial increase or diminution of temperature being the insepara-

ble concomitant of all; and after trying to establish this by instancing in mania, in which the phenomena were never wanting, at least in any of his patients, except during the lucid interval, states that "the same remark attaches to palpitation and temporary cessation of the heart's action, diseases commonly misunderstood, and as constantly maltreated." "That bauble of Laennec—the stethoscope," he says, "which the reader will pardon me for holding in heterodox contempt, is of course employed. The very application of the instrument to the chest deranges the action of the lungs and heart. The patient's attention, in most instances, calling off the influence of the brain, by alarm or otherwise, from the functions of the body."

Now, ye stethoscopists, what is to become of you, after all your toiling in the sick wards of hospitals, endeavouring to train your ears to catch those nice shades and settle differences which serve to mark the morbid from the healthy sounds of the heart and lungs!! Dr. Dickson has blown yourselves and your baubles, and given ye to the winds, by one dash of his powerful pen. We are so overpowered here (for we too have the misfortune to be one of you), that we can proceed no farther; we must consign the remainder of the curious production to other hands, not however without assuring the author, in sober seriousness, that we leave him more in pity than in anger.

BOOKS FOR REVIEW.

Inaugural Dissertation on the Physiology and Pathology of the Brain. By John Hughes Bennett, M.D., President of the Royal Medical and Royal Physical Societies; Vice-President of the Anatomical and Physiological Society of Edinburgh. Edinburgh: Carfrae and Son. 8vo. pp. 80. 1837.

Eloge upon Baron G. Dupuytren, &c., &c. By E. Pariset, Perpetual Secretary at the Royal Academy of Medicine. Translated, with notes, by J. I. Ikini, Surgeon, &c. London: Churchill. 8vo. pp. 60. 1837.

Notice of Patents granted to Joseph Amesbury, of Burton-crescent, in the County of Middlesex, Surgeon, for certain Apparatus used in the treatment of Stiffness, Weakness, or Deformity of the

Spine, Chest, or Limbs; accompanied with Practical Remarks and Illustrations, by the Patentee. London: Longman and Co. 8vo. pp. 24. 1837.

TO CORRESPONDENTS.

Inquirer.—In the event of an action at law, the editor would no doubt at once give up the name of the operator, as well as of the individual who drew up the report.

T. Newcastle.—The case of Dr. Knott is most interesting at the present moment. Could our correspondent oblige us with an authentic copy of the minutes, and of the reprimand given to the cutting surgeon?

W. X.—Must surely have been aware that his communication contains no less than six libels. The proposed indemnity would be of no avail.

S.—John Hunter operated for the first time for popliteal aneurism, by tying the femoral artery, in 1784.

Medicus.—There are cases in which a single grain of the extract of Belladonna taken into the stomach, has been known to dilate the pupil.

A Practitioner.—The best mode of administering the hydriodate of potass, will be found in the Formulary just published.

An Army Surgeon.—The reflux-motatory movements may be employed in all dislocations, and at any period. Preparatory frictions, with veratria, might be highly advantageous.

Tremor need feel no hesitation in presenting himself as a lecturing candidate.

A Modeler.—The casts alluded to may be had at the plaster of Paris manufactory, in Great Russell Court, opposite to Drury-lane, Theatre.

Lithotritists.—The most celebrated physiologists are decided in their opinion, that only a very small portion of a fluid (and by no means a quart) injected into the vesica urinaria, could be rapidly absorbed in a few minutes. It must have meandered into the cavity of the abdomen, as not a drop passed by the catheter, introduced soon after the fluid was injected.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

Vol. I.—(1837.)

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

ROSEOLA.

(A fugacious anomalous eruption.)

Roseola is a non-contagious fugitive exantheme, characterised by rose-coloured spots, not prominent, variously figured, the appearance of which is in general preceded and accompanied by febrile symptoms.

All the points of the surface of the skin may be simultaneously the seat of roseola; in some cases it is developed on some regions only, on the trunk, on the extremities.

Its course is always acute, but varies according to the subjects, according to the cause which has produced it, and the diseases which it accompanies.

Its duration varies, in general, from twenty-four hours to a week.

Symptoms.—In very young children an eruption is sometimes observed of numerous spots, nearly circular, very close to each other, and of a deep rose-colour; they are from four to six lines in diameter, and disappear in the space of from twenty-four to thirty-six hours: their appearance is generally connected with some gastro-intestinal irritation.

A similar eruption is sometimes observed at the time of dentition; then, after vomiting, fever, diarrhoea, and sometimes slight convulsions, they are observed to appear on the surface of the body irregular rose-coloured spots, very distinct, though very close to each other. They often disappear in the space of twenty-

four hours; in some cases they cease and return alternately during several days.

The most intense variety of roseola, is that which prevails principally in cities. (*Roseola estiva*, Willan.) It is most frequently preceded in children by alternations of shivering and heat, by depression, headache, slight delirium, and even convulsions; there is, at the same time, heat of skin, thirst, loss of appetite, constipation, or diarrhoea. The eruption appears from the third to the seventh day, dating from the development of these symptoms. It appears at first on the face and neck, whence it spreads, in the space of from twenty-four to forty-eight hours, over the rest of the body; the redness of the spots is deeper, their form is more irregular than that of measles, and this red colour soon changes into a deep rose tint. The patient, at the same time, complains of severe itching, continued fever, and deglutition is frequently painful. The course of this eruption is very irregular; there may be total absence of the febrile symptoms. The duration is from three to four days; it disappears without perceptible desquamation. Under some circumstances it disappears soon to return, and then its duration may be prolonged.

A similar eruption may be observed to show itself in autumn (*roseola autumnalis*, Willan), and differs from the preceding only in the somewhat greater dimensions of its spots, their seat on the upper extremities, and the absence of fever.

A rather extraordinary variety of roseola is that wherein almost all the regions of the body are covered with rose-coloured spots, in the form of rings (*roseola annulata*, Willan), with central areas still retaining the colour of the skin. These rings, the diameter of which is, at first, about one or two lines, become successively enlarged by having a colourless space in the centre, which is sometimes of considerable size, and sometimes very

limited; sometimes two, and even three, rings reciprocally surround each other, whilst the skin retains its natural colour in their intervals. This variety is chiefly to be observed on the abdomen, below the kidneys, along the buttocks and the thighs. The duration of this eruption is short when it is accompanied with fever; at other times it may continue for an indefinite length of time; in the latter case it often accompanies chronic affections of the digestive passages.

Causes.—Roseola may appear in individuals of all ages, and in either sex, but it is generally observed in children and in females; it is more frequently seen in summer and in autumn than in the other seasons. It may attack the same individual several times. Under some circumstances it seems to prevail epidemically; and M. Biett has observed several epidemic attacks of it, at the dispensary of the Hospital Saint Louis, in very hot summers. Roseola may precede the eruption of small-pox, whether natural or inoculated; in some children it becomes developed on the ninth or tenth day after vaccination. The first dentition, the ingestion of cold drinks, the body being covered with sweat, too much exercise, are frequent causes of the appearance of this exantheme, which may often accompany a gastro-intestinal irritation in children.

Diagnosis.—Roseola has frequently been confounded with *measles* and *scarlatina*; however, in roseola, the spots, which all, more or less, approach the circular form, are circumscribed, of a deep rose-colour, broader than those of measles, smaller than those of scarlatina. Besides it is not contagious. In measles the spots are small, irregularly semilunar, of a bright red colour; those of scarlatina are broad, and of a raspberry colour. Both are contagious, and their general symptoms are characteristic; still the most experienced practitioner may be deceived, particularly at the commencement.

The greater extent of the rings, and the absence of vesicles, distinguish roseola by multiplied rings, from *herpes iris*.

Prognosis.—The prognosis of roseola is never bad; the coincidence of some internal diseases could alone render it more unfavourable.

Treatment.—In all cases, strict attention to regimen, diluent drinks, moderate temperature, and rest, are the only means necessary to be employed in the treatment of this disease. The roseola which deve-

lopes itself in vaccinated subjects, requires no particular treatment. In cases of complication with any essential organ, it is to the latter that the treatment should be directed.

MEASLES.

(*Rubeola—Morbilli.*)

Measles is a contagious exantheme, accompanied, at its onset, by coryza, cough, and fever; indicating itself externally by small red spots, slightly elevated, at first distinct, and which, by becoming mixed together, soon assume an irregularly semilunar form, and leave between them small intervals, where the skin is entirely healthy.

The course of this disease is always acute; its duration is from eight to ten days; but some symptoms very often continue for a long time. With respect to the duration of the eruption, properly so called, it is from three to four days.

Symptoms.—The invasion of measles is marked, in the majority of cases, by a state of general indisposition, lassitude of the limbs, alternations of shivering and heat, nasal hemorrhage and vomiting. Soon after the following symptoms are observed; greater or less acceleration of the pulse, heat of skin, sneezing, coryza, lachrymation, discharge of limpid mucus through the nose, cough frequent and dry, slight angina, thirst, anorexia, nausea, tongue white and moist, constipation, urine scanty and red, headache, drowsiness, and sometimes convulsions in children.

These symptoms are developed in the first forty-eight hours; their intensity, as well as that of the fever, increases from the third to the fourth day; there is then intense heat of skin, general moisture, sweats, acute sensibility of the conjunctiva and eye-lids, coryza, hoarseness, fatiguing cough, dyspnoea more or less developed, redness of the tongue, sometimes vomiting, headache, and occasionally temporary delirium. The uvula and velum pendulum palati are now covered with small red spots, which soon become confluent.

Towards the fourth or fifth day, small red distinct spots, of a circular form, slightly elevated, as if papular, appear on the forehead, chin, nose, and cheeks; sometime after the neck, chest, trunk, and extremities are covered successively with the same kind of eruption. The spots become enlarged, they are slightly pro-

minent, and resemble flea-bites in form. Sometimes there are observed towards their centre small vesicules; their number soon increases, and, on combining, they form larger spots, of an irregularly semilunar form, presenting between them small spaces in which the skin retains its natural colour. In some cases, chiefly on the face and hands, an uneven surface is felt on passing the finger over the eruption.

The redness of the spots generally attains its maximum about twenty-four hours after their appearance, and the eruption is usually terminated in the space of thirty-six hours. The face is often very much swollen at this period, and in some cases the swelling of the lids obstructs vision. After the sixth day of the disease the redness diminishes on the face, whilst it increases on the other parts of the body. On the seventh day the eruption begins to disappear, and from the ninth, slight yellowish spots indicate the place which it occupied. The disappearance of the exantheme, which then takes place in the same order as its development, is followed by a desquamation more or less marked, generally accompanied by intense itching.

Far from diminishing in proportion as the eruption advances, the heat, thirst, coryza, cough, etc., are rather increased; but the pulse becomes less frequent; these symptoms generally cease according as the eruption disappears. The cough usually continues longer than the other symptoms; sometimes nasal hemorrhage is observed at the termination, and frequently a slight diarrhœa supervenes, which seems to accelerate convalescence.

Such is the most usual progress of measles; but in some cases the eruption scarcely appears, whilst in others it is very extensive. Sometimes the redness of the spots is very bright; sometimes, on the contrary, it is scarcely marked.

Measles may be complicated with different diseases. It may become developed in an individual simultaneously with small-pox, but then it always happens that one of these eruptions suspends the progress of the other. Curious facts of this kind are to be found in Hunter. It is seldom accompanied with *p-tetichæ*; but, as has been frequently observed by M. Biett, the spots may assume the colour and form of *purpura simplex*, and then they no longer disappear under the pressure of the finger. The complications which chiefly deserve to engage the attention of the practitioners are, cerebral af-

fections, which are often times followed by serous effusions into the ventricles; pulmonary, as also gastro-intestinal inflammations. It is in these cases that the symptoms called ataxic and adynamic become developed.

Croup is a very serious complication, and fortunately not very common. Divers eruptions, either of a vesicular, bullar, or pustular character, may accompany measles.

Convalescence, independently of these complications, which may interfere with it, may present a variety of different diseases: thus, obstinate chronic ophthalmia may present itself, as also different inflammations of the mucous membrane of the air-passages, otitis with deafness, chronic inflammations of the lymphatic vessels and glands. In persons disposed to phthisis the development of tubercles seems favoured by the continuance of the catarrh consequent on measles: in fine, convalescence from this affection may be retarded, as well as that from scarlatina, by acute dropsy; a phenomenon however more frequently observed to follow the latter disease.

In the majority of cases, measles following a more or less regular course terminates in a return to health. But sometimes the patients die, and then death may be attributed to one of the complications of the disease: thus, in these fatal terminations, we find, on opening the body, more or less palpable traces of inflammation or congestion: the brain, lungs, and stomach are the organs which more frequently present these lesions.

Causes. Measles recognizes for its cause an unknown morbid principle which is transmitted by contact and infection, and which, in general, exercises its influence on the system but once during life. The observations which would tend to show that inoculation of the blood of persons affected with measles may communicate it, are anything but conclusive.

Measles is developed in all climates; it prevails almost always epidemically. In some epidemics the cause may, in some persons, develop only coryza, and symptoms of irritation of the pulmonary mucous membrane; and in some rare cases, the exantheme appears unaccompanied by these symptoms. Such persons are not exempt from a second infection. No age is exempt; but more generally it attacks young persons. It prevails more frequently during winter, and chiefly at the beginning of spring, than in the other seasons.

The appearance of the disease generally takes place from the tenth to the fourteenth day of the infection.

Diagnosis. The progress of the disease, the nature of the symptoms, and the character of the exantheme, are always sufficient to distinguish measles from *scarlatina*. In measles, the symptoms of incubation precede the eruption by three or four days; the spots are smaller, of a bright red colour, irregularly semilunar, and they leave between them intervals of healthy skin. In *scarlatina* the eruption comes out sooner, the spots are larger, irregular, and have a raspberry tint.

As the eruption of *scarlatina* does not disappear uniformly, but at intervals we find towards the end of the fifth day, small, irregular spots, which might be readily confounded with those of measles.

In fine, there are cases where the diagnosis is really very difficult; such are those where large spots of a uniform red colour cover different parts of the body, and where the symptoms of irritation of the mucous membranes approximate very nearly to those belonging to *scarlatina*. In such cases we must have regard to the prevailing epidemic, and to the predominant symptoms of the disease, the circumstance of a former infection will not prevent the physician from instituting an attentive examination; for it is proved that the same individual may be a second time affected with measles.

With respect to *roseola*, the deep rose colour of its spots, their accurately rounded form, their size, and its non-contagious character, readily distinguish it at a certain period; but at the onset, when the ordinary symptoms of measles are wanting, they may be readily confounded.

Again, the different inflammations which may complicate measles will be met with in their proper characters: only it should be observed that their course is sometimes insidious, and requires great attention.

Prognosis. Measles is not in general an alarming disease, but it may become so in several cases: it is chiefly to be dreaded in women who are pregnant or who have recently been confined, and in individuals exhausted by previous disease. In forming a prognosis, we should take into account the general character of the prevailing epidemic; the greater or less severity of the accompanying lesions, and the nature of the affected organs must chiefly serve as our basis.

The appearance of petechiæ, a premature eruption, its abrupt disappearance,

coinciding with much fever and oppression, are unfavourable.

Treatment. Strict regimen, rest, a well regulated temperature, diluent and mucilaginous and tepid drinks, the inhalation of an emollient vapour, and taking care to guard the eyes from too strong light, constitute the treatment in the ordinary course of measles.

The employment of emetics given either for the purpose of favouring the eruption, or in order to relieve gastric disturbance, is general useless, and may even be dangerous; the nausea and vomiting which patients experience in the majority of cases generally disappear with the other symptoms. It should be restricted merely to cases where the measles is complicated with croup. However, in some instances, we have observed the giving a few grains of ipecacuanha drive out the eruption with some rapidity and force. The constipation which exists at the commencement is attended with no inconvenience; at a subsequent period, if it should exist, it might be removed by means of simple lavements.

Should the eruption not come out freely, or should it disappear suddenly, diaphoretics should be employed; the patient should be put into a warm bath to which some flour of mustard should be added, or what is still better, we should give a vapour bath, if it be within our reach.

But when the eruption is delayed too long in coming out, and when at the same time the fever increases in severity, there is some reason for dreading the development of some internal inflammation, and in this case we should hasten to apply a remedy to it.

We shall now pass in review the therapeutic means which may best attain this end.

Among those, *blood-letting*, whether general or local, holds the first place. In employing it, it is necessary carefully to distinguish the symptoms, which naturally accompany the disease and disappear with it, from those which depend on an internal inflammation, and which may more or less compromise the patient's life. Thus, during the eruption there is often much disturbance, and pains in the chest; the cough becomes very troublesome, the oppression increases, and auscultation detects a subcrepitous râle more or less extensive: however it almost always happens that these alarming symptoms disappear spontaneously, and with the appearance of the eruption.

But if they continued we should have

recourse to general or local bleeding, and the quantity of blood to be taken should be proportioned to the strength of the patient and the nature of the symptoms.

Before the appearance of the eruption, when there exist evident signs of pneumonia, or gastro-intestinal inflammation, or else when there is coma, stertorous breathing, and at the same time intense fever, the disease should not be left to nature, we must have recourse to bleeding.

In young children the application of a few leeches to the temples, behind the ears, to the epigastrium or anus, may be advantageously substituted for phlebotomy. In adults or young persons it is often very useful to employ both general and local bleeding simultaneously. Oftentimes after a bleeding performed in such cases we see the eruption come out, and at the same time the symptoms diminish in severity. The time at which we have recourse to bleeding, is particularly important; this means will be so much the more effectual the nearer we employ it to the onset of the accompanying inflammation; at a later period, when nature is oppressed under the violence of the disease, and the different organs have been for a long time the seat of considerable congestion, it is far from being useful, and it may even accelerate the fatal termination. In a word, the employment of blood-letting is a point of great moment, it should not be forgotten that we must regard it as an exceptional mode of treatment, whose object is to combat inflammations, and alarming symptoms, which may aggravate the measles, and not to interfere with the coming out of the exantheme.

Purgatives have, perhaps, been too much extolled in the treatment of measles; the gastro-intestinal inflammations, which so frequently complicate these diseases, should make us reserved in their employment. However they may produce good effects in cases of meningo-cephalite, of pneumonia, severe angina, or croup; they should then be employed conjointly with bleeding. The purgatives to be employed are senna, jalap, calomel, castor oil, &c.

Towards the ninth or tenth day, especially when the ordinary diarrhoea does not take place, cathartics are often employed, syrup of peach flowers, manna in tears, soluble tartar; but they are chiefly indicated when the exantheme beginning to decline.

Sinapisms and blisters should be employed with reserve; they may act use-

fully in certain cases by recalling the exantheme when it is going in.

Lotions with cold water, when the skin is hot and dry, have been extolled by respectable English practitioners. When speaking of the treatment of scarlatina we shall recur to the use of this means, which is probably less applicable to measles, as is observed by M. Guersent, in consequence of the frequent complication of pulmonary inflammation.

With respect to tonics, such as generous wine, bark, camphor, &c., they are very rarely fit to be employed; their employment at least requires great discernment. We may have recourse to them when the pulse is small and very weak, the skin cold, and the eruption pale or livid.

They should never be employed when the skin is dry and burning, notwithstanding the appearance of adynamic symptoms.

During convalescence some warm baths should be used, great care being taken to avoid catching cold; if cough still continues, we should prescribe some laxatives, opiates, a blister either to the chest, or on the inside of each arm. A slow fever sometimes sets in, and the most assiduous care becomes necessary. In fine, in cases of obstinate diarrhoea, opiates, demulcents, strict regimen, a blister on the upper part of each thigh, or on the ileo-cæcal region, are so many means which may become useful.

The prophylatic treatment consists solely in separation from those already labouring under the disease. Though it is not known at which time the contagion is no longer to be dreaded, it is prudent to continue the precautions even beyond the twentieth day.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

Strength and weakness of the constitution, or of the part affected, will produce very different effects in inflammation. Strength produces good effects, and renders the disease more manageable, for it lessens irritability. Inflammation is most manageable in parts in the following order: muscles, cellular membrane, and skin, and the more so the nearer the source of circulation. In other parts, as bones, cartilages, ligaments, &c, which have but little power in themselves, it is less manageable, though the constitution be good, for the constitution feels con-

scious of the weakness of these parts, by which affection of the constitution they become further weakened. In vital parts inflammation also is very unmanageable, though these have power in themselves; but in consequence of their being affected, the universal health is destroyed, and hence the disease is less manageable. If the stomach is inflamed, no operation of the body can go on well, the powers of restoration becoming weaker than ever; hence the greatest danger is to be apprehended.

Strength of the constitution and parts affected, when under inflammation, produces the following effects: viz. a more ready and quick termination, whatever it be. Thus, a wound in a healthy constitution unites more readily by the first intention; adhesive inflammation more readily terminates by resolution. If inflammation have got beyond the first stage, it passes sooner on to the suppurative inflammation; nature going through her operations with greater facility and dispatch in such a state of constitution.

Weakness of the Constitution and Parts.—When a wound is made in a person of a weak habit, the union is more difficult, and the inflammation is more likely to continue; and this not from there being a greater disposition to inflammation, but from want of a power and disposition to heal, nature needing greater and longer exertions to produce the intended effect.

In this state of the constitution and parts we often find that parts seem hardly capable of taking on either adhesive or suppurative inflammation; and in some of these habits inflammation will hardly even follow a solution of continuity. As in dropsy, I have observed that the puncture made by tapping or scarification will hardly heal; a degree of inflammation does take place, but not sufficient to procure a healing of the wounds or suppuration, but mortification soon comes on. If in such a constitution a wound is made, the blood not coagulating sufficiently to heal it by the first intention, dies, and becomes an extraneous substance, causing irritation; suppurative inflammation succeeds, and often mortification, which mostly proves fatal.

Effects of Inflammation on the Constitution.—The sympathy of the constitution upon an act of violence to a part, is probably the most simple act of a constitution. But this varies in different constitutions, because all constitutions do not sympathize equally. It will vary accord-

ing to the stage of the inflammation, and according to the disposition of the parts inflamed.

We find the effects of inflammation on the constitution as various as any other circumstances, which appear to arise from the following causes: first, from the nature of the constitution; secondly, from the nature of the inflammation, whether common or specific; if common, according to the kind, although I believe specific irritations do not produce much variety in the constitution, except the plague, which entirely changes it, and such as by their long continuance weaken the constitution, as lues, when of long standing; but this will be similar to any lasting disease, for at first it certainly does not affect the constitution so far as to alter the disposition of a wound made on any part; thirdly, from the nature of the part inflamed, whether vital or otherwise; and, fourthly, from the different situation of similar parts, as of the muscles or cellular membrane in the legs or arms, &c.

In inflammation we have seldom more than the continuous or the universal sympathy, but sometimes the remote. The continuous causes the inflammation to spread. The general is when the constitution becomes affected. The remote is seen in pain of the shoulder, from inflammation of the liver.

As the effects which inflammation has on the constitution are by sympathy, they will be in proportion to the readiness it has to go into that action; and this is much greater in some constitutions than others: moreover, every constitution sympathizes more readily with some parts than with others. The kind of constitution least affected is generally the most healthy where sympathy hardly takes place, the surrounding parts even seeming hardly to feel what is going on in those nearest them.

The nature of the inflammation produces, I believe, but little variation in these effects; for of whatever kind, the sympathy will be in proportion to the violence of the inflammation, and its rapidity. Hence as the inflammation which produces healthy suppuration is more rapid, it generally produces more violent effects on the constitution than any other.

The effects which inflammation has on the vascular system, and which are chiefly discoverable by the pulse, are very remarkable. In considering the peculiarities of the pulse, it is always necessary to

remark that there are two powers acting to produce it, viz., the heart and the arteries. That one part of the pulse belongs to the heart, another to the arteries, and a third is a compound of both. The stroke, which is the pulse, (as regards the number of strokes in a given time, the regularity or irregularity as to time, and the quickness of these strokes), belongs to the heart. The vibratory pulse and slowness of the systole, with the fullness and smallness of the pulse, belong to the arteries.

As the pulse arises from the actions of the solids on the machine, it is of course according to the nature of the machine at the time; therefore is capable of being in one of two states, natural or diseased.

In most diseases of the constitution, whether original or arising in consequence of diseases of parts in which the constitution becomes affected by sympathy, the pulse is altered from the natural to the diseased state which is according to those affections.

The varieties of which the pulse admits are numerous. It may be increased or diminished in the number of strokes; regular or irregular as to time; quick in its stroke, or diastole and slow in its systole; or it may be hard in its diastole. In all cases probably, when the constitution is in a state of irritation, the pulse will be quick and frequent in its number of strokes in a given time, and the artery being hard, from the constant contraction of its muscular coats, will give a feeling of hardness to the touch; besides which the diastole of the artery is not uniformly and regularly the same, but there are a vast number of stops or intermissions, which are so quick as to give the feeling of vibration, or what we call thrill. In such a disposition the pulse may be either full or small. These two opposite effects do not seem to arise from the difference in the degree of strength and quantity of irritability that the patient possesses at the time, which, when joined, give an antidiastolic disposition to the arteries, so that when the arteries have a full power of contraction and are in a state of irritation at the same time this effect will always take place.

It is certain that arteries in such a state of constitution do not dilate so fully and freely as at other times; and as this varies quickly as the state of the constitution varies quickly, it is more reasonable to suppose that the effect is immediately from the arteries than from an increase or decrease in the quantity of blood. If

this is really the case, we should naturally suppose that the motion of the blood in the arteries would be increased in proportion to their diminished size, unless we should also suppose that the systole of the heart should be diminished in the same proportion, which I think is probably the case, as we find the blood forsakes the surface of the body in such a state of constitution, which must therefore be collected in the larger veins about the heart. But if the heart were to throw out its whole contents at each systole, the velocity of the blood in the arteries would be immense, and must be then forced into the small vessels on the surface of the body, which it certainly is not. A quick hard vibratory pulse is generally attendant on inflammation. The fullness or emptiness of the pulse depend greatly on the parts that are affected, which either increase or decrease the irritability.

Different parts produce different states of the pulse.—In inflammation of common parts, as the skin, cellular membrane, muscles, &c., the pulse will be full and strong, and the symptoms acute, especially if near the heart. Ligaments, cartilages, tendons, and bony parts produce symptoms which are less acute; the pulse is not so full, but quicker, there being in these cases a greater degree of irritability. In the vital parts of the second order, as the brain, the pulse is soft and slow; but in the stomach, and parts with which it sympathizes greatly, as the testicles, upper part of the intestines, &c., the pulse is small, quick, and contracted.

Of the sensations arising from inflammations in different parts.—When the injury is in the head, the pain is often dull and attended with sickness; when in the heart and lungs, the pain is more violent. When in the stomach or upper part of the intestines, it is a heavy depressing pain, and attended with more or less of sickness. When in the colon it is more acute, but attended with less sickness. When the liver, ligaments, or bony parts are affected, the pain is much the same as when the stomach is affected, that is, heavy and depressing: the pain is acute and rousing when the skin, cellular membrane, or muscles are inflamed.

Inflammations in vital parts do not all produce the same effects on the constitution, which would seem to arise from their greater or less sympathy with the stomach; but it is certain that a given quantity of inflammation in a vital part, or its sympathizer, will produce much

more considerable effects than a greater quantity in another part, and the blood will be more sily. When the heart is inflamed, its actions are irregular; if the lungs only are inflamed, the heart still seems to sympathize, and is irregular in its actions, as well as weak. If the stomach is inflamed, the patient feels a depression and a defective action in the heart as well as in every part; simple animal life, or living principle, seems then to be depressed, as the sensitive from inflammation in the brain; and the pulse is low and weak. In inflammation of the uterus the pain is very acute, and the pulse quick and low, the stomach sick, &c. When inflammation occurs in these parts the symptoms come on very quickly; and if it proves fatal, it runs through its stages very fast, debility beginning very early. All this may depend on the stomach being, as it were, the central seat of sympathy, whence the actions of life are interfered with. However animal sympathy soon takes place here, and the sympathy being similar to the first action, a fever of a depressing kind is produced, and death soon succeeds.

Inflammations of parts not vital. of such violence as to affect the actions of life by the general sympathy, render the pulse full and strong. The constitution in this case is strong and not irritable; for when weak and irritable, the pulse is quick, hard, and small in the beginning, as it is in inflammations of vital parts, and the blood though sily is loose in its texture.

Difference from different Nerves.—One cause of the difference in the inflammation of vital parts seems to be the different systems of nerves by which they are supplied. In all those parts supplied by the par vagum, inflammation affects the patient with lowness from the first, these nerves supplying the parts of involuntary motion, and therefore possessing the living principle in the highest degree; whence an inflammation of these parts becomes peculiarly depressing.

Situation of the blood in the commencement of diseases.—In some diseases the blood at first forsakes the skin, extremities, and lips, and the parts shrink and diminish in bulk; this is particularly evident in the eye, and arises from want of power in the constitution, all the powers being called to the citadel, or source of power, and the outworks left. This happens in fainting, agues, hectic, &c., and does not seem to arise from debility at first, but from a novelty of action,

and a consequent inability to perform it. In putrid fevers the external parts first lose their living power, from having a less resisting power.

Of the effects on the constitution from different stages of inflammation.—The constitutional effects arising from inflammation, independent of the difference of parts, situation, nerves, &c., are more or less according to the stage of the disease. When inflammation is in the adhesive stage, it has but little effect on the whole system, and that effect is generally an increase of animal actions. This stage is the one which should be considered as truly inflammatory, as in it the constitution appears to be more regular, more determined, and more at ease, for it is more steady, more capable of continuing the time of action than in any other, hardly any varieties taking place in the time of this stage of the disease. When the suppurative stage comes on, the effects on the constitution are much more considerable and more various. Cold fits or rigors are generally felt on the commencement of suppuration; but they are not lasting, and are often succeeded by hot fits, both being more or less according to the greatness of the present inflammation and the suppuration that is likely to follow, as indeed with the nature of the parts and their situation, whether vital or not, &c.

Cold fits show plainly the commencement of some new action, as the beginning of fever, the absorption of poison, or even from simple irritation, as pricking the finger with a clean needle. They may also be produced by disagreeable sensations and disagreeable states of the mind. These rigors are probably dependent on the stomach, which being the seat of simple animal life and the seat of sympathy, takes part in every constitutional alteration, and we observe how much this viscus is affected by loss of blood, disagreeable sights, &c. What nature intends to effect by this sympathy with the rest of the body is hard to say, but it is worthy inquiry whether she may not intend to relieve herself by rousing the actions of life by means of vomiting. Rigors seems to be the effect of any new action in the constitution, and not at the commencement of a disease only, for even at the close, changing from a diseased action to a healthy one will cause rigors to take place. In a strong constitution, where rigors occur in consequence of a well-formed fever, the consequent actions of a hot fit and sweating go on regularly;

but in a weak constitution there is much loss of power by each rigor, and they will not be followed by a hot fit, but only perhaps by a little sweating.

A boy was attacked with rigor, followed by sweating, and he afterwards continued getting sensibly worse and worse: pulse quick and full, blood sizzly, tongue white. He was worse every other day. After being ill a fortnight, he was again attacked with rigor, hot fit, and sweating, which, contrary to my expectation, who supposed these would be repeated, carried off the disease with that single fit. I think I have seen other cases where Nature has attempted something like this, but has failed.

In many cases the rigor is the first apparent symptom, and is followed by a hot fit, and then sweating, and when these whole actions of the disease have taken place the patient becomes well; but this is not the case where, from weakness, &c., the whole regular actions do not take place, but, as at the commencement of the boy's case above related, the hot fit does not succeed the rigor, and he continued ill afterwards until Nature again took on the rigor, and he was able to go through the stages regularly, and one fit carried off the disease. The boy above mentioned was also a striking instance of the crisis of a disease being like its commencement.

Rigors from a local affection are seldom followed by a hot and sweating stage, and the bark in such cases can be of little service.

The ulcerative stage seldom affects the whole system; but that rigors take place on the commencement of ulceration is, I think, certain, although it cannot be well perceived in all cases, for ulceration will follow so close on suppuration in most cases that it will be difficult to distinguish which was the cause of the rigors. But when suppuration has taken place, and the abscess been opened, (so that the act of suppuration is finished), yet not so opened as to afford a ready outlet to the matter, the pressure of the matter against the most depending part of the abscess will cause ulceration, and thereby rigors will take place; but these rigors will not take place for some time after the first opening, for the first opening will for a time remove the disposition for ulceration all over the surface of the abscess; but when it finds this opening not sufficient to take off the pressure, it then sets to work to make another, and the rigors return. Many have supposed

from these rigors that new matter was forming.

Exacerbations are other symptoms, which have a great affinity to the foregoing, and are common to most constitutional diseases, and to some local ones. They are repetitions of the first attack, but seldom so strong as the first. These have been supposed to be owing to the disease acting on the constitution at stated times; but we must search for some principle in the animal œconomy to account for this, for we cannot suppose an increase and decrease in the cause of disease to account for it. Agues exist in the constitution as much between the fits as in them. If the constitution is strong, the exacerbations are regular; if weak, irregular. These may be partly owing to the fact that an animal cannot exist long together in the same state; life cannot always be affected in the same way.

ON WOUNDS OF THE HEART.

By Mr. LEES.

Mr. Lees has collected from various quarters, and narrated from his own observation, many cases, illustrative of the effects of wounds of the heart. In this country, at this time, such wounds must chiefly interest us in their medico-legal relations. We shall content ourselves with a summary of the more striking facts.

1. Wounds of the heart are popularly considered to be instant death. They are not always instantaneously fatal, but in too many instances they are so. Take a case as a sample.

Case. Dr. Corrigan shewed Mr. Lees a preparation in his possession, of a wound of the right ventricle which was followed by instant death: the case was that of a bailiff who was stabbed in the belly with a long knife, by a person standing upon the stairs under him; the knife penetrated the diaphragm just below the seventh rib, entered the abdomen, and re-entered the diaphragm, and perforated the right ventricle of the heart near the base.

2 The most interesting facts are those which establish the possibility of the individual's living for a short or a long time after the infliction of the wound. Mr. Lees cites some instances of this description.

Case 1. Ambrose Paré states he wit-

nessed a case where a person, after being wounded by a sword thrust in the chest, pursued his adversary for two hundred paces, and then fell dead; on examination he found a wound in the heart large enough to receive his finger, and a large quantity of blood effused on the diaphragm.

Case 2. Hennen, in his Principles of military surgery, quotes a highly interesting case of a soldier, who received a sword wound in the chest, and was left on an open staircase for five days, during winter time; he lived ten days after being brought to hospital, and died of gangrene of the legs, caused by the extreme cold to which he had been exposed; on dissection it was found that the right lung had been wounded, the right ventricle of the heart laid open, but this wound was perfectly cicatrized.

Cases 3, 4, 5. Dupuytren was decidedly of opinion, that these wounds were necessarily fatal; and in his *Leçons Orales* he alludes particularly to the case of a soldier, in whom, six years after the healing of a wound of the chest, a musket ball was found impacted in the substance of the right ventricle of the heart near its apex.

He also gives the case of a man, thirty-four years of age, who was brought to the Hôtel Dieu, May 5th, 1831, having received two stabs of a knife, one in the præcordial, the other in the epigastric region; there was no evidence that the wound had penetrated, as the heart's action and respiration were regular, the patient complained but slightly, and auscultation and percussion discovered no morbid phenomena. He had, however, a general spasmodic trembling. He died on the 13th with symptoms of diseased brain, having been affected with tetanic spasms for two or three days previous to his death; there was a wound of the pericardium of three lines, which also penetrated the cavity of the left ventricle, the pericardium contained 3i. of serosity, and Dupuytren thought he might have survived if the head-affection had not supervened.

He also gives another case of a man who died mad, after attempting suicide by amputating the penis, and in whom six penetrating wounds of the right ventricle were found after death, although during life there were no symptoms indicative of such a lesion.

Case 6. In the Museum of Martinique is preserved a heart, with the end of a sword five inches in length impacted in it.

The case was that of an officer, who in a duel received a sword wound in the right side of the chest, the point of the weapon broke, and the seconds supposing it to have been lost in the grass, walked with him to the hospital, where he expressed so little uneasiness, that the surgeon, supposing it to be a mere flesh wound, allowed him to return on board his ship, where he continued without any suffering the whole of that day, but at night very severe symptoms supervened, and he died next day; on examination, it was found that the point of the sword had passed through the right auricle, and wounded the left lung.

The preceding case is cited in illustration of Harvey's proposition on the insensibility of the heart—a proposition supported by his celebrated case of the young nobleman. Mr. Lees quotes also the experiments of Mr. Carlisle, Demonstrator of Anatomy at Trinity College.

"He mentioned to me that in his experiments on the motions and sounds of this viscus, he found that punctures of its substance affected its motions but slightly, and even on inserting tubes through its parieties into the cavities, though at first there was some slight palpitation, yet it soon accommodated itself to their presence; but he found that if he compressed the nerves going to its substance, by passing a ligature round the aorta and pulmonary artery, much suffering was evinced."

3. Mr. Lees divides wounds of the heart into punctured and contused.

The former he subdivides into simple acupuncture—and punctures complicated either with a copious hæmorrhage, or with residence of a foreign body in the wound.

A. Of the first of these complications, the late Duc de Berri (who was assassinated at Paris in the year 1820) afforded a remarkable example. He was stabbed in the right side, the right ventricle was pierced through, and the hæmorrhage into the cavity of the pleura was so considerable, as to oblige Dupuytren to open the wound every two hours while life lasted, in order to prevent impending suffocation; he lived in this state for seven hours.

B. "The second complication may be caused, either by a fractured portion of a rib, or by a part of the weapon remaining in the wound. In the museum at Park-street, Mr. Thomas Hart had the kindness to show me a preparation of a wound of the right auricle; and Mr. Wilkin, who was clinical resident in Stevens' Hospital at

the time it occurred, has given me the particulars of the case. It was that of a brewer's man, who had fallen under a dray, when it was heavily laden, which passed over his chest; he was lifted up, and complained of pain and weakness, but was able to continue sitting on the side of the dray driving the horse for nearly an hour, when being in the vicinity of the hospital, he thought he might as well get himself examined: he walked in, and lay on a bed, but on turning on his side he suddenly expired. (On dissection, it was found that the fifth rib was fractured, and that the extremity of one portion had penetrated the pericardium, but had freed itself from the heart; and this, as Mr. Wilkin observes, accounts for the sudden death of the man. For it is probable, that the portion of rib had filled up the wound of the heart, and thus prevented any hæmorrhage until his arrival at the hospital; when, on its coming out, the sudden effusion of blood into the pericardium caused sudden death; there had no blood escaped outside of the pericardium."

"As to those cases, in which part of the weapon remain in the wound, Orfila quotes an interesting observation in his *Medicine Legale*, of a workman who, in a melancholic mood, stabbed himself with a sharp stilet, between the fifth and sixth ribs of the left side, on the 24th of May. He was brought to the hospital on the 26th, in a state of great collapse, the pulse small, intermitting, respiration hurried, great anxiety, and severe pain felt; on touching the wound, which was nearly cicatrized, but just below it, a peculiar thrill could be heard, or as it is expressively denominated, a *crepitation onduleuse*, similar to what can be heard in a varicose aneurism: the horizontal position caused great pain. On the 3d of June he had severe rigors, followed by erysipelas of the face, and he died on the 13th, that is, twenty days after the receipt of the wound; on examination of the body, the pericardium was found to contain ten ounces of fetid bloody serum; in the inferior third of the right ventricle was impacted an iron stilet, which, penetrating the septum, could be felt in the left ventricle."

c. The heart occasionally suffers from contusions of the thorax. In the last siege of Antwerp, by the French, some remarkable cases occurred in which this organ was severely contused, and ruptured without any external appearances of injury, either to the integuments or ribs,

in which the death, in some cases instantaneous, was supposed to have been caused by the wind of the bullet. In some of the cases mentioned, a violent acute pneumonia supervened, in others, death followed from an effusion of blood into the cavity of the pleura.

In some instances, though no obvious lesion of the cardiac structure was produced, the heart has suffered so violent a commotion as to cause the suspension of its contractions, and a state of syncope which has occasionally proved fatal. The following case was not mortal, but is curious.

"A case of this description occurred while I was at Paris, and as I knew the parties concerned, and saw the patient shortly after his wound, I can vouch for its accuracy. Two French students quarrelled at supper, they wished to settle their dispute on the spot, however as they were both very tipsy and infuriated we prevented them; the next morning they met, and as they were determined that one should die, their friends prevailed on them only to load one of the pistols, and then leaving both on the table, to draw lots as to who should take the first chance of the pistols, of course being ignorant which was the loaded one; it was loaded with four pellets. They then mutually felt for the point of the chest, against which at that moment each stroke of the heart told with increased violence, and pressing firmly against this part, they fired: one of them fell to the ground in a state of insensibility, but on examining him they found merely a slight flesh wound at the part to which the pistol had been applied, and with a little care he soon came to himself. I saw him about three hours after this had occurred. He was then in a state of great anxiety which he could not account for, as he expressed more unpleasant sensation of weight about his heart than actual pain; there was great tendency to fainting, the pulse intermitted, with severe palpitation of the heart: under proper treatment all these symptoms subsided, and he recovered perfectly in a short time. I consider myself peculiarly fortunate in having witnessed this case, for in affairs of this kind it is generally the right side which is wounded, owing to the position we naturally assume; and also, it exemplifies in a striking manner the power of compressed air resisting the expansive force of gases."

We may not be astute, but we do not exactly see our way through the pre-

ceding case. However, Mr. Lees so positively vouches for its accuracy, that scepticism must necessarily be silenced.

4. The following generalizations are not unimportant, nor are the remarks appended to them unworthy of attention.

"All parts of the heart are not equally liable to be wounded, for in a series of fifty-four cases collected by M. Olivier, the right ventricle was the seat of the wound in twenty-nine, the left ventricle in twelve, both ventricles in nine, the right auricle in three, the left in one. The same author states, that out of twenty-nine cases of penetrating wounds of the cavities of the heart, only two proved fatal within forty-eight hours; in the others death took place at the varying periods of from four to twenty-eight days after the receipt of the wound.

These differences in the time at which death has occurred in individuals whose wounds have presented nearly the same appearances, as also why they are not immediately fatal, have been attributed to the peculiar disposition of the muscular fibres of this organ; for as the heart is constituted of layers of superposed fibres having different directions, if the instrument has divided a great number of its fibres in a transverse direction, the retraction will be considerable, and the probability of hæmorrhage much greater than if the wound run parallel to these fibres; thus, suppose the left ventricle to be wounded, there are three layers of fibres in its substance, the superficial and middle layer take one course, the deep layer takes an opposite direction, so that while one set of fibres are divided transversely, the others are merely separated longitudinally, and thus favour the formation of a coagulum, causing an obstruction to further effusion; at the first merely temporary, but finally definitively; so that we may assume, that wounds which are parallel to the axis of the heart, are *cæteris paribus*, less rapidly fatal than those which are transverse; and it is this action of the fibres which renders wounds of the ventricles less rapidly fatal than those of the auricles."

There are some other observations to which we do not deem it necessary to advert, as our object has been to arrange and present the facts collected by the industry of Mr. Lees.—*Medico Chirurgical Review, from Dublin Journal. See also the Physicians Vade Mecum, by Dr. Ryan, 1837.*

REVIEWS.

A Clinical Treatise on the Endemic Fevers of the West Indies intended as a Guide for the Young Practitioner in those Countries. By J. EVANS, Esq., M.R.C.S. London: J. Churchill, 8vo., pp. 309. 1837.

The endemic diseases of the West Indies are thus described by Mr. Evans, whose ample observations entitles his account to due consideration.

"If we examine the endemics which have arisen from malaria, as they have been described by authors, three classes of symptoms will not fail to strike us. The first is immediate, and often follows the impression of the poison instantaneously; vertigo, headache, fainting, convulsions, coma, or even death itself, belong to it, and point out to us the powerful action which has been produced upon the nervous system. The second sometimes quickly succeeds the first; often, on the contrary, a period of some days intervenes between them. It consists of a series of symptoms, characteristic of abdominal inflammation, such as pain and heat in the region of the stomach, vomiting with more or less effort, thirst, anxiety, agitation, supination, the tongue dry and red at the edges and tip. Other organs soon sympathize, become irritated, and at last inflame; none so frequently as the brain and its appendages, and we have then headache, coma, and delirium superadded. The symptoms of the third class depend upon a disordered hæmatisis, and consist of passive hæmorrhages, petechiæ, ecchymoses, extravasations of blood into the cellular tissue, &c.

"How does malaria introduce itself into the system? is a question which often asked; and by some it has been doubted whether it enters into the system at all. The emanations from the marshes are held in solution by the watery vapour existing in the atmosphere, and therefore come into contact with all those substances which are surrounded by this fluid; consequently with those surfaces of the human body which are in report with the external world, the skin, and the mucus membranes of the aëriform and alimentary passages. With every inspiration a certain quantity of this poison is inhaled and impinges itself upon the capillary and nervous extremities of the lining membrane of the bronchi and air-cells; when this is great,

or when it is concentrated, the nervous extremities become irritated, and this irritation is conveyed to the brain; hence the symptoms belonging to the first class described above. Its mode of action approaches nearly that of the mephitic gases, or of prussic acid, and is equally as incomprehensible. By the venous capillaries or radicles it is absorbed: at least everything would lead us to suppose so, and is carried into the system.

"Has malaria any other local effect besides that produced upon the nerves of the part? No, certainly not; neither pneumonia, gastritis, nor inflammation of the skin, is ever produced by the direct contact of this agent, unless it be at the same time combined with some other, which of itself is a powerful irritant. The men who worked in the swamp in the neighbourhood of Castries suffered from inflammation of the lower extremities; but the nature of the substance amongst which they were treading, and to which these parts were exposed, was sufficient to produce this effect.

"The effects produced by the introduction of malaria into the economy are generally imperceptible at the time, and a certain interval, more or less considerable, elapses before they take place in a manner appreciable to us. A number of men are exposed to the emanations arising from swamp; some are instantly attacked with delirium, stupor, or convulsions; others remain apparently well for a day or two; a third party for a week or fortnight, and a fourth are not affected at all. Now and then the effects have not been perceived for months after leaving the infected source, and then break out suddenly. This was frequently observed after the campaign of Walcheren; and it was of daily occurrence to see men, who leave St. Lucia apparently in perfect health, attacked with intermittents after having been three weeks or a month at sea.

"Another peculiarity in the physiological history of this poison, is the faculty which it seems to possess of gradually accumulating in the body; and when the system is charged with it, suddenly exploding. A series of symptoms are thus produced, exactly resembling those arising from its introduction in a more rapid and energetic way.

"At other times it does not explode in this sudden manner, but, on the contrary, produces a series of nervous phenomena, and ultimately an intermittent."

It appears, from this account, that the

effects of malaria are very similar to those produced in various other countries, though somewhat modified, and closely resemble the symptoms of typhus and putrid fevers in all nations. There are, however, some shades of difference. The effects of malaria on some inferior animals also deserve attention.

"Marsh seems, in general, to produce no injurious effects on the greater number of animals placed below man in the zoological scale. The tiger finds a safe shade in the jungles of Bengal, and the lion watches his prey in the mangrove fens of the African river, unscathed by their poisonous emanations. The cow, the buffalo, and the hog, luxuriate in the rich pastures of the Pontine Marshes; they thrive and grow fat, whilst man, all-powerful man, whom interest or necessity has induced to become their attendant, if he escape their first effects, gradually wastes away from protracted intermittents, or trails along his wretched body, swollen from dropsy, or emaciated from visceral disease. In St. Lucia, the only animals, except man, which appear to be affected by malaria, are dogs. These poor creatures are imported from England in considerable numbers, and are always in demand, as few survive the first year of their transportation, either being carried off by accidents, as the bite of the serpent, (the *trigonocephale* of Cuvier,) convulsions produced by insolation, or (by far the greater number) dying from fever of different types, presenting similar symptoms and pathological appearances as are found in man. When ill, the creature is seen stretching himself out in the sunshine, or under a cool shade, where the air blows freely; his eyes are dull and heavy, his tongue protruded from the mouth, and white; his respiration is quick, and his sleep apparently disturbed by dreams. When his thirst induces him to rise and seek for water, he often trembles in his gait, and seems to reel either from giddiness or weakness. At length, life is terminated generally by a convulsion.

"These symptoms may be intermittent, or they may be continued. That they arise from malaria I think is certain, because they are not seen in the other islands, where this poison is less abundant; and secondly, because they can be produced at will, in recently arrived dogs, by confining them within the range of the action of the swamp. In all the dogs I have examined, which have died with these symptoms, I have found with only

one exception, the cause of death is an inflammation of some part of the gastrointestinal mucous membrane. There was also a perceptible change in the blood, which, though it coagulated to a certain degree when taken from the vessels, and poured into a basin, after death, the coagulation was soft, and the serum contained a quantity of the colouring matter. This was the extreme extent of alteration in its appearance; in one or two it scarcely differed from that found in death from other causes, and seemed, in part at least, to have coagulated in the vessels; yet it did differ. The brain was examined in two cases only, and presented no lesion whatever. In the case which forms the exception, the dog died from an inflammation and purulent infiltration of one lung; the lower part of the ileum was in a state of considerable hyperemia.

"I never saw, as far as I can recollect, ague, or perceptible cold stage, except once, and then it was extremely well marked. The animal shook convulsively, and sought the sunshine, from which it was impossible to drive him. The symptoms continued about an hour, and then gradually subsided; but though he seemed better, he still continued unwell; the paroxysm returned daily, the poor wretch became worn to a skeleton, and at length disappeared."

Mr. Evans next introduces a section on "The Effects produced in Animals by the introduction of Putrid Matter into the economy," in which he details the experiments of Magendie, Leuret, Hamont, Nysten, and Dupuytren, with which our experienced readers are well acquainted. We may, however, remind them, that intermittent diseases have never been produced by the introduction of putrid substances into the circulation; but the experiments have neither been sufficiently numerous nor decisive. Our author sums up his conclusions in the following words:—

"With respect to the other supposed sources of malaria, little need be said. We have already seen that the gases which escape from soil of volcanic formation, under no circumstances can be considered as constituting this poison; and that places, the atmosphere of which contains one or more of the the most mephitic amongst them, in a considerable proportion are free from the diseases of which we propose to treat: thus, in St. Lucia, Castries is extremely unhealthy, whilst the town of Souffriere, situated in the immediate neighbourhood of a prolific source

of these emanations, is the most salubrious quarter of the island.

"Another opinion, that malaria originates from the decomposition of certain plants, as the chara vulgaris or flexibilis, the manchineel or the mangrove, is correct so far as these substances form part of the vegetable kingdom, and therefore capable of giving rise to it no further; true, some of these furnish emanations much more deleterious than others, but they enjoy no exclusive privilege in its production.

"The opinion of Dr. Fergusson that water, during its progress of exsiccation, is the only cause which gives rise to this poison, is an ingenious hypothesis, but has no substantial foundation, and is contradicted by every day's experience.

"To conclude, nothing is known of the chemical properties of malaria. Whatever may be its nature, it has its origin in the decomposition of organic matter; whether it has any other, remains to be proved. It differs little, or not at all, from the peculiar poison which resides in all putrid substances, whether animal or vegetable, as the physiological effects of both seem to be the same, allowance being made for those which may be caused by different matters with which each may be united, and the different ways by which they may be introduced into the economy.

"Putrid substances have an action upon the part to which they are applied, and inflammation of this part is the consequence. To the local affection is added a series of phenomena which terminate in death, and the whole circulating mass is found diseased: the former depends upon the local effects of an irritating substance, the latter upon the absorption into the system of a peculiar matter, which seems to possess a specific action upon the blood.

"When putrid substances divested by filtration of a great portion of the solid matter with which they were before united, are injected into the circulation, convulsions, gastro-enteritis, and fluidity of the blood, are the result.

"We hear of fevers of different types reigning epidemically or endemically, in countries where marsh is unknown, and where the quantity of animal or vegetable matter is so small as to preclude our attributing them to this cause. Do these diseases differ from those of acknowledged marsh origin? Have they their rise in malaria? If so, whence emanates this substance? These questions are not to be answered here. I can only examine

the known causes of the diseases of St. Lucia and the neighbouring islands, and refer those who are curious in this subject to other sources of information.

"When the emanations from the decomposed animal substances are *confined*, and do not escape freely into the atmosphere, new arrangements take place, and certain gases are formed, with which, if man or an animal comes into report, asphyxia, or even poisoning ensues, from the action of these substances upon the nervous system, through the nervous extremities of the lungs; and whether these symptoms will be followed by those peculiar to the introduction of putrid matter into the system, will depend upon the existence or non-existence of *this poison* in the emanations, or rather the proportion in which it enters into combination with them.

"Emanations from marsh or swamp generally consist of malaria, held in solution in the atmosphere, and, when collected in form of dew, do not contain any of these gases, or if they do, it is in so small a quantity as to escape all our researches, and therefore to be incapable of producing any effect. These emanations have a specific action *on the nervous system*, causing ague, neuralgic affections, convulsions, coma, and sometimes, but rarely, death; *on the blood*, by destroying the powers of coagulation which the fibrine possesses in health; *on the gastro-enteric mucous membrane*, producing inflammation of this tissue. M. Caillot says, in his work, 'Sur la Fièvre Jaune,' that every physician who has treated bilious fevers in their most intense form, within the tropics, must be struck with the similarity which exists between the effects produced by certain mineral poisons and those arising from malaria. This remark is very true, and to which every one, acquainted with these diseases and with the researches of Sir B. Brodie and Dr. Orfila, cannot fail to subscribe."

Several cases are given in illustration of the diseases of the West Indies, some of which we shall quote:—

"Cases of Intermittent Inflammations.

"*Intermittent Pleuropneumonia*.—Lucille, a girl of colour, aged twenty-three, has been unwell for two or three days with what she calls a cold, but has not been confined to the house until yesterday, when she was suddenly attacked with a severe pain in her side, cough, and fever, about nine o'clock in the morning. The symptoms ceased toward evening,

and she remained tolerably well until this morning, August 21, 1833, when they again returned. At noon I found her as follows:—Pain over the sixth and seventh ribs on the right side, increased on inspiration; dry cough, crepitating *râle* over the seat of the pain; no uneasiness of the epigastrium; bowels regular; skin dry and warm; tongue natural. She had no cold stage, nor was the attack preceded by a sense of coldness. *Diet*—*demulcent drink*; *castor oil*. Evening—the patient is perspiring; expectoration on coughing; the pain has subsided; the *râle* is mucous. 22nd.—The patient has had a return of the paroxysm; the pain in the side is greater than yesterday; several fits of coughing, with expectoration of small quantities of very viscid mucus; *râle crepitant*; pulse ninety-six. Evening—perspiration, and mitigation of symptoms; expectoration free; the sputa white and frothy; there is still some pain on inspiration; the pulse is eighty-four; bowels open. 23rd.—The paroxysm commenced two hours before its usual period; I saw the patient at noon; she is much worse than she has yet been; the sound, on percussion, over the seat of the disease is somewhat dull; breathing very painful. Evening—The disease is advancing; there is no appearance of intermission; sound on percussion dull; centre of the diseased part does not appear permeable to air: at least the crepitating *râle* in its neighbourhood hides the sound, if any exists; sputa viscid, adherent, and of a rusty colour. V. S. $\frac{3}{4}$ xvi.; hirudines xx. lateri; decoction of marsh-mallow, in which antim. tart. gr. vi. are dissolved for drink. 24th.—The patient is better: to continue. Evening—Amelioration very great; great prostration from the effects of the antimony, of which the patient has taken nearly eighteen grains. 25th.—Expectoration free; *râle* mucous; pain nearly gone; pulse seventy, small. To take the medicine only now and then. 26th.—Convalescent.

"The carpenter of the ship, Cuba, up to this period in the enjoyment of good health, married, and father of three children, has been unwell for the last week or ten days, with pains in different parts of the body, but is laid up to-day for the first time. He says that he has a good day and a bad day. The pains first commenced in the loins, then attacked the shoulders, and are now in the left knee and ankle; the knee is somewhat swollen and warm; the patient complains of excruciating pain on moving it; the ankle

is not swollen, but is warmer than natural; the pulse is ninety, and full; the tongue clean, and the bowels open from medicines which have been given him. Warm fomentations to the knee, and to take twenty drops of the vin. colchici thrice a day. The following morning—the patient is walking about; the pains are gone, and nothing but stiffness remains. On the third and fifth days from the period of my first seeing him, the pains of the knee returned, accompanied by a pain and swelling of one wrist; the paroxysms continued about fourteen hours. The patient was completely cured by a few doses of quinine."

First Principles of Medicine. By ARCHIBALD BILLING, M.D. A.M., &c. &c. Second Edition. 8vo. pp. 130. London: Highley. 1837.

We were the first to offer our approbation of the work before us, and we are happy to see a new edition of it. The want of a work of this kind led the author to prepare an epitome of the principles of medicine, which he was induced to draw up for his own use; and, finally, to place before the public. He informs us in his preface that—

"The so-called systems of Cullen, Brown, Broussais, Rasori, &c., seemed mere individual opinions totally differing from each other; and which was I to follow? each, confident in himself, despising his adversary, their followers almost coming to blows in arguing, as much for victory as the love of truth. I visited the different schools; and, though the students of each hinted, if they did not assert, that the other sects killed their patients, I found that, provided the physician of each was a man of talent and experience, the mortality was fairly balanced. I thought that there must exist some true general principles by which the apparent inconsistencies of correct practice might be reconciled, and by which the contest between such systems as were essentially at variance might be decided. But, though there were to be found innumerable volumes of cases, and interminable heaps of insulated precedents, there was no treatise upon first principles. After twenty years of intense application to clinical practice, as student, assistant, and professor, I ventured to publish what I had drawn up, condensed to 130 pages. The trouble which it cost me in condensation makes me pleased whenever the term "little" is

applied to it, and I cannot deny myself the satisfaction of transcribing the words of Professor Stromeyer, of Hanover. "Dr. Billing's book is a very clever little *Pathologia generalis*; his views certainly go beyond those of most pathologists, by his taking the nervous system into consideration. Upon the whole, I think it as much written for fully educated medical men as for students. Books like this are very rare; almost every writer strives, whatever little original ideas he has, to bury them in a mountain of generally known matter, whilst Dr. B. gives us a very intellectual (*geistreich*) view of his peculiarities." I must acknowledge also that I derived much satisfaction from the favourable notices of the Medical Reviewers, especially of the *Med. Chir. Review*, the *London Med. and Surg. Journal*, and the *London Med. and Phys. Journal*, 1831, as their testimony gave me more confidence in the approbation expressed by private friends."

Though this is no more than an outline of the principles of medicine, yet it contains much important information. Dr. Billing claims the merit of having first given Clinical Lectures in London, and set an example which is now generally followed.

"The subject of clinical lectures is connected closely with the attempt to reduce the science to general principles; much just censure has been expressed, in medical publications, of the neglect of clinical instruction, and of the omission on the part of Hospital Physicians and Surgeons, to render their experience available to the profession in general, and consequently to the public. In 1822 there were no clinical lectures given in London. In that year I had the honour to be elected Physician of the London Hospital; in the same year I commenced giving clinical lectures, and not merely instructed the pupils in the wards and theatre, but attended and explained post mortem examinations. This course I pursued, at a great sacrifice of time, and some of health, for six or seven years, when the rising generation of my clinical secretaries, Dr. Machraire and W. J. Little (now Professor of Comparative Anatomy, alumnus dignissimus of Muller and Grant), Messrs. Hamilton, Adams, Curling, &c., being able to relieve me, I continued only the lectures, instructions in the wards, and once a week on anatomical demonstration, illustrating cases by recently obtained specimens, or from the extensive collection of pathological ana-

tomy in the Museum. In this mode I persevered up to the present session, when, from being appointed to the University of London, it would be impossible for me to continue it. I have since then had the satisfaction of finding that the example has been very generally followed in this metropolis, besides that of witnessing the success of the school in which it was first regularly begun. The London Hospital was amongst the first that were mainly instrumental in *introducing* auscultation; but it is not yet by any means generally *adopted*. It is a source of real regret to me to find, how few medical men have taken the trouble, or known how, to avail themselves of this invaluable and indispensable method, of detecting, so as to combat, the most deadly diseases of the chest. On this score Dr. T. Davies has gained a well-earned celebrity. He not merely gave lectures to pupils, but collected the men in practice at the east end of the town, at his house, and instructed them in this almost new sense of perception; and from the time he became one of the medical officers of the London Hospital, in 1822, I enjoyed immense assistance from him in the clinical department, in the instruction of those young gentlemen, who have had the good sense to avail themselves of the opportunities afforded them of learning auscultation and the use of the stethoscope. One cannot be much surprised, that the multitude are slow in adopting what, in some instances, has been treated with neglect, and in others has met with decided opposition by men in high reputation and practice. As to the stethoscope, I wish it were understood that it is not absolutely necessary, except from motives of delicacy, as the apparent difficulty of using it deters some persons from commencing auscultation, and as given, occasionally, an opportunity for opponents to use a tremendous substitute for reasoning—ridicule. It is disagreeable to apply the ear to the chest, if the patient, as occurs sometimes in charitable institutions, be not clean; and, if the patient be a female, it is objectionable for other reasons; hence, the artificial elongation of the meatus auditorius externus, called stethoscope, becomes sometimes eligible, though no better than the naked ear to judge by. I am in the habit of using a very simple one, which is merely Laennec's, abridged, instead of being complicated, as it has been by other *improvers* of his instrument; it is rounded and cut away in the middle, to make it light and convenient;

the flat end being turned to the chest answers the purpose of the obturator; it is only four inches long, which is sufficient for the purpose, as to stethoscoper and and stethoscoped, and may be obtained from any wood-turner for a few pence.

"One great difficulty in the way of learners of auscultation is their attempting to begin on patients; this is like trying to study morbid anatomy before acquiring a knowledge of healthy structure. If beginners would first learn the sounds of respiration, and of the heart, in healthy persons, which may be done in about ten minutes once for all, they would have little difficulty in detecting any unhealthy deviation from the normal state, and would very soon arrive at just diagnosis. But I warn them that they must soon do it, or be disgraced. Many affectionate parents are in the habit of feeling the pulse, and looking at the tongue when they suspect disease to exist; they will soon also begin the very simple process of applying their ear to the chest, and thus put the medical attendant to shame, if he cannot make use of his."

We cannot assent to the opinion that the sounds of healthful respiration can be learned in ten minutes, or that the normal sounds are detected so very speedily as our author supposes; neither do we think that the reasons urged in favour of the employment of auscultation, are the best that could be adduced. He next alludes to the progress of science in these words:—

"But the progress of the schools has been slow enough: it is only now that comparative anatomy, which is the only sure foundation of physiology, is *beginning* to be taught in London; and it required the energy and talents of a Grant, with a firm footing in a great school, to carry it into effect, and to compel the other schools to follow the example. Professor Macartney, with all his energy and talents (and he does not require my testimony to establish his claim to both), fully imbued with its value, could not find support in his laudable attempt to establish it thirty years ago in Bartholomew's Hospital; but I consider myself most fortunate in having early met with him, and imbibed a taste for physiology. The ingenious and persevering German comparative anatomists, with their microscopes, are unravelling many a dignus vindice nodus; and I am gratified to find in their recent publications, confirmations of opinions advanced in this work seven years since; as, for instance, my expla-

nation of the cause of a limb being 'asleep,' benumbed, by reference to the medullary part of the nerves being in tubes (as asserted by Fontana), has been demonstrated by Ehrenberg (*Darstellung eines merkwürdigen Baues des Seelenorgans*, Berlin, &c.), who has proved also, that not only are there two sets of nerves, of animal and organic life, but that there is a third set, of the senses, all recognizable by their structure, when an isolated piece of either is subjected to the microscope; and Remak (*Archiv sur Anatomie Physiologie*, &c. von Dr. Johannes Müller Jahrgang, 1836, Heft 1 & 2) has shewn the difference between the motor and sensitive roots of the symmetrical nerves, that the latter possess, in addition, some organic filaments, and that the glosso-pharyngeal belongs to the same order as the optic, auditory, and olfactory; thereby confirming Pannizzi's opinion, that the hypoglossal is the motor, the lingual branch of the fifth sensitive, and the glosso-pharyngeal the gustatory nerve of the tongue. Schwann (*Müllers Handbuch der Physiologie*, Goblentz, 1833), by experiment on the mesenteric arteries of small living animals, has demonstrated that I was right, as to the *modus operandi* of cold as a remedial agent in inflammation. Schwann and Eulenberg again have shewn, that the middle coat of the arteries is not muscular in structure, but elastic, as asserted by me, consisting of that distinct tissue constituting the *ligamentum nuchæ* of ruminantia, the *ligamentum flavum* of man, &c. The veterinarians also have contributed in their comparative department. Hausmann has added fresh proofs, by direct experiment, to my theory of inflammation. Sewell, of our own Veterinary College, twenty years ago, published plates shewing the muscular coat in the bronchi of the horse; indeed, the muscularity of the bronchi was shewn by Morgagni. Nevertheless, it has been lately spoken of as a discovery, as mentioned in Youat's valuable *Journal*, March 1837, in the Report of the Veterinary School of Alfort. Not that I agree that the muscularity of the bronchi can assist in natural expiration, for that is contrary to the physical structure of the chest; it merely serves to expel any noxious matter, whether generated there or introduced through the windpipe.

"But there is no end to reclamations. I learn from the *Medical Gazette*, that I have to apologise to Dr. Marshall Hall, for not having mentioned him as having preceded Gooch in the description of the

affection alluded to, which was the fact; at the moment I was merely thinking of an authority, and Gooch's being great as a practical man, and his book in the hands of all practitioners, I mentioned him. In Dr. Marshall Hall's paper in the *Transactions of the Royal Society*, 1833, "on the reflex functions of the medulla oblongata and spinal chord," there is one original discovery of great importance—the establishing that various nerves influence each other so as to produce reaction, in consequence of the uniting medium of the spinal cord, independent of the brain: this independence of the brain, and the proving it physiologically, is the originality. As to pathological subjects, the *rationale* of which he says was not previously given, and that they were '*untouched*,' it will be found that they were freely *handled* by me, in this publication two years before, and more than ten years before that in my lectures on the *Institutes of Medicine*; the very term *reflection* was applied to the phenomena by Pfaff as far back as 1801, (*Grundriss*, &c. Copenhagen, 1801). To shew this, I have changed but one word in my text, putting the modern term, nervous centre, instead of brain, which reconciles the passage to Dr. Hall's discovery, leaving the *rationale* as I originally gave it.

"At page 104, I gave the rationale of the involuntary re-action (equivalent to reflection), which takes place in Hysteria, Epilepsy, Tetanus, &c., producing spasms of the voluntary muscles, and of convulsions from worms in the intestines; but in which, I did not contemplate the possibility of the phenomena taking place without implicating the brain: but at page 79, I shewed the re-action of the uterus on the hip, and of the liver on the shoulder, of course necessarily in consequence of their nerves meeting in the spinal cord; and the cramps in the calves of the legs, produced by diarrhoea, may be accounted for on the same principle, as I had been in the habit of explaining to my class. The '*relaxation of sphincters from mental emotion*,' is *not* explicable on the principle of reflex function nor of re-action, but of direct derivation or abstraction of nervous influence, as explained in the phenomenon of blushing, and indigestion. But I had no idea of claiming originality for what seemed to me plain inferences from phenomena constantly before the eyes of practical men."

Our readers will observe that Dr. Billing claims no small part of Dr. Marshall

Hall's discoveries, and adduces proofs which cannot be easily set aside. But we shall leave the claimants to defend their respective rights, and proceed with our exposition of the merits of the work before us. Our author next alludes to his discovery of the nature of the sounds of the heart, which Bouillaud claims as his own.

"Before concluding this preface, I wish to take the opportunity of advertizing to one or two matters which will be found in the work. At page 12, to the note originally published on the heart, I have added, that the sounds depend on, or are produced by, the valves. I would not burden the text with proofs of what I feel assured will shortly be generally received as a fact as well ascertained as the circulation of the blood; but as it is still disputed, not merely by individuals, but by associations, and committees by them appointed to investigate the subject, I will here repeat my arguments already published, which have not, to the best of my judgment, been answered; and, besides, by referring to their own experiments, I think I can disprove their assertions. I first stated publicly, in an Essay read at the Anniversary meeting of the Hunterian Society, (9 Feb. 1832, and reported in *Lancet* 19 May, 1832,) 'The push or beat is caused by the ventricular muscles in their systole to expel the blood. The first sound is caused by the tension produced in the shutting of the auriculo-ventricular valves, and the second sound is caused by the tension produced in the shutting of the ventriculo-arterial valves,' &c. &c. 'This is a simple unsophisticated explanation of the causes of the beat and sounds of the heart; and you will find that the morbid signs are all explicable as alterations of these.' Some exemplification follows, unnecessary to repeat here. Subsequently Rouanet brought forward the same explanation in his Thesis, which was noticed in the *Journal Hebdomadaire* (Sept. 1832) and copied into the *Medico-Chir. Review* (April 1833) as well as an extract from my Essay, in which I had advanced, as I thought, sufficient to enable any practised physiologist to confirm my positions from the suggestions of his own mind; finding, however, from some observations that this did not appear to be the case, I published the following additional remarks in the *Lancet*, (November 33, 1833.) 'The succession of phenomena of the heart's action is as follows:—First the auricle contracts, then the ventricle, by the action

of which the auriculo-ventricular valves are shut, by the pressure of the blood against them. Upon the relaxation of the ventricle, the semilunar valves are shut by the backward pressure of the blood in the artery. The first sound takes place exactly synchronous with the impulse and action of the ventricle; hence it might be supposed, that the action of the muscle (as averred by some) produces the first sound; but the second sound takes place at a time when there is no action of the heart going forward; and this is peculiarly evident when there is an intermitting pulse, as there is then a marked pulse after the second sound—so that, in fact, there is nothing but the semilunar valves in operation to produce sound at the instant." I have thus shewn the second sound can be produced by nothing but the valves, I have shewn therefore the tension of the valves, to be a sufficient cause for the first sound; and as nil frustra natura facit, according to the laws of reasoning in Physics, more causes than are true or sufficient are not to be assigned (*Newt. Princ. Lib. 3 Reg. Phil. 1*), so I discard muscular action as cause of the first sound. These are my proofs published between February, 1832, and November, 1833."

"Now as to their experimentum crucis (to show that muscle produced the first sound), putting the finger into the heart after the valves were destroyed, or a sound proceeding from the contraction of the heart, with air, *carneæ columnæ*, and bloody moisture in it, without the fingers, doubtless there was a sound produced independent of the valves, but not *the* sound of the heart. I say my proof is legitimate, their assertion a sophism of non causa pro causa; it is the tympanic sound of the membranous valves which with the time of the beats produces the rhythm; and we judge of the existence of certain states of disease by the degree and manner in which they are out of tune. Looking at the subject physiologically and pathologically, valvular sound is the one we have to depend upon; for granting for argument's sake even that any other exist as a normal accompaniment, it has no more to do with *the* sound than the drone of a bagpipe has to do with the tune. In his last Appendix Dr. Hope began to allow that the first sound may be 'possibly partly valvular,' but still adheres to the 'bruit musculaire.'

"According to the Report of the London Committee of the British Association the subject appeared to be in the position

agreeing with the vulgar notion of a suit in Chancery. (*Med. Gaz.*, Dec. 10, 1836.)

"With respect to the assertion of a celebrated experimenting physiologist, that the sound is produced by the heart coming pit-a-pit against the parietes of the chest, it is only necessary to refer to Mr. Bryan's beautifully ingenious experiment (*Lancet*, February 8, 1834), by which he proved, that the heart never quits the anterior, but remains in opposition during both systole and diastole.

"A few days after the Hunterian Anniversary (1832), I gave the same explanation to my class, exemplifying how the sound was produced, by a strip of paper two or three inches long, and half an inch wide, suddenly stretched, the sound of which was heard all over the Theatre. Dr. Hope subsequently mentioned, in his Appendix 1835, his having employed a piece of tape for a similar purpose. Very recently Dr. Watson has published a case in the *Med. Gaz.* to shew that disease of the ventriculo-arterial valves masked the second sound. I suppose it had escaped his notice that I published, five years before, not only that fact, but the explanation of what particular kind of disease of the valves would produce a single bruit, and which a double bruit.

"Dr. Watson thinks it possible Rouanet may have had the suggestion, respecting the cause of the sounds of the heart, from Dr. Carswell. It would not astonish me if Rouanet had it from the brain, as well as myself; or, if communicated to him, it was possibly by one of my audience at the Hunterian Anniversary (at which Dr. Carswell may have been present, among a number of other scientific gentlemen,) or by some one of my intelligent pupils, several of whom have since visited Paris. Mr. Bryan published the same theory, (*Lancet*, January, 1833); but when he became acquainted with my priority, he very candidly wrote an acknowledgment, in a critique on the Report of the Dublin Committee of the British Association, (*Lancet*, December 26, 1835, and February 27, 1836.)"

Our readers will recollect our articles on the physiology of the heart's action, published in this journal last autumn, in which M. Bouillaud concluded, before any other writer on cardiac diseases, as far as he knew, that the sounds of the heart were valvular. We had not Dr. Billing's work by us at the time, or we certainly should have set forth his claims, and have now much pleasure in doing so.

The next subject alluded to by our

author is the pathology and treatment of cholera, but here his observations, like those of his contemporaries, afford us little if any practical information.

"My observations in the first edition were published previous to the terrific visitation of the cholera in 1831. Relying on accurate descriptions which I had received of the disease from my former pupils, and other medical friends in India, I had ventured to add some remarks upon the treatment. Before I had an opportunity of personal observation, I was led to make a too-limited estimate of the symptoms, referring chiefly to the (old English cholera morbus) affection of the stomach and bowels, and thence deducing the collapse. When, however, I encountered the enemy hand to hand, I saw at once that it was like ague, not merely, as there hinted, in its epidemic and miasmatic origin, but almost, if not altogether, an ague of a fresh type; and I often thought of what the great Sydenham candidly said of his first encounters with new epidemics. From thence I inculcated a system successfully adopted in ague, and borne out by the previous experience of Kennedy, Lefevre, and others, in cholera, *i. e.* bleeding, with emetics and neutral salts, but modified and combined with opium and stimulants in some of the stages. Subsequently, both in the cold stage of ague and cholera, I have depended much upon antim. tartariz., with or without neutral salts, and dispensed more with either bleeding or stimulants, and with even more flattering success. Upon this analogy between cholera and ague I would address a few words to men of practical experience. What is called *the fever*, is well known in India, beginning with chills and shivering, rigors, &c., followed by intense heat; after which, in favourable cases, there is perspiration, with relief of symptoms; but, as we also see here in ague, sometimes the sweat does not come on, but the skin remains hot, in a state of continued or remittent fever. Who that has seen the cholera does not recollect some cases with this routine? Again, *the fever* of India, when it goes through the ague stages, does not, like our agues, continue for weeks, a second, or at most a third paroxysm, is usually fatal, in the severe cases which the physician cannot check. Who has not seen patients die in cholera after they had become quite hot, that fever heat exciting fallacious hopes? There was once an epidemic, the Bombay fever said to have destroyed the patients in the cold stage,

and it was inferred that had the patient lived, the hot stage would have come on: who will decide now whether that was cholera or ague, or which is which? for, though called fever, the description agrees with cholera. Whoever has had much experience in ague, has seen all the modifications of cholera;—the cold stages with convulsions, (clonic spasms,) spasmodic cholera; ague with nausea and diarrhoea, and of course little or no urine, the purging cholera; ague with blueness of the skin and shrivelled fingers, like a drowned person; blue cholera; ague, passing into continued fever: a common termination of cholera, &c. &c.”

We have now placed a fair specimen of our author's work before our readers, and leave them to form their own opinions on its merits. It is, in our opinion, entitled to much praise for originality and lucidness in exposition of the science of which it treats.

The London Medical

AND

Surgical Journal.

Saturday, September 2nd, 1837.

HOSPITAL REPORTS.—THEIR VALUE AND EVILS.

WHEN for the first time HOSPITAL REPORTS were published in this country, and for which important event the medical profession, as well as the sick poor, are indebted to an able contemporary; the great advantage to be anticipated from such documents was, that they would contain a true and faithful account of each case, so that the effects of remedies and surgical operations, and the result of the practice of individuals, many of whom occupied a high position in the estimation of their professional brethren, should be accurately and distinctly known. Hospital Reports faithfully drawn up were likely to possess much value, more particularly to young prac-

titioners, from the great and, indeed, almost insurmountable difficulty, which must be encountered by the student to become acquainted with the result of operations, and the medical treatment of diseases in private practice. Whilst the Hospital Reports which were first published, created great interest throughout the profession, giving publicity to mistakes too often the result of ignorance or carelessness, they excited not only greatest animosities and unjustifiable conduct towards the Editor of the *Lancet*, and also against those who contributed to that Journal, but ultimately led to a variety of stratagems to conceal from the pupils of the different Hospitals, as well as from the public, the serious medical errors and blunders which the physicians and surgeons of these Institutions were constantly committing. As a last resource they were accordingly compelled to publish Clinical Reports of *their own* cases, for which purpose, so essential to their professional reputation and mundane purposes, was instituted the celebrated GAZETTE! by which Journal the selfish *subscribers* were each enabled to introduce such an “authentic account” of his blunders and unfortunate mis-givings as he considered best suited to conceal the truth, and blind the public.

The same system of *selecting* cases, and of giving only such *portions* of them as would best suit the purposes of the medical officer, has, we lament to say, been gradually introduced into other Journals, and hence, at this time, the reports of cases which appear in every Journal, except our own, have, generally speaking, been drawn up by interested persons, who have instructions to collect only such cases as may be suitable for the particular purposes of the Editors; or they are drawn up under the immediate direction of the surgeon himself,

such parts being absconded as might in any way derogate from the supposed talents of the operator, and such *puffings* introduced as shall have the effect of giving a false impression of the results of the operations. But the most effectual method that talented editors and ingenious operators have yet been able to devise, has been that of not taking the least notice of any case, however important, or of any operation, however interesting, when the result has been such, that by any species of twisting or serpentine winding, a detail of the circumstances of the case could not give eclat to the practitioners, far less if there was the smallest danger of any disclosure being made which could injure their professional reputation.

A reference to the medical hebdomedaries for the last few months sufficiently proves the assertion we have now made; and by a reference to this Journal an account of cases of the most interesting importance will be found, of which even no mention is made in the reports of these Journals, which profess to give an account of the practice of certain Hospitals, and which in their stead, contain a detailed account of many cases of the most frivolous description, and from which no instruction neither can nor ever was intended to be derived.

These observations are especially called forth on the present occasion, on account of some cases which occurred in the North London Hospital, and which, notwithstanding the great interest that they excited, and the useful practical, though painful, lessons to be learned from them, were not alluded to by the *special* Journal of that establishment until many weeks after their occurrence, and then only after notice had been taken of them in this Journal.

We are quite aware, and have severely felt, in conscientiously fulfilling our edi-

torial functions, the difficulty we have too frequently encountered in placing confidence in reports and communications from certain quarters; and therefore we are on all occasions ready to sympathize with our fellow-labourers when any individual, or phalanx of individuals, for selfish purposes, have imposed upon an editor. We hazard this observation on the present occasion, because we are convinced the knowledge of the law of libel which the honourable member for Finsbury has so ably exhibited on more than one occasion, as well as his love of justice, and, above all, his regard for the vital interests of the student, would never have permitted the insertion in his independent Journal, had he not been imposed upon, of an article purporting to be an Abstract of a Clinical Lecture, delivered by Mr. Liston, on the fatal case of lithotrity which was lately operated upon by him at the North London Hospital. In that report, which we, in justice to the individual whose professional character has been therein so grossly misrepresented for the purpose of concealing the *REAL* cause of the patient's death, have printed verbatim in our last number, in order that we may have it in our power, on a future occasion, to expose the whole details of this transaction.

In the mean time, let us anticipate that even should the Editor of the *Lancet* make no effort to investigate the facts concerning this unfortunate operation, or contradict those statements, which we have every reason to believe will be contradicted in a higher tribunal,—that the investigations which have been instituted by the Members of the University College, and the great excitement amongst the students, will be the means, not only of eliciting the truth, but, on all future occasions, of protecting their students against any one of their own body, who might endeavour

by resorting to unjustifiable means, to injure and blast the hopes or the future professional reputation of their students. Nothing could be so disastrous, far less to the respectability, of a medical school, if any of its teachers was permitted to make use of a reckless authority to the injury of the student; and constituted as University College now is, by charter, they are possessed of the means of protecting the pupil's interests, and controlling the different lecturers, more than the officers of any other medical school of this Metropolis.

THE ANATOMIST.

PECULIARITIES OF THE FŒTUS.

The principal anatomical peculiarities of the fœtus, by which it is distinguished from the adult, are the following:—

The *thymus gland* occupies the anterior mediastinum,—the *kidneys* are lobulated, and each is covered by a cellulo-vascular called *Renal capsule*, which is larger than the kidney itself,—the *liver* is very large, particularly its left lobe,—the *lungs* are compact, and of a deep red colour, and sink in water, the bronchial tubes and their ramifications being void of air,—the *auricles* of the heart communicate by the *foramen ovale*,—at the bifurcation of the pulmonary artery an arterial trunk about nine lines in length, called *ductus arteriosus*, proceeds to the aorta, into which vessel it opens,—the *umbilical vein* proceeds to the liver where, having distributed some branches to its left, it divides into the *communicating branch*, which unites with the portal vein; and the *ductus venosus*, which opens into the vena cava inferior,—the *internal iliac arteries*, under the name of *umbilical* or *hypogastric*, turn upwards and forwards along the sides of the bladder, pass through the umbilicus, and run a tortuous course along the umbilical vein to the placenta, and the urinary bladder is in the abdominal part of the pelvis, from the summit of which a ligamentous chord, called *urachus*, passes to the umbilicus. Until the seventh month the pupil is closed by a membrane, called *membrana pupillaris*, and in the male the *testes*, are contained in the abdomen.

THE CERVICAL FASCIA

consists of a superficial and a deep a layer. The *superficial layer*, which is in intimate connexion with the fibres of the platysma-myoides muscle, is in connexion superiorly with the lower jaw and the parotid gland, and cartilage of the ear of either side; and, extending over the anterior and lateral parts of the neck, is continued downwards over the forepart of the thorax, where it becomes thin and continuous with the common subcutaneous cellular tissue. The *deep layer* passes behind the sterno-mastoid and omo-hyoid muscles; adheres to the upper part of the sternum, the inter-clavicular ligament and the sheath of the carotid vessels, and behind the angle of the jaw, it adheres to the styloid process and stylo-maxillary ligament.

THE SUPERFICIAL FASCIA OF THE ABDOMEN

passes downwards from the thorax over the abdominal muscles, and Poupart's ligament to the thigh. In the median line it passes off the pubis upon the penis, forming its suspensory ligament, and in the female it descends into the labia. In the male it passes on either round the spermatic chord into the scrotum and becomes continuous with the fascia of the perinæum. After having passed over Poupart's ligament it forms envelopes for the inguinal glands and adheres to the fascia lata presenting a cribriform appearance (vide fascia lata); and continuing its course downwards becomes identified with the sub-cutaneous cellular tissue of the lower extremity.

FASCIA TRANSVERSALIS AND FASCIA ILIACA.

The *fascia transversalis* is a layer of condensed cellular tissue, placed between the transversalis muscle and the peritonæum; it is very strong inferiorly, and is connected to the internal tip of the ilium, and to the whole length of Poupart's ligament, and is continuous, behind the rectus muscle, with the fascia of the opposite side. As the external iliac vessels are passing beneath Poupart's ligament, a production of this fascia extends along the anterior aspect of their sheath, and becomes identified with the cribriform fascia in the groin. The spermatic chord in the male, and the round ligament in the female perforate this fascia about half an inch above Poupart's ligament, and midway between the spine of the

ilium and the symphysis pubis; this opening is the internal abdominal ring.

The *fascia iliaca* is much stronger than the *fascia transversalis*, it is connected to the minor tip of the ilium, passes over the iliacus internus muscle, adheres to Poupart's ligament, from which it passes behind the sheath of the femoral vessels into the thigh, and is connected with the capsular ligament of the hip-joint, and the pectineal portion of the fascia lata.

When the fascia iliaca arrives at the outer aspect of the external iliac artery, it sends off a layer of fascia which passes anterior to the external iliac vessels to Poupart's ligament, and from this crosses the femoral ring to become continuous with the fascia transversalis. This layer of fascia forms the *fascia propria* of a femoral hernia. Having sent off this layer the fascia iliaca continues its course behind the external iliac vessels as far as the brim of the pelvis; it here takes the name of *pelvic fascia*. The *pelvic fascia*, from the brim of the pelvis, lines the parietes of this cavity as far as the upper origin of the levator ani muscle, where it divides into two layers: one layer (the outer) is called the obturator fascia, which descends between the obturator internus muscle and the levator ani, and is inserted into the great sciatic ligament, the tuberosity of the ischium and pubis. The ligaments of opposite sides become continuous with each other, by extending across the arch of the pelvis, formed by the rami of opposite sides, and thus form the triangular ligament of the urethra, or the deep perineal fascia. The *internal layer* of the pelvic fascia, called also *vesical fascia*, passes downwards along the minor surface of the levator ani muscle to the inferior margin of the symphysis pubis from which it is reflected on the prostate gland and neck of the bladder, forming the anterior true ligaments of the bladder, and laterally it is reflected on the sides of this viscus forming its true lateral ligaments.

THE SUPERFICIAL PERINEAL FASCIA

adheres to the rami of the ischium and pubis of either side, and extends across the perineum, being continuous anteriorly with the superficial fascia of the scrotum derived from the superficial fascia of the abdomen.

THE DEEP PERINEAL FASCIA OR TRIANGULAR LIGAMENT OF THE URETHRA,

is connected, on either side, to the rami of the ischium and pubis, its base looking towards the rectum, its apex towards the

pubic ligament, and is pierced by the membranous portion of the urethra, which passes through the ligament about three quarters of an inch below the pubes. It consists of two layers, between which are situated the artery of the bulb and Cowper's glands; one layer (*the anterior*) is expanded on the bulb and keeping that body in its situation; the other (*the posterior*) is continued along the membranous portion of the urethra to the prostate gland, forms its capsule, and becomes continuous on the bladder with the vesical layer of the fascia iliaca.

FASCIA OF UPPER EXTREMITY

Consists of tendinous fibres, which are stronger in some situations than others; it invests the entire arm, and sends partitions between the several muscles. It takes its origin superiorly from the spine of the scapula; adheres to the condyles of the humerus, and to the ridges which lead to them; passes from thence on the forearm, where it is very strong, particularly at its posterior part, and, binding down the several muscles, reaches the wrist-joint, to the annular ligaments of which it is connected.

The *Palmar fascia*, of a triangular form, is very strong, and takes its origin from the anterior annular ligament; from this it expands over the palm, and near the fingers divides into four fasciculi, each of which is forked and inserted into either side of the sheaths of the flexor tendons, and into the ligaments of the first phalanges.

THE FASCIA LATA.

The fascia takes its origin from the crest of the ilium, the spines of the sacrum, the os coccygis, Poupart's ligament, the tuberosity of the ischium, and the rami of the ischium and pubis. From this extensive connexion it extends down the thigh, confining the different muscles in their situation, and also sending partitions between them. At the posterior part of the thigh it adheres intimately to the linea aspera, and at the knee-joint to the condyles of the femur and the capsular ligament; it is then continued over the heads of the tibia and fibula, to which it adheres and forms the fascia of the leg.

Upon the anterior and upper part of the thigh, the fascia lata, from its special arrangement, has been divided into the iliac and pubic portions, and about an inch and a half below Poupart's ligament, and between the iliac and pubic portions of the fascia lata, presents the opening

for the saphena vein. This opening is semi-lunar, the concavity being directed towards Poupart's ligament; it presents an internal and external cornu, and its edge, turning inwards on itself, becomes continuous with the sheath of the femoral vessels.

The *pubic portion* of the fascia lata covers the pectineus muscle, adheres to the spine of the pubis and the linea ileo-pectinea, passes behind the sheath of the femoral vessels, and becomes continuous with the fascia ilaca.

The *iliac portion* of the fascia lata covers the sartorius, tensor vaginæ femoris, rectus and iliac muscles, and presents, towards the pubic portion, a *creascentic* or *falciform edge*, the aspect of which is directed downwards and inwards; the inferior cornu of this edge is continuous with the outer cornu of the saphenic opening and its superior cornu extends along Poupart's ligaments, crosses the femoral vessels and is inserted into the linea ileo-pectinea.

The *cribriform fascia*. The superficial fascia, in passing over Poupart's ligament to the groin, adheres to the crescentic edge of the fascia lata, and to the edge of the saphenic opening, and is attached to that layer of the fascia transversalis, which passed anterior to the sheath of the femoral vessels; this portion of the superficial fascia is perforated by numerous small blood-vessels, and by the anterior superficial absorbents of the limb, which gives it, when distended, a cribriform appearance, from which it derives its name.

The *fascia of the leg* adheres to the heads of the tibia and to the spine of the tibia, to the annular ligaments of the ankle-joint, and to the malleoli; it binds down the muscles, sends partitions between them, which pass from its posterior surface to the bones of the leg and interosseous membrane, and from the anterior annular ligament it is continued thin upon the dorsum of the foot.

The *Plantar fascia* is very strong, and arises from the under aspect of the os calcis, is attached to the sides of tarsus and metatarsus, and sends to processes between the muscles of the sole of the foot, dividing them into an internal, a middle, and an external set. At the base of the toes it divides into five portions, each of which bifurcates, and is inserted by its two fasciculi into the lateral ligaments of the joints, and into the sheaths of the flexor tendons. This fascia is strengthened by transverse fibres.

DR. ELLIOTSON

AND THE

APOTHECARIES' COMPANY.

To the Editors of the London Medical and Surgical Journal.

Gentlemen.—The letter signed "A Lover of my Profession," which appeared in one of your late numbers, is, I am very sorry to say, calculated to do serious injury to the classes of the London University College next session. The open attack of Dr. Elliotson on the Worshipful Company of Apothecaries, has tended to create already great alarm in the minds of several students, and I know one gentleman who has declined, for the present, to go up for examination at the Hall, until the sore effects of Dr. Elliotson's stinging attack have, in a degree, subsided. It is almost a pity that Dr. Elliotson did not, in the first instance, write a letter to the Court of Examiners of the Apothecaries' Company, on the manner in which they examined his pupils, before appearing so hastily in public. I, myself, have been a pupil of Dr. Elliotson's, and I have derived great and many useful hints from studying the doctor's lectures and practice. I am not, however, a Licentiate Apothecary, and as my answers to many questions, which doubtless I might be asked at my examination, would be given in the, to me correct, phraseology of Dr. Elliotson, I am as fearful to present myself as my friend, for fear of rejection.

I had hoped that the absurd letter I have alluded to, would have produced but little interest in a certain quarter, but I assure you such is not the case; for myself and others know, from unquestionable authority, that it has been quoted in a spirit of triumph against Dr. Elliotson.

I am, Sir,

Your obedient servant,

A STUDENT OF UNIVERSITY COLLEGE.

LABOUR, WITH PLACENTAL PRESENTATION, WHERE TRANSFUSION WAS TWICE PERFORMED.

Reported by Mr. JOHN JAMES JACKSON.

Hannah C—, aged 39, a delicate-looking woman, with dark hair and eyes, and of a consumptive family, applied on the 3d of December, to be attended from

the Guy's Hospital Lying-in Charity, with her ninth child. She stated, that her feelings were different to what they had been during any previous pregnancy; and that, at times, she experienced an uneasy sensation, which she referred to the womb. She likewise had a cough, which was relieved by the common linctus of the hospital. On the 18th, when getting out of bed, she was seized with a severe fit of coughing, followed up by a sudden discharge of blood from the uterus, amounting to about half a pint. When I saw her shortly afterwards, her countenance and general surface were exsanguineous; pulse 100, irritable; considerable dyspnoea, with an anxious aspect; bowels constipated. She was ordered, acid. sulph. dil. m.x.; mag. sulph. ℥i.; inf. rosæ comp. ℥xij.; to be taken immediately, and repeated every five hours. All the bed-clothes, except a sheet, were withdrawn; and she was cautioned to take no warm fluid; to retain the recumbent posture, with elevated hips, and perfect quietude. In the evening, she was greatly improved: her pulse had fallen to 82, and the hæmorrhage had entirely ceased; she complained of grinding pains, for which she was ordered opii gr. i., to be taken at bed-time. The remedies being continued for a few days, she recovered from her weakness, and could not be kept quiet any longer. On the 14th of January, at three o'clock in the morning, I was again sent for; and found she had lost nearly a pint of blood; owing, as she thought, to anxiety of mind, caused by the recent loss of several relatives, the dangerous illness of her brother, and the unkindness of her husband, who had alarmed her, by his violent behaviour, that night. I exhibited similar remedies to those used before; enjoined a strict observance of the horizontal position, her hips being raised by a firm cushion; and applied cloths dipped in cold vinegar and water to the lower part of the abdomen. This was attended with success, as far as regarded the bleeding; though the pains continued at intervals till Friday night, the 22d, when suddenly there was another discharge of blood: her spirits became depressed; her pulse quick, and small; severe pains occurring every twenty minutes, accompanied with the expulsion of clots of blood: the liquor amnii was also trickling away. Availing myself of a pain, I examined, and found a small portion of placenta projecting over the posterior edge of the os uteri, which was yielding. I now sent for Mr. Lever.

After his arrival, there was no further uterine effort, or bleeding: the pulse was 120, small, and the patient excessively low: on examination, he found the presentation, as stated—the os dilatable, and the head within reach. He ordered tinct. opii m. xxv., and enjoined quiet. During the two following days, the liquor amnii continued to escape: she was more comfortable; took her medicine; and, an anodyne being exhibited at night, she slept tolerably well. On Monday morning, although no subsequent hæmorrhage had occurred, there was sudden dyspnoea, with jactitation of the upper extremities; pulse quick, and small; no uterine effort; and every indication for a speedy emptying of the uterus. I ordered brandy, slightly diluted with water, to be administered to her, by means of a tea-spoon, every five minutes; and went for Mr. Lever, who immediately delivered her of a still-born child, by turning; Dr. Ashwell being present. After the child had been withdrawn, and the placenta removed, Mr. Oldham and myself alternately continued a steady grasping of the uterus for several hours; during which she had some mild nourishment, with brandy given to her at intervals. The hæmorrhage consequent on the turning, although slight, had been sufficient materially to aggravate her already prostrated condition. The abdomen was tightly bandaged; and she was desired to keep perfectly still, avoiding even conversation with those around her. An opiate was given in the evening, but she obtained little sleep. Early on Tuesday morning, she begged to have her linen changed, and the nurse, unfortunately, acceded to her request: soon after which, the jactitation of the limbs became more violent, and it was found impossible to prevent her throwing herself about on the bed: she spoke incoherently about her brother; and it was evident she was rapidly sinking. I gave her brandy repeatedly, and the julep ammoniæ at intervals, but without success. At 3 P.M. Mr. Tweedie performed the operation of transfusion, taking the blood from Mr. Lever; and about ℥vij. were injected into the median basilic vein. The effect of this, for a time, was surprising: her pulse, from being excessively rapid, and at times imperceptible, became full and distinct; her eyes regained their natural expression; and she spoke rationally and calmly. We now gave her tea-cup-full of rich soup, repeating it and the brandy, at intervals, every quarter of an hour. At 4 P.M. she had

again relapsed into a state of insensibility; when Dr. Ashwell repeated the transfusion, taking blood from her husband: she, as before, rallied for a time, but not to the same extent; then rapidly sunk, and expired a few minutes after five o'clock.

REMARKS.

This case is instructive, as shewing that not only after large hæmorrhages, but even where the loss has not been so considerable, there is something wanted to revive and re-establish the living principle, which the supply of blood cannot furnish; and although I am far from believing that in all the instances where the recovery has followed transfusion, the result would have been equally favourable without it, still I believe that an exhausted brain, even where sensibility remains, cannot be thus restored, where real sinking has fully set in.

PREGNANCY WITH IMPERFORATE UTERUS.

Reported by Mr. TWEEDIE.

Eliza P—, aged 23 or 24, an Irish woman, residing at 105, Little Suffolk Street, Southwark, a patient of Guy's Lying-in Charity, was taken in labour, with her first child, on the 14th or 15th of November, 1836. Mr. Roe, the gentleman to whom the case had been entrusted, was called to her at seven o'clock in the morning. He was informed that she had been in strong pain since the preceding evening, but there had been no show as yet. Mr. Roe observed the pains to be urgent and very powerful; but although he remained several hours with her, he had not succeeded in discovering the os uteri.

Puzzled with this novelty (for he had attended a great number of confinements), he requested me to visit her. It was now two o'clock: the patient was on her bed. On examination, I found a firm, uniform, globular mass forcing down into the vagina at every pain (which was of great force), but no irregularity upon its surface could be detected; and a very careful examination of the entire vagina, whose extremity was easily reached at all points, failed in detecting the os uteri. As her bowels had been confined for two days, Mr. Roe had administered a dose of castor oil: so we waited a few hours, to see what nature would do, as well as to afford the oil time to operate.

In the evening, I again met Mr. Roe, to see the patient. Labour-pains had persisted, and were of unusual severity: the castor oil had acted once. A most careful investigation of every part of the vagina failed to detect any os uteri. At the upper part of the canal, at each pain, there was forced down this tight, tense, globular body, of the bulk of the child's head; and conveying the impression of an entire uterus, without orifice.

About the spot where the os uteri should have been, was a minute portion, somewhat thinner than the surrounding parts; but the whole was uniformly smooth, and contained no break whatever.

On the receding of the mass, in the absence of the pain, something like a child's head could be felt within.

Inquiries were now made, and the following facts elicited:

Mrs. P— was married on the 4th of February preceding, 1836. Since the age of 14, she had menstruated every four weeks, sometimes every three weeks. The discharge was always pale and scanty, and continued from two to three days. She never suffered pain at those periods. She has not menstruated since her marriage.

Both before and subsequent to her marriage, she has had robust health; and, in the necessary duties of her vocation, has undergone an unusual degree of laborious exertion, but she has not had a day's ill health. For two or three days before labour came on, she noticed a rather copious reddish discharge, that continually drained from her: but there was no pain. On the subsidence of this, about the 12th, slight pains in the back were felt; which went on till the night of the 14th, when they assumed the severe and urgent character which occasioned her to summon her medical attendant at the time already stated.

Having satisfied myself, at this second examination, that there really was no orifice into the uterus, and the pains continuing of a severe character—and the existence of a living child being proved by the pulsations of the fetal heart, which were distinctly audible, about twice as fast as the mother's pulse—I sought the advice of Dr. Ashwell.

The Doctor lost little time in arriving: and having, by a most careful investigation, positively confirmed the statement of the condition of parts already made, he determined upon losing no more time in making an artificial opening across the above-named spot, where the globular

body seemed slightly thinner than elsewhere. The patient's pulse was about 120 to 130: very irritable; the pains violent; the skin irregularly hot and cold; the features anxious; the mind irritable; general restlessness: the bowels had now been twice relieved by castor oil. Accordingly, having placed her on her left side, the Doctor introduced his left forefinger as a director; upon which he passed up a curved, sharp-pointed bistoury with his right hand; and having punctured the spot already fixed upon, he incised forwards towards the bladder (which was empty), and backwards towards the rectum. At this last incision, a few drachms of dark blood flowed out. The liquor amnii of course escaped; and the head fell upon the artificial opening, which proved to be of the diameter of an inch and a half, or perhaps nearly two inches, and about a line in thickness.

The Doctor did not incise laterally, lest he should wound any of the branches of the uterine arteries. At one o'clock A.M. of the 16th, he left the patient, in charge of Mr. Roe and myself. The pains abated for a brief space after the operation, the performance of which occasioned no suffering; so that she seemed not to be conscious of any thing, beyond the inconvenience of manual interference. Pains, however, recurred; but little advance at dilatation appeared to be made for some time, till about four A.M., when, under the influence of a severe pain, the edge of the orifice tore suddenly towards the right side; and soon after, another rent took place, whilst my finger was at the part, backwards, towards the left sacro-iliac synchondrosis. At this, she became faint: the pulse was 140 or 150, feeble; the skin cold and clammy; and she fell exhausted. Æther, ammonia, brandy and opium, were administered, and she rallied. After resting for about two hours, pains recurred gradually, and became as powerful as at any previous time.

The extent of the laceration on the right side could be reached by the finger; it had not extended to the reflexion of the vagina: that on the posterior part was beyond reach. No gush of blood attended these lacerations. The head became engaged in the pelvis, and was delivered at 11 A.M.

The latter pains were very inefficient; and much stimulant was administered towards the close. With the child there was a more than usual degree of hæmorrhage: the infant (a male) was asphyxiated, and was with difficulty revived.

The placenta was taken away in half an hour, and the uterus contracted well. Nothing further could now be detected, on examination, but several ragged shreds about the orifice at the top of the vagina.

The tongue was dry, and brown at tip; the head ached; the pulse was 110, jerking, (doubtless irritable, in some degree, to the stimulants). Towards the close of the labour, the bowels had afforded three copious motions.

A day or two after the last-reported visit, the discharge assumed a reddish character, and so continued between three and four days: it commenced, continued, and ceased like the catamenial fluid, and was attended by no increase of symptoms. She is now nearly free from discharge; and though weak, is at the tub, washing.

The following is the result of a careful investigation:—The vagina is short: its extremity, and every part of it, can be readily reached by the shortest fore-finger: it presents no other peculiarity.

There is no cervix uteri. The uterus seems reduced nearly to a normal unimpregnated size. At the extremity of the vagina, there is a puckered irregular orifice, into which the tip of the finger can enter: it is soft, with smooth and thick edges, not perfectly circular, in consequence of certain indentations, as if from the drawing together of several small rents.

It might be compared to the base of an apple; whilst this part of a normal uterus would better resemble the apex of a pear.

Radiating from this central aperture, can be distinctly felt three ridges, like lines of adhesion; one passing forwards, towards the right ilio-pubic junction, traceable nearly to the reflexion of the vagina; one opposite to this, backwards, towards the left sacro-iliac synchondrosis, whose extremity is lost in the reflexion of the vagina; and the third, of short extent, about one-third of an inch long, passing backwards and to the right. These were distinctly ascertained, by both Mr. Gaselee and myself, to centre in, or radiate from, the aperture above named.

REMARKS.

This case is so singular, and is so accurately detailed, that it is scarcely necessary to make more than a single observation. I am not aware that a precisely similar instance is anywhere recorded: nor do I think that there can be any hesitation about the treatment proper to be employed. The safety of the incision consists in its prevention of unlimited and extensive laceration. So long as the

division by the knife, and the subsequent tearing of parts, is confined to the os and cervix, and does not extend beyond the reflexion of the mucous surface of the vagina over these parts, recovery is highly probable: whereas, if the parts be left to rupture of themselves, the body and fundus of the uterus, and their peritoneal investment, are pretty sure to be implicated, and the result will most probably be fatal.—*Guy's Hoep. Rep.*

ON ATROPHY OF THE HEART.

By PROFESSOR ALBERS.

Professor Albers thinks that the English, French, and German practitioners have mistaken the accidental smallness of the heart for the real atrophy of this organ, in persons dying of phthisis, diabetes, cancerous diseases, &c. &c. But in the same individuals other organs are reduced to a small size, and if in these cases we examine the heart, its thickness will be found to correspond with the cavities; its weight, colour, and consistence are generally the same as in its normal state; and as during life, the accidents depending on a change in the heart have not been observed, we are authorized to enquire if the smallness of this organ may not be considered as a morbid state.

If the hypertrophy consists in the thickness of the walls, without any marked increase of the organ, as hypertrophies are found without this increase, hypertrophy cannot exist where the thickness of the coats is normal, and when decrease of size is the only apparent phenomenon. In this view of the case, according to Laennec, Andral, Bouillaud, there will be no real atrophy; this state of the heart must be termed a normal smallness, and not atrophy, it should be rather classed as microcephaly of the microphthalmia.

Professor Albers has been so fortunate as to witness real atrophy of the heart, which has no connection with the smallness of the heart mentioned by Laennec, and which is directly contrary to hypertrophy. Real atrophy of the coats with their cavities, in a normal size, constitutes atrophy of the heart. The heart is less ponderous than usual.

Thus, the heart of a strong man, after the vessels were taken away, weighed two ounces and a half; a weight not only anormal, but having very little connection with the size and strength of the indi-

vidual. The thinness of the walls in these cases is remarkable; the wall of the left ventricle is not so thick as that of the right is naturally, and the wall of the right ventricle is equal in thickness to the auricle.

In cases where the heart weighed two ounces and a half, the walls of the left ventricle had at least one line and a half of thickness, and the right ventricle one line. In the other cases the left ventricle had immediately above the tricuspid valve two to four lines, and if we admit seven or eight lines as normal thickness of the ventricle, on this point the difference will be found very great.

In all these cases the thickness of the walls had every where decreased: they were soft, and of slight consistence; the colour of the muscular substance was sometimes dark brown, sometimes pale. The heart is rather dilated, particularly towards the right auricle, which is the consequence of the slightest resistance that the muscular atrophied mass may oppose to the blood. Atrophy may be circumscribed to the right or left of the heart. Professor Albers had met with atrophy of the right heart.

This atrophy of the heart exists without atrophy of the other organs, and without phthisis.

The following symptoms, according to Professor Albers, are the characteristics of this disease:—

In the first instance, there is difficulty in the respiration; the patients are much agitated, and cannot sleep; slight cough; respiration is difficult, and sighing frequent; the heart beats irregularly, and the patients feel a sort of shuddering at the precordial region; the hand applied to this part does not feel the heart beating. by the stethoscope they appear very weak. These phenomena return by fits, and are in these moments very manifest.

The pulse, during these fits, becomes insensible, and afterwards beats 120 and 140 pulsations. These fits last two or three days, and then diminish till there remains nothing but oppression and weakness in the beating of the heart. In the early stages of the disease, these fits occur every two or three months; they afterwards become more frequent. The chief cause of this disease is long continued sorrow.

A woman of middle age, good constitution, had given birth to eleven children, and had just been naturally delivered of a twelfth. For seventeen years she had been tormented by her husband's ill tem-

per; she led a sorrowful and unhappy life; for the last twelve years she had been troubled with constant head-ache and oppression; she felt an anormal shuddering at the precordial region, with the pulse, or pulsations of the heart being scarcely perceptible; she seemed in a state of great anxiety, and had a slight cough. During this period she was confined five times; the catamenia appeared regularly, and excepting during her attacks when she was obliged to keep her bed, she seemed in good health, and walked up stairs with perfect ease. After having consulted several medical men, without deriving any benefit, she came to Bonn to ask my advice.

When I first saw her, there seemed great oppression and anxiety; she could not sleep, was very pale, the extremities were cold, the pulsations of the heart and pulse insensible; the stethoscope only conveyed slight dumb sounds. These symptoms were somewhat allayed by repose and slight derivatives; the beatings of the heart were restored, but they were weak and almost imperceptible; the oppression remained, and the hysteria frequent. A month after the last confinement the patient caught cold, and died in a week.

On a post-mortem examination, besides lesion of the lungs, the heart was soft, separated from the large vessels; it weighed three ounces and a half. The wall of the left ventricle had three lines in the thickest part; the right ventricle rather more than a line. The right heart was slightly dilated. The heart was atrophied in all directions, and the fleshy pillars were smaller than usual.

Mr. de B—, strong and well constituted, fell from his horse, ten years since, after which he had an inflammation of the brain; he recovered, but continued in a state of melancholy. He was impressed with the idea that a great misfortune was to happen to him, which made him melancholy, and deprived him of sleep. In the latter years of his life, the beatings of the heart was so weak that they were not felt, and could scarcely be heard; the pulse was very weak.

The patient had continued in this state six years, when having been caught in the rain, he had an attack of gastric fever, which was speedily cured by evacuations. But when the fever had disappeared, a pain was felt between the tenth rib and the umbilic. There was tension in the hypocondrium; want of appetite, great thirst, constipation, fever came on, the

pulse was 120 to 140 pulsations, and the patient died in the course of five weeks.

Thirty-two hours after death, a post-mortem examination was made; there was nothing remarkable in the cavity of the skull, excepting three osseous protruberances existing in the internal side of the occipital, which depressed the dura mater and the pia mater, which were thick at their level. The heart was small, soft, and flaccid; of a deep red; separated from the large vessels; it weighed two ounces and a half. The left ventricle was two lines in thickness; the right one a line thick. The cavities were empty; the fleshy pillars were so thin, that the largest was only one quarter of a line thick.

In the abdomen the capsule of Glisson formed a pouch filled with pus, the size of the fist; the serous of the liver, the intestines, the cellular tissue, contributed to its formation. It was filled with pus, two large biliary calculi, and several small ones; beside which it contained the remains of the biliary vesicle, and the cystic canal, which was obliterated. The hepatic and choledoc conducts were free, but deviated, and red. The stomach, the duodenum, and the vena porta, were slightly adherent; the peritonitis was injected all round.

TREATMENT OF PLEURITIC EFFUSIONS.

By M. BAUDELLOCQUE.

Hospital for Sick Children.

Pleurisy does not spare children more than adults. This phlegmasia gives rise to serous sero-albuminous, purulent, and sero-purulent effusions. When the patients come to the hospital in the early stages of the disease, and there is inflammation of the pleura, intense fever, acute pain in the side, dyspnea carried to a high degree; the vein may be opened, if the age permit; if not leeches or cupping on the side the pain is felt. When notwithstanding the antiphlogistic treatment adapted to the age of the patient, and intensity of the phlegmasia, the effusion is formed, or else, if the patients are received into the hospital at this stage of the disease, the following treatment is had recourse to, and has proved most beneficial when there has been no complications of the malady. No bleeding, either local or general; no derivatives; no blisters, nor

setons, nor stibiat plasters on the affected side of the thorax.

The patient should keep his bed, wear a flannel jacket, take little food; these simple means have sufficed to induce reabsorption of effusions filling the whole of the pleura. Thoracentesis was not even thought of. This mode of treatment has now been resorted to for five years, and has proved most beneficial.

The same rules are applicable in pleuritic effusions of adults, and they afford equal benefit.

M. Lombard de Genève, ignorant of M. Baudelocque's experiments, wrote as follows on the treatment of pleuritic effusions:—

"Some time since, I judged it right to have recourse to very active treatment; cupping, blisters, mercurial frictions, and frequently repeated purgatives; but I found this active therapeutic did not generally accelerate the reabsorption of the purulent liquid; so that I am at present rather inclined merely to advise the use of hygienic means, at least in cases unattended with fever, cough, and difficulty of breathing.

"The last cases I treated without any medication, went on very favourably, and quite as speedily as when active medicines were administered. However, I give this opinion with diffidence, intending, at a future time, to make known the result of clinical experience, which can only be solved by figures."

The results obtained by M. Baudelocque, for the last four or five years, leave no doubt as to the superiority of this method. Among the most recent facts, we shall give the following;—

Pleuritic effusion on the right treated by simple hygienic means; speedy reabsorption.

Barbe Blondin, a child of nine years old, strong constitution, general health good, was received in the hospital, having been ill a month.

Cough, pain in the right side of the chest, dyspnoea, vomiting; the young patient was obliged to keep her bed for a week. During the three following weeks the pain in the side was gone, but the cough continued; the right side of the chest was developed; there was no fever in the morning, but it came on at night; the appetite was good, but the strength did not return; and the parents made up their minds to bring the child to the hospital.

The 3rd of January she was in the following state:—lying on her back, natural

countenance, pulse 90, respiration 24; heat of the skin natural, dry and frequent cough, no expectoration.

We proceed to the exploration of the thorax, and we find a morbid complication on the right side. The circumference of this side exceeds that of the opposite side by an inch and a half; the sound is *most* in the two lower thirds of the right side; the respiratory noise is slight and distant in the middle parts; there is none in the inferior ones. There is no bronchic or bronchophony, or egophonic respiration heard. On the left side there is tympanic sonorousness; the respiratory noise is clear and loud in the whole extent of the lung; the tongue is large and moist; the appetite good; stools scanty. The chest was covered with flannel, and infusion of marshmallows taken as a beverage, and broth.

On the 4th, the percussion and auscultation of the thorax furnished the same signs, and confirmed the diagnostic obtained the preceding day.

On the 10th the chest was measured, and there was little difference between the right and left side. The respiratory noise is louder, the cough is less frequent, the functions are in a fair state; broth twice a day.

The 20th of January, a diminution of nearly half an inch on the affected side; the pulse is calm, the heat of the skin natural, respiration free, urine abundant, and daily stools. A quarter of the infusion was given, and the patient allowed to walk up and down.

At the end of the month no difference existed between the two sides of the throat; the sound was nevertheless clearer on the right than on the left, probably owing to the presence of false membranes. The patient left the hospital early in February.

The result of auscultation and percussion of the thorax when the patient was first put under our care, left no doubt as to the existence of an effusion in the right pleura. These signs, as we have already had occasion to notice several times, are as striking as in the adult.

This effusion had been preceded by acute inflammation of the pleura, which had taken place a month back.

A phenomenon we had forgotten to notice, and which a few days before her admission into the hospital, had given great uneasiness to the mother, was vomiting after the evening repast; this is easily accounted for; the child's appetite was good, and effusions are towards even-

ing generally accompanied by slight fever, which interferes with the digestion. Vomiting did not take place in the hospital, because the regimen was more strict. Under the influence of this regimen, and repose, the absorption of the effusion took place, and by the assistance of percussion, auscultation, and mensuration of the chest, we were enabled to watch the disease.

ON THE TREATMENT OF ACUTE RHEUMATISM, BY STRONG DOSES OF NITRATE OF POTASSIUM.

M. Gendrin, physician at the *Hôpital de la Pitié*, has written a paper on nitrate of potassium administered in strong doses in the treatment of rheumatism. This medicament was given to five patients exclusive of every other remedy. Four of these patients were rapidly cured, and the fifth still being treated; the pain after having attacked various articulations had settled in the knees.

Nitrate of potassium was administered to all the patients in the following manner. A quart of barley water with three drachms of nitrate of potassium to be taken every day, besides a mixture of eight ounces, containing three or four drachms, of the same salt, with a few drops of nitric acid to dissolve the precipitate.

As to the regimen, it was broth one-eighth, quarter, half, three quarters. With the exception of one patient, they all become used to the medicament.

The most immediate effect of the treatment was the cessation of fever. The most remarkable secretion, the urine, which has always been considerably increased.

This treatment was adopted in the following cases.

A coachman, forty years of age, was admitted into the hospital the 31st of October. He was attacked with rheumatism for the second time. The second day he had acute pain between the shoulders, fever, and shivering; soon afterwards, a pleurodynic which disappeared the fifth day; both the knees, feet, and scapulo-humeral articulations were invaded. Nitrate of potassium was administered. The fever gave way on the fifth day, the pleurodynic on the ninth. All the other pains disappeared excepting those in the knees, which persisted to the thirty-sixth day. The other

case was more fortunate. A woman aged forty was also attacked with rheumatism the second time. She had been ill five days when she came to the hospital. The wrist, the hips, the knees, the right-foot, were successively invaded. The pain shifted from the right to the left side five days after her entrance, and all the articulations were attacked.

The influence of the treatment was only felt on the eleventh day. The fever was gone, and the other accidents gradually disappeared. The patient left, perfectly cured, after thirty days treatment. The three other patients were subjected to this medication for eight, fifteen, and twenty days.—*The Continental Rev.*

ON THE USE OF TANNATE OF LEAD IN GANGRENOUS SORES.

By DR. YOTT.

This medicament was spread on a sore of a young girl, attacked with a severe nervous fever, whose shoulders, vertebræ, sacrum, left thigh, had become the seat of gangrenous eschars, some of which were very deep. Hitherto all topical applications had failed giving relief, but the sore was healed a fortnight after the *tannate* of lead had been used. This same medicament had not succeeded when put in a liquid state on the gangrenous sores of a young girl who had a nervous fever, with ulcers on both thighs, yet proved most successful employed with salve. Used in this manner, with a little boy four years old, his gangrenous sores were healed in a week.

Tannate employed in this case was obtained by pouring acet. s. plumbi, drop by drop, on a decoction of oak, until there was no precipitate, then leaving the liquid to settle, and collecting the precipitate from the bottom of the vessel. Spread it on a bit of linen as if for a plaster. The salve used in this case is employed in the following manner:—

Dried Tannate of plumbi 2 drachms.

Salve 1 ounce.

Well mixed and applied to the sores.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

SCARLETINE.

(Scarlatina.—Morbilli confluentes.)

Scarlatina is a contagious exantheme, presenting itself in the form of small red points, soon succeeded by large irregular spots, of a raspberry tint, which by uniting generally covering large and extensive surfaces. A fever more or less ardent, and more or less intense, symptoms of irritation of the mucous membrane of the mouth and larynx precede and accompany the eruption.

It is generally speaking from the third to the sixth day after exposure to contagion that scarlatina becomes developed.

Symptoms.—With respect to the severity of the symptoms, this disease presents many varieties; it may be very slight, at other times it is more severe, and oftentimes complications of greater or less severity excite alarm for the patients life, which the most judicious treatment does not always succeed in saving.

Scarlatina in general commences towards evening and suddenly, by a febrile accession accompanied with depression, momentary shiverings, nausea, pains in the loins and in the lower extremities. The pulse averages from 120 to 140 a minute; respiration frequent and irregular. The skin on the trunk is hot, the feet cold; in some cases, but seldom, convulsions occur.

On the next day, and sometimes even during night, the eruption appears; at first occupying the neck and face, it then

spreads over the entire body in the space of twenty-four hours. It consists in a multitude of small red points, crowded so closely together, that the skin presents a general red tint, and feels rough to the touch. This membrane is at the same time the seat of an intense heat, and of very troublesome itching. Large spots of a bright raspberry red colour occupy those regions on which the body rests; the colour is likewise much deeper in the folds of the joints. Not only the skin, but the tongue also, the pharynx, the velum palati, the inner surface of the eyelids, nostrils and cheeks, are at this period of a scarlet red colour, and deglutition is at the same time painful.

Oftentimes the edges and apex of the tongue alone present this tint, whilst its surface is covered with a whitish coat of mucus, through which the papillæ point and project more or less, presenting a bright red tint.

The eruption is generally accompanied with greater or less disturbance of the system; sometimes there is delirium and drowsiness, and swelling of the face and extremities. In some cases the febrile disturbance diminishes in severity on the appearance of the exantheme; but it usually continues as also the other symptoms, as for instance, the burning thirst, general heat which is very annoying, nausea, constipation, and greater or less difficulty in swallowing.

The raspberry redness of the exantheme is always more intense at night, more especially from the third to the fourth day; it begins to diminish towards the fifth and ordinarily disappears towards the seventh, the period desquamation sets in.

The different symptoms which accompany the eruption disappear with the exantheme: deglutition becomes easy, but the redness of the tongue continues; often a copious sweat takes place at this time,

or diarrhœa; or else the urine deposits a sediment which is sometimes very copious. The furfuraceous and frequently lamellated desquamation is accompanied with a very troublesome itching; it may be prolonged for a very considerable time, sometimes for thirty or forty days, and be several times renewed. (*Scarlatina simplex*, Willan.)

Such is the course of the slightest variety of scarlatina, the duration of which is from eight to ten days. But in other cases the fever is higher, and above the angina is more severe; it is the predominance of this last symptom which has procured for this variety the name of anginous scarlatina (*Scarlatina anginosa*, Willan.)

In this last variety the angina often precedes the fever, and the precursory symptoms of the eruption are much more intense than in *Scarlatina simplex*. The patient from the very commencement complains of a strong sensation of rigidity in the muscles of the neck and lower jaw: the mucous membrane of the pharynx is intensely red. The constitutional symptoms soon become developed: from the second day the tonsils are very much swollen, the voice becomes hoarse; deglutition is very painful and difficult, sometimes even impossible: the drink is then passed by the nazes, the breathing is more or less embarrassed, and a very painful sense of constriction is felt in the throat.

The other symptoms are great frequency of the pulse, great heat of skin, headache, drowsiness, slight delirium, epistaxis, nausea, and sometimes vomiting.

In this variety the exantheme presents nearly the same appearances as in the scarlatina simplex; but it does not always show itself well the second day; often it does not appear till the third day. It is also less generally spread, and it consists of broad scarlet spots of an irregular form, scattered over different parts of the body, but more particularly over the parts on which the patient rests. In many cases the pillars of the velum palati, the amygdalæ and pharynx are covered with thick mucosities, or with flocculi of a pulraceous substance of greyish white colour, which sometimes continues adherent for several days, and is sometimes renewed in the twenty-four hours. In general no ulceration is observed on the tonsils; sometimes, however, slight ulcerations are observable on these glands, on the velum palati, or at the posterior part of the pharynx. The pulraceous exudations may be coloured black by extravasated

blood; the tongue often is dry, as also the lips, which are chopped; and the blood on drying forms black crusts which cover their surface.

In this variety the exantheme often disappears in the space of twenty-four hours, and sometimes re-appears in an irregular manner in different regions at different periods. In these cases the constitutional symptoms are seldom aggravated; but the duration of the disease is prolonged, and the desquamation less regular. This termination may not take place even when the exantheme has been very slight, whilst in other cases the desquamation still continues beyond the third and fourth week.

Besides, in this variety there is a vast number of degrees, the most prominent characters of which it is sufficient to have presented. The angina is the most obstinate symptom.

Scarlatina may again assume a still more serious form, and then it goes by the name of *Scarlatina maligna* (Willan). But the fact is, all these varieties are in reality mere degrees of severity; and the disease from being slight at first, may soon become malignant.

The *Scarlatina maligna* presents at the onset the same symptoms as the preceding; but it soon exhibits after the first or second day characters of an extremely serious nature. The eruption ordinarily appears in the twenty-four hours, but it is often slow. There is considerable sinking, burning thirst, dryness of surface and burning heat of skin; much anxiety and oppression, vomiting: fullness and frequency of the pulse. At the end of some hours the symptoms have still further increased in severity; great agitation and delirium supervene; the tongue becomes dry; the pulse loses its strength, but not its frequency; the skin is always burning, the eyes are injected and languid, the eyes are of a crimson red colour, the breath is fetid, and a blackish exudation covers the tonsils and the adjacent parts. In young children there may be coma, stertorous breathing, swelling of the neck, retroversion of the head; at the same time the pulse which is scarcely perceptible is very much hurried. Sometimes there supervene hemorrhages either nasal or intestinal, or an eruption of petechiæ, the extremities soon become cold, and the patient dies. This fatal termination often occurs without the eruption having disappeared or even become pale, and the acrid heat of the skin sometimes continues even to the last moment.

This variety may, as we have said, ter-

minate in death, which supervenes at the end of some hours, or which may not take place till the end of the second, third, or fourth day, or even at a later period. When the patient does not die in this way, very serious consequences may follow. Gastro-intestinal inflammations may supervene, and profuse suppuration succeeding ulcerations may form in different parts of the body.

Different cutaneous inflammations may complicate scarlatina. A miliary eruption frequently occupies the chest, the temples, the neck, the hairy scalp, the shoulders, and soon disappears, either by absorption, or by the effusion of the fluid contained in the vesicles. The complications of scarlatina with measles, erysipelas, and small-pox, are much more uncommon.

Plastic inflammation (angine couzenneuse) of the mouth, pharynx, and posterior nasal fossæ constitutes one of the serious and unfortunately rather common complications of scarlatina anginosa and maligna. Most of the epidemic cases of angina gangrenosa described by Fothergill, Huxham, &c., were probably nothing else. And without directly rejecting the possibility of the complication of a gangrenous angina, it is reasonable to suppose that before the works of M. Bretonneau, many cases of diphtherite were thus designated. But croup is an uncommon complication of scarlatina, neither MM. Biett nor Bretonneau have observed it.

Scarlatina when very intense is almost always accompanied with inflammation, whether of the brain, thoracic viscera, or of the gastro-intestinal mucous membranes. Oftentimes all the great viscera appear to be simultaneously affected, and nature, weighed down by the severity of the disease, soon sinks.

The partial gangrene which supervenes in certain cases, announces considerable obstruction in the circulation.

We often observe, after scarlatina, abscesses in the tonsils, bronchitis, ophthalmia, otitis with deafness, inflammation of the parotid, inflammation of the testicles in adults, and engorgements of the submaxillary and inguinal glands in children. It is sometimes followed by a state of alarming debility. But the result most to be dreaded in convalescence from this disease, is acute anasarca, and the serous effusions which may take place into the several splanchnic cavities. The anasarca may be partial or general. It becomes developed eight or ten days after the disappearance of the exantheme, particularly

when the latter has been very extensive. It is remarked that this phenomenon is more frequent and more serious in children than in adults; during winter than summer, and that the impression of cold and moist air exercised great influence on its development. The precursory signs are sadness, a state of depression and languor, loss of sleep and of appetite; the pulse becomes frequent and concentrated; the skin hot; the urine is scanty, and deposits a sediment. The œdema commences at the eye-lids, then it attacks the entire face, and it is soon observed on the lower extremities; it may seize the entire body. Its duration is from six to twelve days; it is not attended with any danger when confined to the subcutaneous cellular tissue. Diarrhœa, and some other symptoms of gastro-intestinal irritation, may complicate it. In some rare cases, rapid effusions take place into different serous cavities, and death may take place in a very short space of time.

Necropsy.—In persons who have died of scarlatina, the skin generally presents broad spots of a livid red colour, which are seated in the surface of the cutis; sometimes, on the contrary, it presents no trace of the eruption; but, as happens with all inflamed tissues, putrefaction of this membrane very soon takes place. The mouth, nasal fossæ, pharynx, and even the trachea, often present some redness, and on their surface a greyish pulpy matter, in greater or less quantity. In the majority of cases, there is found a well-marked injection in the brain, and in the vessels which transverse its surface. Sometimes the lungs are healthy, sometimes they are gorged with blood and easily torn; in some cases their tissue is very dense, as it were cornified, of a bright red colour, and not easily torn. The mucous membrane of the stomach and intestines presents, in general, a little redness, sometimes even a peculiar violet colour, but most frequently no appreciable lesion, even in cases where diarrhœa has been one of the prevailing symptoms.

Causes.—An unknown contagious principle propagates scarlatina; infants and adolescents are much more frequently attacked with it than adults; it attacks the same individual but once, and out of two thousand cases, Willan has not seen a single instance of its re-appearance. In some epidemics it seems that the specific cause may, under certain uncommon circumstances, develop the general symptoms without the eruption, or the eruption without the general symptoms.

Scarlatina is not restricted to any season in particular; it is seen to prevail epidemically in any season, but particularly in autumn, after heavy rains followed by great heat. The situation of certain places, in vallies, in the midst of woods, and in general everything which tends to interfere with the free circulation of the air, seems to predispose to the development of this disease. Lastly, it is to be noted, that persons who have had scarlatina may communicate this disease during the entire period of desquamation.

It would even appear, that it is chiefly at this time that the contagion is most active.

Diagnosis.—We shall avoid confounding scarlatina with measles, by recollecting that in the former the eruption usually appears in twenty-four hours, dating from the symptom of the invasion. The extent of the raspberry tint of this eruption, the nature of the symptoms of irritation of the mucous membranes, which, in scarlatina, chiefly affects the pharynx, will prevent any mistake.

In *roseola* there often exists a well-marked angina; but the eruption never presents broad patches like that of scarlatina; the tint is not the same; finally, in *roseola*, the duration is short, and the course often irregular.

Prognosis.—Scarlatina, when simple, is in general a disease of little danger, though more dangerous than measles. Its prognosis is more unfavourable for the two last varieties. Lastly, it is much more alarming if it attack women who are pregnant, or who have lately been delivered, or if it be complicated with other more serious diseases.

Treatment.—When the disease is slight attention to hygiene, and the simplest sort of antiphlogistic treatment is all that is necessary; moderate temperature, strict regimen, cool, mucilaginous, and acidulated drinks, either with lemon-juice or hydrochloric acid, or any other acid (for this latter does not seem to possess any specific property, as has been stated), emollient gargles, possessing slightly deversive properties, are the means to be employed. The constipation which may exist at the commencement is to be treated by simple enemata or aperients.

It is not necessary to administer emetics at the onset; the nausea and vomiting rather indicate gastric irritation than any saburral disturbance of the prima via.

To these means, which are sufficient for scarlatina simplex, it will be necessary to add others of a more active kind, in the

case of scarlatina anginosa and mangial, particularly if there exist symptoms of inflammation of one or more internal organs. In these circumstances blood-letting is by all means indicated. One or more applications of leeches to the anterior part of the neck, when the angina is severe, produce marked relief, especially in the case of swelling of the cervical and sub-maxillary glands; the same may be said of local bleeding over the epigastrium, when there exists nausea or obstinate vomiting, accompanied with pain in this region. General bleeding, ordinarily useless in scarlatina simplex, may be advantageously employed when the disease assumes a serious character in young persons, and in robust and vigorous adults; in these cases, one or more large bleedings at the commencement, may prevent or mitigate any unpleasant occurrences. In scarlatina maligna, where the course is very rapid, and, when in the space of a few hours, the symptoms have assumed a very serious character, we must have recourse at once to this means; for if once the congestion is established in the different organs, it becomes much more difficult, and often impossible, to relieve it. At a more advanced period of the disease we must not expect much benefit from blood-letting, which, if then employed, even when it appeared fully indicated, has often appeared useless, and even injurious. Lastly, blood-letting is principally applicable when there exists inflammation of one or more important organs; thus, we may apply leeches to the neck, or to the mastoid processes, when there are symptoms of cerebral congestion, and we must have recourse to it early.

In the case of *angine putacée*, it is useful to employ acidulated gargles, and what is still better, albuminous gargles; but in the plastic variety (*angine couenneuse*) we must act with vigour, and instantly modify that peculiar inflammation, by touching the diphtheric spots with hydrochloric acid, or nitrate of silver, &c. In all these cases there is no time to be lost, and there are numerous instances of the fatal termination of this alarming form of angina, which has been entirely mistaken, or discovered only when it was too late.

Laxatives and purgatives are at least useless in the scarlatina simplex, which pursues a regular course; but when there exist symptoms of cerebral or pulmonary congestion, they may be employed boldly, conjointly with bleeding.

Their use is again useful when the an-

gina is very intense. In their administration we should not attach too much importance to the redness of the tongue, recollecting that this redness, oftentimes of a bright red colour, and similar to that of the skin, is a symptom of the disease. Often again, if the signs of gastric irritation are well marked, it will be right to employ them in the form of lavement.

Emetics are indicated only when it becomes necessary to free the pharynx from the matters which obstruct it, a circumstance which principally occurs in children.

Warm baths are often very useful in the decline of the eruption, especially in cases of bad complication, or else where the eruption has disappeared spontaneously. Cold effusion, which has been employed in France, has been employed with advantage in England by distinguished practitioners. This treatment, which has, without reason, been looked on as dangerous, has been employed with success in several epidemics of scarlatina, particularly when the eruption has attained its greatest height. It generally diminishes the heat of skin, the frequency of the pulse, and all the other symptoms. It must be confessed, that, in France, these effusions are very much dreaded. In the most simple cases, it will be quite sufficient to apply a sponge, soaked in cold water, or in vinegar and water, to different parts of the body, more particularly to the forehead, face, and forearms. Some pathologists have objected to the use of this remedy, that it might favour the developement of anasarca, in consequence no doubt of their recollecting that this effect was generally produced by the impression of cold air. This reasoning does not appear to us correct; for the influence of cold in the inflammatory stage of scarlatina should not produce the same effect as in convalescence. Besides how far can we compare these two influences?

The use of sinapisms, blisters, and other irritating applications, must be restricted, in general, to those cases where it becomes necessary to establish a revulsion. The application of blisters to the fore part of the neck, in scarlatina with very intense angina, augments the irritation of the skin without removing the internal inflammation; we have occasionally seen gangrene produced by them.

The convalescence requires much hygienic care, and a frequent use of the warm bath. In case of obstinate constipation, if there were no contra-indication, gentle laxatives might be adminis-

tered. The patient should avoid exposure to cold air, and all irregularities in diet. When anasarca supervenes, it must be combated by rest, strict regimen, warm diaphoretic drinks; if there be much fever, diarrhoea, gastric symptoms, leeches should be applied round the anus or to the epigastrium. Vapour baths might also be advantageously employed in the treatment of anasarca.

As a preservative against scarlatina, after removal from all intercourse with persons affected with it, belladonna has been proposed; and it has been employed with success in several epidemics in Germany and Switzerland. M. Bielt has seen this disease prevail epidemically in a high valley of Switzerland, and keep clear, almost without any exception, of all the children to whom belladonna had been given. We should not hesitate then to have recourse to it, in whatever situation we might be, every time that scarlatina should seem to be epidemic.

The tincture is the most convenient preparation, and the form in which it seems to act with most efficacy. We give, as a common dose, six drops of it per day, to children of from eight to ten years of age; it is needless to add that the dose should be increased or diminished progressively, according to the age of the individuals. The use of it should be continued for ten or twelve days. It was clearly ascertained, that in the small number of individuals not preserved, the scarlatina was always simple, benign, and of short duration.

Lastly, there is still another preservation which seems to have been employed with advantage, namely, a combination of the golden sulphuret of antimony with calomel. The dose for children of from two to four years of age, should be from a sixth to an eighth of a grain of calomel, united to an equal quantity of the golden sulphuret of antimony, and mixed with a little sugar or magnesia; and this should be repeated three or four times a day.

LECTURES ON SURGERY

By JOHN HUNTER, F.R.S.

Of the state of the Blood in Inflammation.

It is reasonable to suppose that the blood is affected in the same manner with the constitution, and that disease has nearly the same effect on it that it has

the body, because the same living principle runs through the whole. We find this to be really the case; for till the disease has affected the constitution the blood continues the same as before; but as the constitution becomes affected the blood also becomes affected, and undergoes changes which are probably owing to contiguous sympathy between the vessels and the blood. So that we shall find that the changes in the blood are often as expressive of disease as in any other part of the body. When the action of the solids is of the inflammatory kind, or, what is perhaps the same thing, when there is too great action of the solids, the blood under such a disease more readily admits of a separation of its component parts; the red particles subside more to the bottom of the coagulum, and the coagulation of the lymph, though more slow, is firmer; the upper part of the coagulum being of an opaque white, in which state the blood is said to be *sizy*. It is not easy to say whether this change in the blood is not the first produced, and that the constitutional is not an effect of the change. I have before said that I can conceive the death of the blood to take place independently of the solids, and it appears to me that the diseased state of the blood is capable of coming on as suddenly as the corresponding state of the solids.

A man received a stab in the abdomen. I saw him a little time after the accident, when there was no degree of fever or constitutional affection, but he complained of considerable pain; I therefore took away some blood from him, which was entirely in the natural state: in about a quarter of an hour constitutional disturbances came on, and the blood appeared very *sizy*.

Whether the disposition for inflammation and the change produced in the blood arise from a real increase of animal life, or whether it is only an increase of the disposition to act with the power that the machine is already in possession of, is not easily determined; but it appears certain that is either the one or the other. However, some circumstances incline me to suspect that it is the last, because we often have inflammation when the powers are but weak, where there appears to be only an exertion of very weak powers, arising from some irritation produced. This appears to be equally the case in local inflammation and inflammatory fever, or the symptomatic fever. On the other hand, there are some reasons for thinking that it may be a real increase of

animal life, for women who are breeding and who are in perfect health, yet have *sizy* blood; and this is the case with all animals in a similar situation. Now it would appear necessary for an animal, when put into a situation where greater powers are wanted, that these powers should be increased. In breeding females there is a process going on which, though natural, is uncommon, and which requires a greater quantity of power than usual; therefore we have greater powers produced.

If these observations are just, the blood should not be inflammatory blood, but blood whose powers of life are increased.

On the other hand, where there is great debility in the solids, where the powers of preservation are less, and therefore action weak, where the body must therefore have a tendency to dissolution, we find the very reverse of the former appearance in the blood; there is no distinct separation, but the whole mass continues mixed. This effect takes place in those who die instantaneously, and I suspect that the blood dies first, and instantaneously.

When the pulse is quick and hard, and has a kind of vibratory thrill, we generally have *sizy* blood. This may arise from fever, or such inflammation, &c., as affects the constitution or the vital parts, these being diseased, so as to keep up a constitutional irritation, which will always be an attending symptom.

But when we have neither a quick nor hard pulse, but rather small, no visible fever nor inflammation, but perhaps some strange and undetermined symptom, such as pain, which is moveable, sometimes in one place and sometimes in another, yet seeming to impede no natural function, we shall nevertheless, on bleeding, find the blood *sizy*, as happened in a gentleman who had severe pain shifting about, with a small slow pulse: he was blooded, and the blood found *sizy*. After the bleeding the pulse became fuller and harder, and did so after every bleeding, which, on account of this circumstance and the continuance of the pains, was repeated several times. Something like this is observable when an oppressed pulse becomes liberated by bleeding; but what was remarkable here was its increasing in hardness. We may even have the blood contract so strongly in these cases as to cup. So that the pulse and the appearance of the blood do not always agree with one another.

The manner in which inflammation begins is generally from a point. It afterwards spreads from this in proportion to the violence and the disposition of the surrounding parts. This is the case in accidents; the accident is limited, but the inflammation arising from it is not: it is most violent in the first point and gets weaker and weaker as it spreads from this until it is lost insensibly in the surrounding parts. This extension is owing to sympathy; and hence, according to the susceptibility of sympathy will be the spreading; and from the difference of disposition to sympathy will result great differences as to the diffusion of inflammation: the more healthy the less the sympathy.

Swelling of the parts in inflammation, like the inflammation itself, is greatest in the middle, and gradually lessens from that till it is lost in the surrounding parts. It is owing to the extravasation of coagulable lymph and some serum, the serum being squeezed out as the coagulable lymph thickens, and is deposited around the inflamed part, causing œdema, which is less in proportion as the parts are healthy.

Of the colour of inflamed parts.—The colour of an inflamed part is visibly changed from the natural hue, whatever it was, to red. This red is of various hues, according to the nature of the inflammation; if healthy, of a pure scarlet red; if less healthy, the colour is rather more of a purple, and so on till it shall be of a blueish purple.

This increase of red would appear to arise from two causes; first, dilatation of the vessels, by which a greater quantity of blood is sent into those vessels which naturally admit serum or lymph (an example of which we have in the conjunctiva of the eye when inflamed); and, secondly, the formation of new vessels in the extravasated uniting coagulable lymph. From which circumstance there is a greater quantity of blood in the part than in a natural state, according to that law of the natural œconomy, that where a part has more to do than to support itself, red blood is thrown into it in larger quantities.

The true inflammatory colour is scarlet, that colour which the blood has in the arteries; hence we should suppose that the arteries were chiefly dilated, or if the veins are equally distended, that the blood undergoes no change in such an inflammation in the passage from the arteries into the veins, which last I think most probably the case.

Heat of the inflamed part.—The inflamed part is hotter than common; but this most obvious in the skin, from its being a part most disposed to carry these sensations to the brain. Heat, I imagine, is a sign of strength and power in the constitution, though it may often arise from increased action in weak constitutions or weakened parts. It is an immediate action, while cold is the reverse, and often arises from a diminished action of strong parts. It has not been considered whether an animal has this power equally in every part of his body, though from what is generally advanced on this subject, it is probable that it exists in every part. Nevertheless, I am inclined to suspect that there is a principal source of heat, though I do not think with many that this source is in the blood, but rather that this is affected by the source of the blood being near to the source of heat.

That this principle resides in the stomach is probable; at least of this I am certain, that affections of the stomach will produce either heat or cold. Eructations often give a sensation of heat, but whether this is increased heat, or only a sensation, it is difficult to say. Certain substances taken into the stomach produce a glow. Certain affections of the mind also produce a glow. This would appear to contradict my opinion, but I suspect that the stomach sympathizes with the mind.

We find that inflamed parts become hotter; but let us see how far the increase goes. From all the observations I have made, I do not find that a local inflammation can produce local heat above that which is natural to the animal; and when in parts whose natural heat is inferior to that which is at the source of the circulation, it does not rise so high. A man had the tunica vaginalis laid open for the cure of hydrocele: I introduced a thermometer into the wound, and placed in contact with the testicle, and it stood at 90°; by night it had risen to 98½°, a rise of 8½°; but this is not greater than the heat of the blood at the source of the circulation. A wound was made in the belly of a dog, and the bulb of the thermometer immediately applied to the diaphragm, which gave 101°, and did not increase above that. Another dog's rectum gave 102°, and when inflamed very much, which it was by injecting a solution of corrosive sublimate, the heat was not increased a degree. The rectum of an ass, 96°, was injected with a strong infusion of mustard and ginger several times repeated, but without increasing

the heat at all, nor did a strong solution of corrosive sublimate have this effect; at last a much stronger one was injected, which brought on a very violent inflammation, but the heat was only increased to 100°. A similar experiment was made with nearly the same result on the vagina of the same ass, and in no stage of this wound did it raise the thermometer above 100°. A wound was made in the belly of the same ass, and an injection of a strong solution of common salt thrown into the belly, which produced violent inflammation, and even symptomatic fever; yet the heat of the part was very little altered. From all which observations and experiments I do not find that a local inflammation can increase local heat above the natural heat of the animal; and when in parts where the natural heat is inferior to that at the source of the circulation, it does not rise even so high. Yet, that in some instances the heat of parts may be increased beyond its natural degree in those parts which have the greatest natural heat, is certain, from the following experiment: the bulb of the thermometer being held in the stream flowing from the abdomen of a man tapped for dropsy, raised the mercury to 104°. In most of the above experiments there seemed a difference of 1° between the heat at night and in the morning, and this difference seems to exist in the natural state of the body.

I suspect that the blood has an ultimate standard of heat in itself when in health, and that nothing can increase that heat but some universal or constitutional affection, and that the whole power of local inflammation is only to increase it a little in the part, but cannot bring it above the stated heat of the constitution, nor even to it in parts far from the source.

Of Cold.—The production of cold certainly is an operation which the more perfect animals have a power of performing

I suspect that coldness in disease arises from weakness of the whole constitution, joined with a peculiar mode of action at the time. That universal or constitutional cold arises from the stomach is evident, for whenever we are made sick universal coldness takes place. This is best proved by producing sickness in animals that we can kill while under the influence of the affection of the stomach. I threw three grains of emetic tartar into the stomach of a bitch, and repeated the experiment with a grain more: she vomited and strained very hard, and

brought off a good deal of froth, that is, mucus, from the stomach, mixed with air in coming up. I opened her body, and, contrary to what we generally observe, I found the intestines, liver, and heart not warm. I have known people who had affection of the stomach say that they had plainly a feeling of coldness in their belly. I knew a gentleman who said, whenever he threw wind off his stomach it felt cold to his hand.

Affections of the mind also produce general coldness, but such effects arise from the sympathy of the stomach with the mind, producing there such a sensation as we mean by the expression "turning the stomach with sickness;" the sensation proceeds to the shoulders, which, with the rest of the body, are put into motion by what we term shuddering.

Of pain in Inflamed Parts.—The immediate cause of sensation is an alteration in the natural position of the solids, arising either from violent action or mechanical or chemical effects, joined with its being produced in a given time; for this alteration may be produced so slowly as not to keep pace with sensation, as in many indolent tumours; or, on the other hand, this alteration in the natural position of the parts may be so quick as to exceed sensation.

Pain is not the same in all the stages of the inflammation. In the adhesive stage it is generally but inconsiderable, especially if it is to go no further, and is perhaps more a heavy than an acute pain. But when the inflammation is passing from the adhesive to the suppurative, the parts are undergoing greater change, and the pain gets more and more acute until it becomes very considerable and becomes pulsatory, being increased during the dilatation of the arteries. The nerves, too, acquire a degree of irritability which renders them much more susceptible of impression than in a natural state. When suppuration has taken place, the pain in some degree subsides; however, as ulceration begins, it in some degree keeps up the pain, and this more or less according to the quickness of the ulceration. The pain attending ulceration gives more the feeling of soreness.

Of the Subsidence of Inflammation.—Whatever disposition it is which produces inflammation, and whatever the actions are which are produced by this disposition, yet when the disposition arises either from the constitution or part, it can be removed, and of course the actions raised in consequence of it cease.

If the disposition for inflammation has taken place, and the vessels, which are the active parts, should have dilated thoroughly, they will allow the blood to enter them, so that the part shall look red; but no hardness or fullness shall be observed, and the whole will subside before adhesions have taken place: or if inflammation is gone so far as to produce swelling, which is the adhesive state of the disease, yet by certain methods it can be assuaged, and suppuration be prevented from taking place, and then the parts will fall back into their natural state, which is called resolution. And as the first symptom of inflammation is pain, the first symptom of resolution is the cessation of pain.

Why an inflammation of any kind should cease after it is once begun is very difficult to explain, or even to form an idea of, unless it is on the principle of what I call custom that the parts adapt themselves in time to their present situation; and therefore, in order to keep up inflammation, it is necessary that the cause should increase in proportion as the parts become reconciled to their present circumstances. But this will not account for their returning to their original state when this increased irritation ceases. We may suppose that the removal of the original cause is sufficient to stop the progress of inflammation; and when stopped, the parts cannot easily remain in the inflamed state, but by their own efforts begin to restore themselves to health, like a spring which is bent by a weight, but the moment the weight is removed the spring returns to its former state.

Restoration of injured parts.—All alterations in the animal frame arise from a disposition to act, and these preternatural actions, in consequence of injuries, may be caused,—1st, by a disposition to restoration, in consequence of injuries, which is the most simple; 2nd, by a disposition of necessity, as thickening of parts, ulceration, &c., which is rather more compounded; 3rd, by disease, which is the most complicated. There are a great many cases requiring the assistance of a surgeon but which cannot be strictly called disease, but are injuries done to the body. In disease there is a disposition to wrong action, which goes on until the disposition is worn out, or is put a stop to by remedies; but the actions in consequence of accident are widely different, for here, by reason of the stimulus of imperfection in the injured part, a disposition to restoration is excited, and action,

different from the former, comes on. In disease the restoration to health is produced by a prevention of the continuance of diseased action; in injuries, or alteration of structure by violence, something is required different from the ordinary and natural actions, which will differ in some respects according to the nature of the violence and of the part; and this alteration is of the most simple nature, being the action in consequence of a disposition to restoration, and consequently, if it requires any assistance from art, it is of the most simple kind. The affections from accidents may be divided into two kinds, those which take place in sound parts, and those in parts before diseased. The first I shall only treat of now. Accidents, then, may be divided into two kinds; first, those which do not communicate externally, as bruises, sprains, ruptured tendons, simple fractures, &c.; secondly, those which have also an external communication, as compound fractures, wounds, &c.; yet these may be, and often are, brought under the first head. Bruises, which have destroyed the life of a part, might be considered as forming a third head. The first class, when in a simple state, requires a most simple treatment; but they may be so complicated as to require our utmost exertion. The most simple of these is the bruise, when the continuity of parts is not broken through; here the parts have nothing to do but recover themselves. The rupture of a small vessel is next, the blood being effused into the cellular membrane; but the vessel must not be in a part of any consequence to life, or the extravasation may kill, as in the arteries of the brain. The cure in this case will be next in simplicity, the vessel being closed by the contraction of its muscular coats, and the union effected by means of coagulable lymph, and the extravasated blood being taken up by absorbents. The differences in these cases will arise from the magnitude of the injury and the nature of the injured parts. Some accidents of the first class, as fractures, will require the aid of a surgeon to restore the parts to their natural situation, and then nature falls to work and completes the business. Sometimes the quantity of blood extravasated is so large as to prevent nature from going through these processes directly, and forms a tumour called an ecchymosis. Ecchymosis may be said to be of two kinds; one is where the blood coagulates; the other is where it does not. That which coagulates commonly subsides gradually

from the blood being absorbed, and gives but little trouble, which is likewise the case sometimes with those in which the blood does not coagulate, though not generally. I have seen where a small wound has led to the cavity containing the coagulium, which not being meddled with, the sides of the cavity have gradually contracted, and have as gradually squeezed out the coagulium.

A woman fell with the labium pudendi on the edge of a pail. I found a very considerable tumour, which I thought was of blood; there was evidently a fluctuation. I bled her, and ordered a poultice, but did not open it, as I thought the presence of the extravasated blood might serve to stop the orifice of the vessel. In a little time the tumour burst, with a small opening, and on examining with a probe I found the coagulium filling a space the size of a goose's egg. The cavity grew less and less, but always kept exactly filled with coagulated blood; and thus it continued diminishing until the orifice healed. Thus the blood being allowed to remain in the cavity, and not acting there as an extraneous body, nor even allowing the stimulus of an imperfect cavity or inflamed surface to contract all round the blood until had disappeared. Now, what would have been the consequence if I had followed the old method of laying open the tumour, scooping out the blood and dressing the internal surface with turpentine? I should have had a sore of the whole extent of the tumour, and given considerably more trouble both to the patient and to myself.

The second species of ecchymosis or that where the blood does not coagulate, does not always terminate so well as the former. It has often the appearance of an encysted tumour, but from being the immediate consequence of some accident to the part its nature is understood. The cause of this blood not coagulating must arise, I conceive, from some peculiar mode of action of the vessels arising from the injury, for I apprehend that in such cases the blood dies as it is extravasated, or in the act of extravasation, like the menses. This species of ecchymosis happens very commonly to children in birth under the scalp. In such cases nothing should be done but to wait with patience, and the whole will be absorbed. In many cases the accident has been so violent as to deaden the cellular membrane under the skin, or as to produce inflammation in the surrounding parts; these sometimes resolve, but they are seldom allowed

to do so, for surgeons are led to open them early, from seeing the inflammation and feeling fluctuation, two strong enticements to use the lancet when all circumstances are not well attended to. But in such cases I should wait until I saw the signs of suppuration, viz., thinning of the skin over the matter and pointing of the contents, which are the only true marks of the formation of matter and of its approaching the skin.

Sometimes ecchymosis are removed by pressure, which without this would remain. Parts cannot bear pressure, so that the extravasated blood being pressed against the sides of the cavity, the absorbent vessels are under the necessity of absorbing it.

When ecchymoses are not absorbed, but suppurate, abscesses are formed, which must be treated as abscesses in common, only waiting with a little more patience than when wholly the consequence of inflammation. In many of those cases of accident not only the skin shall be deadened, in consequence of which it will slough and leave a sore, but often the skin shall preserve its living powers, and only the cellular membrane underneath shall be deadened and slough, and produce an abscess, which was not at first expected. In cases where the skin in one part is killed by a blow, and the cellular membrane in another part, while the skin over it remains sound, the deadened skin will come off, granulate, and heal kindly; but then inflammation shall take place, perhaps, an inch or two from it, where the cellular membrane was deadened, and an abscess shall be produced.

If these injuries are not very great, little effect will be produced on the sensitive principle, no sympathy or irritation taking place; but sometimes the accident will, by its irritation, produce another action of the parts, causing inflammation, the end of which is either adhesion of the divided parts, or suppuration for getting rid of the substances become extraneous. The most simple accident may be attended with such circumstances as will prevent the most simple process of nature from taking place; such, for instance, as the magnitude of the vessel ruptured, or a fractured rib wounding the lungs, &c.

The second division I made, was where wounds communicate externally.—These are subject to greater variety than the former, yet often admit of the same mode of cure. A wound may be either simple or compound. The simple, which

is what I mean to speak of now, is a solution of continuity in part, which must be made with a cutting instrument. In such cases a number of vessels are always divided, blood is effused, and the cells of the cellular membrane exposed, as well as other internal parts. The former class required only rest, but in these there is a necessity for replacing the divided parts. The present class admit of both a natural and an artificial cure. By the natural is meant union by the first intention; when this cannot be obtained, a new bond of union takes place—adhesive inflammation; and if this is lost, a third mode—granulation. In that by art we have to imitate the natural, we are to bring the divided surfaces into contact; the living extravasated blood, being then retained and coagulating, unites them; the mouths of the vessels shut, and the remaining blood is absorbed: the red globules are indeed absorbed, and only the coagulable lymph remaining becomes the bond of union. This is an imitation of nature; but surfaces cannot always be brought to unite in this manner, and the blood in some parts loses its living principle, and then it becomes a source of irritation, exciting inflammation, which is the case sometimes in simple fractures, and which I shall call, for distinction's sake, simple compound fractures.

The best time of replacing the divided parts is perhaps during the time that the extravasation continues, but it may also be done when the discharge of coagulable lymph in the adhesive or first stage of inflammation takes place. Sometimes the inflammation runs so high as to get into the suppurative stage; the extravasated fluids may lose their living principle, and become a stimulus exciting inflammation.

By adhesive inflammation different parts of the body may be united to another by coming into contact; but the most extraordinary union is that of removing parts from one body and uniting them to another. Here is the testicle of a cock, separated from that animal, and put, through a wound made for that purpose, into the belly of a hen; which mode of turning hens into cocks is much such an improvement, for its utility, as that of Dean Swift when he proposed to obtain a breed of sheep without wool. The hen was afterwards killed, and the testicle was found adhering to the intestines, as may be seen in this preparation, where the parts are preserved. Here is another preparation, in which the spur of a cock has been inserted into the comb of another;

and here a human tooth, inserted into the same part, and united by means of vessels, which you see injected, from one to the other. These living bodies thus applied to each other produce adhesive, not suppurative inflammation. In the same manner, the eggs of one animal laid in the flesh of another do not excite suppurative inflammation. This would not be the case if the inserted body did not contain the principle of life, for the part would run into suppurative inflammation, as would be the case with a pea so introduced. While the guinea-worm is endowed with the living principle it gives but little trouble; yet if killed, it gives the stimulus of an extraneous body, which produces suppuration through its whole length.

In this preparation you see a maggot deposited, just below the skin, on the back of a reindeer: here the first stage of inflammation took place only; coagulable lymph was poured out, which has formed a chamber in which the insect resided. A similar power is observable in vegetables. Here is an oak-leaf, which I picked up in my garden; you observe on it seven or eight protuberances, exactly circular and uniform. These have been formed by the insertion of the eggs of an insect into the leaf; and I cannot but think the process would have been different if any substance not possessed of the vital principle had been inserted. It is on this principle of union by the first intention, that the union of parts by suture has been recommended, which has been found the best practice where it can be done. The dry suture in superficial wounds answers very well, the quilled is sometimes useful, and the interrupted is very often useful. The two last are properly called sutures. In many cases it is improper to keep the surfaces together, as when the wound has been attended with considerable contusion, which generally occasions sloughing of the parts. When much blood is extravasated, suppuration becomes necessary, in consequence of the blood acting like any other extraneous body; but when laceration only is present, union by the first intention may take place, especially when on the head, and over other superficial bones, as Mr. Cline has observed. The machine is not at all disturbed by this most simple operation; there being perhaps even no local action except the contraction of the vessels, the union being performed by the blood only.

DESCRIPTION
OF A
REMARKABLE SPECIMEN
OF
URINARY CALCULUS:

TO WHICH ARE ADDED,

*Some Remarks on the Structure and Form
of Urinary Calculi.*

BY DR. HODGKIN.

The specimens of calculus which I am about to describe, were taken, after death, from the much thickened bladder, of a boy about two years of age: they were nearly of equal size. The larger was about as big as a pigeon's egg, and nearly of the same shape; but rather longer, and not quite so broad: they were of a whitish colour, like many calculi composed of the phosphates.

Instead of presenting the hardness and resistance of solid bodies composed of earthy matter, they possess, on the surface at least, a degree of softness and elasticity, as if covered with a fleshy layer; a circumstance which explains the uncertainty of the evidence of calculus existing in the bladder, when the little patient was sounded, on suspicion of that being the case. Besides this peculiarity in the texture of the exterior layer of these calculi, the material, of which the surface was composed, exhibited a slight degree of translucence, not unlike that of some blighted acephalocyst membranes. These unusual characters induced, at first, some doubt respecting the nature of these bodies. A section made through one of them showed that they, in part, consisted of an opaque white substance, having an earthy texture, arranged in concentric but fragile layers. Two or three thin layers, consisting of a material precisely similar to that of which the external coating of the calculi was composed, were situated between the layers possessing the earthy character. Although the earthy layers were so brittle as to be crushed by the act of making the section, the fragments were so completely retained in their relative situations by the tenacity of the membranous layers, that the two portions into which the calculus was divided were able to retain their form and cohesion. The resemblance which the membranous layers bore to the membranes of acephalocyst hydatids was such as to induce an idea, in the minds of some who examined them, that such hydatids

had really been concerned in the production of these calculi. I am, however, disposed to adopt a different explanation: 1st Because it is inconsistent with the nature of acephalocysts, either to exist in the bladder, except when accidentally admitted into it through a preternatural opening from some other situation, or to be formed as an investment to any foreign body; and, 2dly. Because, if I am not mistaken, a more plausible explanation may be offered. Preparation No. 878, in the Museum of Guy's Hospital, is a specimen of fibrin, passed with the urine from the bladder of a lad who was in the habit of passing what appeared, when recent, a milky fluid, very slightly tinged with blood, giving it very much the appearance of some specimens of chyle. It also resembled chyle in spontaneously coagulating, like blood; and forming a mass of crassamentum, moulded to the form of the vessel in which it stood. The preparation in the Museum is a specimen of one of these coagula. I am inclined to believe that the little patient who produced the specimen of calculi which I have described, must, at times, in consequence of the derangement of his kidneys or bladder, have produced urine having somewhat of the character which had become constant in the lad who furnished the specimen No. 878; and that a nucleus existing in the bladder at the time became invested with coagulated fibrin, as a stick does when agitated in recently drawn blood;—that when the character of the urine again changed, the disposition of the phosphates took place, and inclosed the fibrinous layer. The repetition of these occurrences appears sufficiently to account for the production of these calculi, and to be strictly analogous to the process by which other alternating calculi are formed. The sight of this section immediately suggested an explanation of the production of a peculiar appearance which I had noticed in one of the sections of calculi preserved in our collection, and which had hitherto seemed not very easy to account for.

The calculus in question was composed of concentric layers of very different degrees of density; some being firm and compact, and others so loose and friable as to afford a very feeble support to the denser layers. The peculiarity to which I refer, consisted in one of these layers having been broken into fragments, which, though very much disturbed as respects their relative position, still surrou-

by other unbroken layers, concurred to form one solid calculus. The interruptions and irregularities in the broken layer, produce an appearance resembling, on a small scale, the interruptions sometimes seen in the sections of a stratified country. The difficulty had been, to account for the rupture of the compact layer having taken place, without the fragments having become detached and separated from each other in the bladder: whereas it is evident that they must have remained, not only in approximation to each other, but have admitted of little or no motion amongst themselves; seeing that the layers of soft phosphates have been deposited upon them without disturbance. This difficulty seems to be satisfactorily solved, if we admit the idea, that the firm layer was inclosed in a membranous layer, similar to those in the calculi before described, at the time when the force which ruptured it was applied. This closely investing layer of a flexible material, by retaining its cohesion whilst that of the layer within it was destroyed, would necessarily retain the fragments in juxta position, although they had been somewhat displaced. The disappearance of other proofs of the existence of such a layer does not present any insuperable difficulty, since we might conclude, *a priori*, that such a layer, composed of water with a little animal matter, unsupported by organization, would soon be decomposed, and that its place would be partially occupied by depositions from the urine which the loose texture of the calculus would allow it to imbibe.

The inspection of a large number of urinary calculi has at different times suggested to me some ideas respecting their varieties of form and structure; which it may not be amiss for me here to offer, in addition to those contained in the preceding remarks.

It is evident, in many instances, that the particles separated or precipitated from the urine to form calculi assume a crystalline character; and the mode in which this crystallization takes place around a small nucleus materially influences the structural character, and the form of the calculus. The structure is radiated, and the form more or less rounded. Even the evident marks of increase of superposition by layers does not destroy this radiating character; and the surface is often roughened by manifest crystallization.

Such specimens of calculi bear considerable analogy to certain zeolites, and

to some specimens of radiated quartz. The cystic oxide affords one of the best specimens of decidedly crystalline calculi. The state of purity in which this substance generally exists is; perhaps, one of the circumstances the most favourable to the production of a distinct crystalline character. Some of the phosphates appear to come next to the cystic oxide, in presenting this character. Calculi, consisting of oxalate of lime, frequently present evident traces of crystallization, but, for the most part, under certain modifications, which render it necessary for me to speak of them separately.

In many instances, the molecules which unite in the composition of urinary calculi do not possess a perceptible crystalline form; and the resulting substance is what mineralogists would call massive, with no other indication of structural arrangement than more or less distinct traces of superposition in concentric layers. Calculi of this class present a great variety in their mechanical structure, as well as in their chemical composition. In some, there appears to be a slow and uniform deposition, like that of the well-known incrustations of carbonate of lime formed in the baths of San Fillippo, near Radicofani. Such calculi possess a firmness of texture, which admits of a very fair polish. In other cases, the precipitated particles are so loosely coherent, that the substance of which they are formed seldom admits of section without crumbling to pieces. There is considerable variety in calculi of this description; some possessing a granular texture, which might be compared to a coarse sort of sandstone; whilst in others it is soft and earthy, like some of the softest specimens of chalk or tufa. The lamellar arrangement is very differently perceptible in different specimens of this kind of calculus: in some it is strongly marked, and the calculi, which are easily crushed, separate in shell-like flakes; whilst others, in which the arrangement is less conspicuous, break up almost indifferently in all directions.

As forming an intermediate link between calculi possessing a distinct crystalline character, and those in which the texture may rather be regarded as amorphous or massive. I mention those calculi which present a mammillated surface, and which, on close inspection of a section or fracture, appear to have their several lamellæ made up of short fibres, at right angles to the plain of the lamellæ. These are often an assemblage of acicular

crystals: indeed, the crystalline form is sometimes evident upon the surface. This form of calculus is most frequent and remarkable in those specimens which are composed wholly or chiefly of oxalate of lime; and the name of mulberry calculus is doubtless derived from the resemblance to the surface of a mulberry, which the assemblage of round elevations or mammillæ produces; whilst the dark colour common to these calculi tends to render the similarity more striking. This arrangement is not, however, peculiar to calculi composed of oxalate of lime. It may be seen though less frequently and less remarkably, in calculi wholly or principally composed of lithic acid. This modification of crystalline arrangement is exhibited in various minerals: it is not very uncommon in hæmatites and other oxides of iron, in black oxides of manganese, and in magnesian limestone. The mammillated elevations are sometimes elongated in a very considerable and remarkable manner; and although they all seem to radiate from a common centre, they differ most essentially from acicular crystals, which are also frequently seen shooting from a common centre. The elongated mammillæ do not take so straight a course; and instead of terminating by regular angular facets, they are blunt and rounded, and often present smaller mammillated elevations upon their surface. The only calculi, I believe, which present this extension of the mammillated form are those composed of oxalate of lime: in which it sometimes proceeds so far, as to produce a perfectly stellate figure. The most remarkable and beautiful specimen of this kind which I have seen, was shown me by my friend Professor Mussey, of New Hanover, in the United States: who has, I believe, published a description of it, accompanied with a figure. The radii in this specimen must have been at least half an inch in length, and not more than the tenth or twelfth of an inch in diameter: they were united by a very small central nucleus. The whole constituted a star of such delicate form, that it was truly surprising that it should have remained unbroken in the bladder.

The shape of some calculi is evidently influenced by that of the body which constituted the nucleus upon which the material composing the calculus is deposited. We may see this in the incrustation which, in the course of a few days, envelopes the catheter left in the bladder. A needle had found its way into the blad-

der, and become the nucleus of a long and slender calculus. Sir A. Cooper used, in his lectures, to mention a similar example, in which the nucleus was a silver tooth-pick, which had been introduced into the bladder.

The intestinal calculi occasionally found in horses and other inferior animals sometimes exhibit the influence of the nucleus, in modifying the form of a concretion. In the Museum of Comparative Anatomy, there is a specimen of this kind, presented by Luke Howard. It has the form of a very oblate spheroid, evidently dependent on the nucleus, which, in this instance, was the metallic disc of a button.

Urinary calculi not unfrequently owe their form to that of the cavity in which they are lodged. The most striking examples of this are seen in nephritic calculi, which, in some specimens, are completely moulded to the form of the pelvis and infundibula. A similar influence is occasionally exhibited in biliary calculi; sometimes a single one, and sometimes two, completely filling the gall-bladder, and assuming its form, and even extending, to a short distance, into the ductus cysticus.—See Specimens in the Museum, No. 1978, and 1987.

Although the form of urinary calculi is modified by the nucleus upon which the calculous matter is deposited, and partly by the form of the cavity in which they are lodged, these are not the only causes by which their figure is affected. The greater thickness of the deposited layers, at a particular part of the calculus, frequently alters the form, by occasioning a more rapid increase of size in one direction than in another. The thickest and most rapid deposit appears to take place at that part of the calculus which is exposed to the largest bulk of the urine. It is consequently, towards the fundus of the bladder that the calculus receives its deepest, but, at the same time, its most fragile layers. This fact is most remarkably seen in sections of calculi composed of the crystallized phosphates. This unequal increase of calculi in different directions, is a complete proof that they do not change their position in the bladder nearly so much as might have been expected. Even calculi of small size sometimes exhibit this unequal disposition in a very remarkable manner. It is occasionally seen in lithic acid calculi; although, in general, calculi of this description are composed of very uniform layers. The fact, that the loose, soft, and white calculi, composed principally of

the phosphates, most frequently possess this inequality, tends to confirm a remark, already made by Dr. Marcet and Baron Heurteiou, that these phosphatic calculi depend as much on the diseased secretion of the bladder itself as on any peculiarity in the urine, as transmitted from the kidneys.* The compressed and flattened form of many calculi cannot, in my opinion, be very satisfactorily accounted for. Baron Heurteiou ascribes it, in some instances, to the original nucleus; but in the lithic-acid calculi, which principally assume this form, the nucleus is generally so small, that the addition of numerous layers of uniform thickness would necessarily tend to produce a sphere. We are therefore obliged to admit, that these flat calculi must maintain, if they do not originally receive, their form by more copious deposition at their circumference. Something may, perhaps, be ascribed to the circumference being always ready to receive accessions of deposit, whilst of the flat sides one only is exposed at a time.

It might not unreasonably have been supposed that the urine descending from the kidneys would deposit its salts upon that part of the calculus which corresponds with the orifices of the ureters; just as incrustations of carbonate of lime accumulate where water charged with that salt is constantly poured out; or, to offer a still closer analogy, as the molar teeth become encrusted with tartar opposite to the duct of the parotid gland. Were such a deposit to take place, it is probable the misery of patients labouring under vesical calculus would be greatly increased; since processes from the calculus would be formed, which would not merely irritate a very sensible

part of the bladder, the neighbourhood of its neck, but the passage of the urine from the kidneys to the bladder, might, in some instances, be seriously interfered with. When we see that the urine, as it is secreted in the kidney, is liable to deposit calculeous matter of different kinds, before it has been concentrated by retention in the bladder, as is shown by the formation of renal calculi, this exemption is the more remarkable, and the cause of it not very evident.

When two or more urinary calculi exist in the bladder—and the remark will apply to a plurality of calculi in other cavities also—their form is modified by their mutual contact, and their opposed surfaces sometimes appear worn by attrition. The surface thus produced is not always flat: the one may be convex, the other concave, so as to represent a part of a ball-and-socket joint. If we make a section through such calculi, we may observe that the appearance of attrition is, in some degree, fallacious; for we may clearly perceive, that even on the opposed surfaces, deposition has been proceeding, and that the number of layers has been increasing on that part of the calculus, but that they have been thin and compact compared with those situated on other parts of the calculus. When a considerable number of calculi exist in the bladder, they are sometimes rounded by mutual contact, like the pebbles on a beach: in other cases, they assume a cubical or polyhedral figure, but more frequently the former. This disposition is strikingly seen in a collection of a hundred and forty-two calculi, removed, at one operation, from the urinary bladder by Sir A. Cooper. This, however, is not the only mode in which a cubical figure may be given to urinary calculi. It sometimes happens, that the elongated processes which I have described as projecting from the surface of the calculi, wholly or principally composed of oxalate of lime, are not of equal length on all parts of the calculus. Hence, instead of giving to the general outline of the calculus a spherical figure, they produce one which is angular: and, if I may judge from two specimens in Guy's collection, the figure is apt to approach very nearly to the cube. This is strikingly remarkable in the specimen No. 2138, which has a very regular cubical figure of about two inches in diameter. The section clearly shews that this calculus was originally spherical; and that it assumed its present form by the disproportionate increase at eight op-

* The production of pseudo-membranous layers, and of earthy salts, by the mucous membrane of the bladder, when in a state of disease, in the human subject, appears to be not altogether without analogy to the normal and abnormal productions of a part of the urino-genital mucous membrane in birds and reptiles: the normal productions being the shell and some of the humours of the ovum. The abnormal are eggs without yolks; and masses composed of concentric layers, of a more or less membranous character. The texture and thickness of these layers is by no means uniform. (See Preparations in Museum of Comparative Anatomy.)

posite points, corresponding to the angles of the cube—the intervening parts of the surface having received such additions as to produce six sides; which though presenting the ordinary inequalities of mulberry calculi, obviously tend to produce a flat surface.

Some calculi, which towards their circumference are evidently composed of nearly parallel layers, and therefore seem to have been formed by superposition upon a nucleus, are, nevertheless, found to be hollow at the centre. One of this description has, externally, rather an irregular figure and surface; but the asperities are rounded off; there is an appearance of minute crystallization on some parts of the surface. The section of this calculus is of a pale, yellowish brown colour; the texture is, generally, close and compact. Towards the circumference the parallel layers are very evident. The centre of the calculus is hollow; and the cavity it presents has a very irregular surface, suggesting the idea of a soft mass having being dried, leaving the residuum fissured. The parallel layers, towards the internal surface, are interrupted, as if broken by this process after their deposition. I imagine such calculi must have been formed upon a nucleus almost entirely composed of coagulated blood or fibrin, which becomes but imperfectly penetrated with the urinary salts which compose a calculus; and that, although absolute desiccation does not take place, they nevertheless have their solid particles brought together in close approximation and cohesion. Fissures are thus produced, as in the drying of starch; whilst the external portion of the calculus, being originally deposited in a firm compact form, and consisting chiefly of calcareous matter, remains unchanged. Such calculi may therefore be compared to the masses of Lias found in the London blue clay, which are of a *nodulous* figure, and of a uniform texture externally; whilst internally they present numerous irregular crystalline veins; which veins are evidently produced by the filling up of internal fissures, produced in the manner above described; namely, the aggregation and cohesion of the solid particles of a once soft mass. They bear, however, a still closer resemblance, in size and figure at least, to some small nodules of carbonate of lime which were found imbedded in a seam of clay, and which were hollow internally.

When a stone in the bladder has acquired a very large size, so that for a

length of time it must have filled the organ, and rendered it impossible for the urine to collect to any notable quantity, it generally happens that the calculus loses the pyriform shape which the model of the distended bladder naturally presents, and assumes a figure which may be compared to that of an hour-glass; except that the contraction does not take place in the middle, so as to divide the calculus into equal portions; the depression is likewise comparatively slight, and its direction, instead of being vertical to the action of the calculus, is considerably oblique. The degree of obliquity is nearly the same in all the specimens in which I have observed this peculiarity. Such uniformity evidently points to some cause inherent in the bladder itself; but I confess that I have not been able satisfactorily to account for it. I am not aware of any partial superiority in the contractile fibrous coat of the bladder, in the situation and direction required to produce such a depression. I have thought it possible that the ureters might, in some way or other, be connected with it; either directly, by their action on the bladder, or indirectly, by the stream of fluid which they are pouring into it. As I have never examined a bladder containing such a calculus, I am without facts, either for the confirmation or refutation of this idea. —*Guy's Hospital Reports.*

CASES AND OBSERVATIONS

ILLUSTRATIVE OF

DIAGNOSIS

WHERE

TUMOURS ARE SITUATED AT THE BASIS

OF

THE BRAIN;

OR WHERE

Other parts of the Brain and Spinal Cord suffer Lesion from Disease.

By DR. BRIGHT,

—
In a former number we inserted the commencement of this able paper and now resume it.

Nightingale Wells, aged 43, was admitted, under my care into Guy's Hospital, October, 22, 1834.

It appeared, that in the year 1817, being then in the army, he received a wound from the bursting of a gun, by

which his cheek-bone was much injured, and from that time the sense hearing became very defective in the left ear; but no other ill consequences were suspected till about eighteen months ago, when an offensive discharge took place from the left ear, which, after continuing for eight months, suddenly stopped about Christmas last. This was quickly followed by a pain across the forehead, and a sense of weight towards the back of the head. About four months ago, the vision of the left eye became imperfect; and in another month the right eye was likewise affected.

At the time of his admission, the vision of both eyes had, for the last month, been so defective, that he was unable to find his way into the street. During the last six weeks, he had been attacked, three or four times almost every day, with a convulsive agitation, chiefly affecting the left side; and he stated that his memory had become very imperfect respecting recent circumstances, but was more retentive of those of earlier date. His pulse was variable in strength and frequency, generally about 96. He remained under my care nearly three months, during which time a seton was kept open in his neck: his bowels were freely acted upon by various purgatives; a grain of calomel was, for some time, given three times a day: leeches were several times applied to the temples, and behind the ears: the head was shaved, and a cold embrocation applied. Tartrate of antimony was rubbed into the scalp. All, however, proved, as has been fully anticipated, of little or no avail. The chief variations which took place, during the time he remained, were the occasional recurrence of very severe headaches. He once or twice fell to the ground, in fits of giddiness; and was often unable to move, from what he called the heaviness of the head. He had occasional difficulty in passing his urine; and his bowels were costive. On the 13th of January, he left the Hospital, being at that time totally blind; and never afterwards could distinguish light from darkness. He was quite deaf in the left ear, and the hearing of the right was at times much affected. He had then the perfect use of his limbs; and was in the habit of being led out for walks to a considerable distance. I was informed by Mr. Thomas Griffith, who, with Mr. Dewsnap, saw him occasionally, and was kind enough to obtain for me what information he could, that this state continued till about the middle of the summer of the same year (1836), when he was suddenly

attacked one day while walking in the garden, and fell insensible. "When he recovered," says Mr. Griffith, "he was hemiplegic on the right side, and the mouth was drawn to the left. On the side affected, there was total loss of sensation. He recovered, in some degree, sensation, and the power of motion in the arm and leg; but the effort to use either was always accompanied with violent shaking. He could not stand without support. He at all times had the power of retaining and voiding his feces and urine: the bowels were very torpid, requiring the daily use of full doses of aperient medicine to procure relief. He was subject to convulsive attacks; which came on sometimes three times, sometimes only once a day, and sometimes with an intermission of a day or two. His mind was at times childish, but his reason was not gone: his sense of taste was entirely destroyed: his hearing varied, being sometimes very good, at others imperfect. Though I had not seen him for many months, he immediately recognized me by my voice. This was about two months before his death: he then articulated with much difficulty: he uttered his words suddenly, and after a prolonged effort. His tongue was drawn forcibly to the roof of his mouth; and in the effort to speak, there was apparently great difficulty to depress the lower jaw: he frequently, however, gaped, and yawned to the full extent. It appeared that the muscles of the right side of the jaw had in a degree regained their power; for, the distortion, when I saw him, was in no great degree; sensation, however, was entirely lost on this side of the face. He was a man of irritable temper, and passionate; but I did not observe that he was lately more so than usual." For a considerable time before his death, his arms were so paralyzed, that he could not feed himself; and for the last ten weeks, he could not leave his bed on account of the paralyzed state of his legs.

He died at his residence at Hammer-smith, on the 23th of October 1836; and on the 25th Mr. Griffith conducted the examination of the body, in the presence of Mr. Dewsnap, Mr. Bowling, and myself; when the following appearances were observed.

SECTO CADAVERIS.—Raising the calvaria, the dura mater appeared tense, but not remarkably vascular. Two or three large glandulæ Pacchioni stood out on its surface, by the side of the longitudinal sinus, like little fungoid excrescences.

When the dura mater was removed, the convolutions appeared flattened, from the effusion of fluid in the ventricles. The arachnoid was not very vascular, and there was no serous effusion.

On cutting into the substance of the brain, there were decided marks of congestion internally, and very distinct mottling. The corpus callosum was a little raised. The ventricles were distended to three times their natural size, by limpid fluid: the parietes and septum lucidum were firm: the foramen of Monro was large and open: one long vessel ran meandering along the under edge of the plexus choroides: the plexus itself was exsanguine.

The optic nerves were remarkably small, hard, and of a yellow colour, very different from the pure white by which they are usually distinguished. Their section was oval and compressed. The infundibulum was rather thicker, and of firmer consistence than natural.

Beneath the tentorium, a tumor, as large as a chestnut, was found on the left side, apparently attached by a peduncle to the petrous portion of the temporal bone, pushing aside the tuber annulare and the left hemisphere of the cerebellum, compressing the medulla oblongata, and pushing the fifth nerve upwards. This was found to be a firm dark tumor, the section of which was mottled with grumous blood; and it altogether bore the appearance of a fungoid growth, arising from the cancellated structure of the bone, but closely attached to the anterior portion of the cerebellum. The cancelli of the bone were soft, containing a puriform fluid. The tympanum was quite gone; and the ear contained some purulent matter.

The other viscera, both of the abdomen and chest, were natural; except, that in the lower part of the thorax, on the left side, an empyema of some standing was discovered, with a thick layer of lymph covering the pleura, and circumscribing the disease.

The two cases which I have now detailed afford as many points of similarity as are often found, or indeed as we can well expect to meet with, when we consider the varying combinations which the human frame constantly presents.

In both cases, we have individuals, little past the prime of life, dying in consequence of tumours similarly situated within the skull; and, as they are both in

other respects healthy, their symptoms had suffered no important complications from the co-existence of other diseases. In both, we have reason to connect the aggravation, and probably the existence of the disease with the exposures and accidents of military service. In both, the disease has been marked by its gradual progress; has first shown itself by affections of the senses; and then slowly produced paralysis of motion or sensation in various parts, affecting the intellect little, until an advanced period of the disease, and probably not before it had led to extensive serous effusion into the ventricles.

The symptoms may be more specifically stated; as, an almost total loss of sight, total loss of hearing in one ear, and to a great extent in both, gradual paralysis of the extremities, slight and temporary affection of the sphincters, great diminution in the sense of taste, and a protracted death from sensorial oppression.

In these two cases, the left ear lost its sensibility not much less than twenty years before death; in the one, from the concussion of a cannon; in the other, after a severe wound in the face, and, doubtless, concussion of the temporal bone. What predisposing influence was exercised by the violence inflicted at the time, in either case, it is impossible to say; but the circumstance should not be lost sight of, in the record of facts.

In both cases, the vision was impaired and destroyed, even before the hearing of the right ear; and it is not easy to account for this affection of the sight. I am sorry that I cannot find any observation after death on the condition of the optic nerves in the first case; and I therefore suppose that no remarkable change was observable in their appearance, or that it was passed over unobserved. In the second case, a very obvious alteration presented itself, the nerves being small, hard, and dark-coloured, with a yellow tint, and, to all appearance, unfitted for the discharge of their natural function; but how this change was induced, whether by pressure on any part of their course, or by interruption to the circulation through their substance, or by the irritation of contiguous parts, or in consequence of the serous effusion taking place in the ventricles, I do not pretend to say. The loss of vision, in both cases, leads us to suppose that it forms an important part of the consecutive history of the disease. The loss of sight in the left eye took place, in each, rather more than two years before death; and

the loss of vision in the right eye followed very shortly after that in the left. The left ear, though its power was diminished to a very great extent in both cases, and was entirely lost in the first, retained its faculty of receiving impressions longer than either of the eyes.

The situation of the organic mischief, which might be said, in both cases, to encroach upon the mechanism of the right ear, and which made pressure on the auditory nerve of that side, afforded sufficient explanation of the destruction of its functions; but it is probably to the pressure communicated, through the pons Varolii, to the auditory nerve on the opposite side, as the tumors enlarged, that we may ascribe the slow diminution of sense in the left ear.

With regard to the sense of taste, it seems to have been impaired, in each case, as the disease gradually advanced; and neither is any specific notice taken of it, till a few months before death. This is one of the most peculiar and interesting symptoms, because one of the least frequently noticed in cases of cerebral lesion; and I have no doubt that it arose from pressure made by the tumor on the fifth pair of nerves, which gives origin to the gustatory branch; for, in both cases, the fifth pair suffered the most obvious and decided displacement and compression. The obtuseness of the sense displayed itself in the total want of preference with respect to articles taken into the mouth, as observed in the first case, so that the most nauseous medicines were taken with the same indifference as the most grateful beverages; and, in the second case, the inability to distinguish flavours was freely admitted.

The impaired functions of the senses, more particularly of the sight and hearing, preceded, by a considerable time, any important loss of power in the voluntary muscles, or any diminution in the common sensibility: in regard to which, some slight want of correspondence is observable in the two cases, more particularly as to the spasmodic or convulsive action which occasionally displayed itself in the second case, but was not present in the first. In both cases, however, something analogous to fits of congestive apoplexy occurred, as the irritation and embarrassment of the brain gradually proceeded; and doubtless the serous affection and consequent changes in the ventricles had a considerable share, both in impairing the muscular power, and in inducing that feebleness and oppression of the intellect

which formed no part of the disease in its earlier stages.

In connection with the foregoing subject, it is instructive to trace the effects of lesion, as they occur in the different portions descending along the course of the spine; and the opportunities of doing this are frequently afforded us, both by disease, and as the result of accident: and a very interesting paper on this subject, which was read last May, before the Royal Medical and Chirurgical Society, by Sir B. Brodie, is published in the present volume of their valuable Transactions. Cases of an analogous kind are very frequently occurring in the practice of the physician, where disease has produced partial paralysis, more or less traceable to local derangement. In one case, which was under my care in the hospital within a few months, a female, somewhat advanced in age, suffered paralysis of the glossopharyngeal and laryngeal nerves, so that she could with great difficulty swallow, and was quite speechless; and, being unable to write, expressed herself entirely by signs; while she had no other symptom of paralysis. A man, who had evident disease in the superior cervical vertebrae, had lost his power of articulating, except in a whisper; while, at the same time, the lower extremities were paralyzed, so that he was unable to walk; and, although he recovered the use of his extremities in a very great degree, under the use of setons, he left the hospital still unable to speak above a whisper.

The London Medical

AND

Surgical Journal.

Saturday, September 9th, 1837.

THE UNIVERSITY HOSPITAL.

It ought to be distinctly understood that the additional fee which it is intended by the Gower Street Joint Stock Company to be extorted from those students who wish to attend the North London Hospital, but who at the same time decline becoming pupils of the Lectures in the London University, is solely intended

as a bonus to the lecturers themselves ; it having been *settled by the disinterested professors* that only the former rate of charges for attendance at the Hospital should be *appropriated to the support of its inmates*, whilst the additional £10 were to be divided amongst the physicians and surgeons, according to their mutual arrangements.

The EMINENT PROFESSORS, after several years *gratuitous* labour in the HOSPITAL, had for some time most bitterly complained that such labour had not brought with it a suitable pecuniary remuneration, and, consistent with the LIBERAL principles of the company, they were impelled maturely, to deliberate in what manner a portion of their hitherto *charitable labours* could be converted to fill their own purses. After much serious reflection, and numerous private meetings, which the very *interesting* nature of the subject demanded, the PROFESSORS came to the decided and unanimous opinion, "that it would be inexpedient, at least for the present moment, to appropriate any of the funds of the charity to their personal advantages ;" whilst at the same time every one of them was fully satisfied that "an additional sum might *judiciously* be levied upon those students who entered to their hospital," for *no other purpose*, and with *no other recommendation* than the *smallness* of the fee, compared at least with the enormous honorarium demanded by the *regular corruptionists*.

It is not to be wondered at, that the servants of the Joint Stock Company should have felt *humiliated* at their North London Hospital being made use of by a great mass of students merely for *economical* purposes, as was too evident from the same students not condescending to attend the lectures, of the CELEBRATED *professors*. They therefore deserve no small degree of credit for contriving a new

regulation, which will compel those students who had anticipated the advantage of so *economical* an establishment as the North London Hospital, either to "fork-out" £10 to the medical and surgical cormorants of the charity, or submit to attend the soporific discourses delivered at the University College.

The Middlesex Hospital, which is in the immediate neighbourhood, and which had only been relinquished by the economical student on account of the largeness of the fee, now offers no barrier ; and we augur that few of the extra ten pound extortions will come within the reach of the iron grasp of the carnivorous bipeds of the North London Menagerie.

It will be seen, however, by the bill of fare which contains the terms of the company for the ensuing session, that it has admirably been contrived to secure a larger fee for attendance on the lectures of their school than is demanded by any other establishment in the metropolis ; so that under the hypocritical garb of a *cheap hospital* these LIBERALS expect to enveigle the unsuspecting and unguarded youth, and extort a sum of money for his medical education which he never had contemplated, and which he might never have summed up until he availed himself of the able assistance and arithmetical pen of their erudite secretary.

In adopting this system of recommending themselves to the public, the Joint Stock Company of Gower-street, have only imitated the ordinary usages of a certain class of tradesmen in this metropolis, who, by advertisements and placards, pretend to sell apparently good commodities at a "reduced price ;" but the unfortunate purchaser, when he comes to examine the account carefully, is astounded to find that *items* are ingeniously introduced which he never anticipated he would have to pay for.

So that what between the placarded super-excellence and cheapness of commodities, of only ordinary goodness, and the artful introduction of items, the innocent purchaser finds he has "paid considerably dearer for his whistle" than had he, in the first instance, purchased from a tradesman of consistency and respectability.

PRIVATE MEDICAL INSTRUCTION—GRINDING.

It is the intention of the Editors of this Journal to offer to their readers a full and particular account of the system of GRINDING, not only in this metropolis but also in Dublin and Edinburgh.

The materials for this novel and no less useful purpose, have been carefully collected and arranged from authentic sources—so that they will form a full and comprehensive vade-mecum of every kind of knowledge which is required from candidates for diplomas and degrees at the examinations of the different constituted authorities of the three kingdoms. The system of grinding may be viewed in many different aspects, all of which are equally interesting to the student, the examiner, and likewise to the lecturer himself. Perhaps there is no subject which could come under discussion in which the interests of three parties are so interwoven and dependant upon each other. It is essentially necessary that every encouragement should be held up to the student of medicine, otherwise both the examiners and teachers would not reap the same harvest. A grinder, therefore, fills an important chasm, by infusing the required quantity of knowledge in a certain time, he becomes the organ of satisfying the conscience of the examiner, and at the same time of giving eclat to the teacher.

The student is equally delighted with the functions of the grinder, acquiring his honours with so little intellectual exertion; and he is the more readily prompted to the large disbursements, perhaps the most essential ingredient in the triturating system, from the consideration of having been compelled by the legalised authorities to have extorted from his pocket comparatively larger sums for knowledge, often promised, but not always received.

The grinding system is pursued in London upon various principles, and by individuals some of whom fill high and important professional positions, and the operation is performed at various prices, and on very different terms. There are several eminent professors, especially some distinguished persons of the King's and University Colleges, St. Bartholomew's and Guy's Hospitals, the Westminster, St. George's, and the Middlesex, who all devote themselves conscientiously to perform the duties of the MILL. The next are those connected with private schools, whose time being less valuable, they are able to devote themselves more zealously to the discharge of their duties, as triturators. And there is still another class, better known by the title of BACK MOLARS, who keep themselves aloof from all connexion with teachers and examiners, who devote themselves entirely to the welfare of the student, which individuals have, as might be anticipated, the largest classes, and the most extended reputation.

The expences of grinding, by these several classes, are very different, though all expect a honorarium, it is comparatively small to the fees extorted from students by the recognized lecturers. The first class, such as King's and University College-men, *expect* ten guineas, though a less sum is frequently taken, which pre-

vents an application being made to the second division or class of grinders. The second class require five guineas to perfect each candidate, but like the first class, often reduce their price, and take three guineas, as they consider it their bounden duty to prevent as many students as possible making application to the third class. The third class of grinders or the *MOLARS*, aware of the difficulties with which they have to contend, and to prevent the frequent attempts which have been made by each of the other two classes to form a monopoly, perform their task at the moderate sum of three guineas, and occasionally even a less sum has been taken; but the greatest inducement which they hold out to the student is to indulge him during his hours of active intellectual exertion, with an occasional recreation of pipes and porter. Such is the accommodation afforded by the different grades of private instructors in this metropolis.

THE MEDICAL JURIST.

We have long endeavoured to impress our contemporaries with the absolute necessity and vast importance of that science which is very improperly termed Medical Jurisprudence in this country. We have elsewhere given a history of Medical Police, State Medicine, and Public Hygiene, as well as of Forensic, Legal, Judiciary or Judicial Medicine, or what is termed Medical Jurisprudence.* It is scarcely necessary to remark that medical evidence may protect or destroy reputation, liberty, and even life. A series of articles on the subject cannot fail to be interesting and, as the science of State and Judicial Medicine exists amongst us, instructive to many readers. We shall therefore insert a series of papers upon this branch of Medical Science.

* Manual of Medical Jurisprudence and State Medicine, &c., &c. 1836. Second edition. Sherwood and Co.

INSANITY.

Mental Alienation, or Insanity is of four kinds:—1. *Mania*. 2. *Monomania*. 3. *Dementia*. 4. *Amentia*. The medical jurist should be able to indicate the leading symptoms, and most judicious treatment of each variety; and also to detect feigned cases of insanity, and to prevent real lunatics being treated as criminals. A wide field of speculation is opened to him by this interesting subject. Some of the questions he will have to decide are, how to distinguish the disease, and to prove a man insane, if he has real lucid intervals; what period of life is most liable to insanity; and what diseases are most liable to be confounded with it?

1. *Mania*.—*Mania* has periods of exacerbation and decline like other diseases. Pinel recommends that regular accounts of these periods should be entered in the case-books, instead of the oddities and extravagancies of the patients. He would divide maniacs into three classes, according as they exhibited the exacerbation, or acmé of the disease, its decline or convalescence.

At the commencement of the disease the sensations are very different in different persons. I knew a female, (says Dr. Traill,) who slept in the open air, although snow was on the ground, and yet complained of heat in the chest and abdomen. There is often great watchfulness, sleep being sometimes not enjoyed for a very long time. The patients sometimes bolt their food; but at others under anorexia, and act on a determination to starve themselves to death. In the latter case you must force liquid food upon them. Be attended by a strong force of keepers, for if you have only one or two the patient will resist. Lay him on his back; let the nostrils be closed, and the mouth forced open by an instrument inserted between the teeth, and pour down the fluid from a double-spouted vessel. The sexual appetite is sometimes lost, but at other times it is outrageous.

After the maniacal access has passed the patient sometimes wakes up as from a dream; perhaps with a loss of consciousness of all that has taken place, though, occasionally, a dislike to certain persons or things may remain. During the fit this dislike is often taken to persons or things before agreeable. Recovery is generally gradual, and the best symptom is a return to the subject of hallucination without being much affected by it, especially if the return be voluntary. In one case

Dr. Traill was examined on a commission of lunacy, where the person appeared quite well. On asking him if he had not been ill-used, he answered—Yes; that he was Lord Ellenborough, and had been deprived of his estate. At the Bicetre, a man, who was about to be discharged, subscribed himself “Jesus Christ.”

It is wrong to think that mania is incurable, and that it always depends on organic lesion of the brain. In old standing cases of insanity, the brain is found much harder than natural. Out of fourteen which were examined in the Liverpool Asylum, one could be rolled, and even kicked, round the room, without being broken. It resembled liver in consistence. If the disease has been of less duration, there may be ramollissement of the brain, but in the generality of cases, there is only increased vascularity.

2. *Monomania*.—In monomania, or melancholy, there is generally increased pride. Dr. Traill had a patient which conceived himself the most perfect of beings. He thought that when he moved the world vibrated; and that his wealth had been confiscated to pay the national debt. He was very harmless, and used to be employed in the kitchen of the asylum peeling potatoes. He said, that, if let out, he must kill several persons, having received a commission from heaven so to do. He is still alive.

The fear of hell is very common. A happy mother suddenly became wretched from this cause; and several times attempted to commit suicide. She was quite coherent on other subjects, and was cured by a change of air and scene. A man who had become insane from drinking, thought one night that God sent an angel to tell him to cut his liver. With a razor he made an incision into his *left* side; opened the descending colon, and ever afterwards had an artificial anus. Dr. Traill told him the message could not have been from God, for He would have known better on which side the liver was. This hastened his return to sanity. I do not think religion is so frequent a cause of insanity as is generally supposed. Many monomaniacal patients have fears on religious subjects who before their illness were not religious. Ardent spirits send more patients to asylums than all other causes put together.

Some patients have taken their physician aside, and described accurately the hallucinations of their fellow-patients, and have then reminded him, in a whisper, how differently they were to be

treated, since *they* were noblemen, and in one case the Deity himself! One gentleman went mad after studying political economy. He wrote a most eloquent letter to Pitt, full of correct views; but concluding with a proposition for stretching land, “as the curriers stretch leather,” in order to extend Britain into the Atlantic. I saw another, who had invented a machine for making diamonds, “as fast as peas from a hopper,” by compressing the carbonic acid of the atmosphere. He also said he had drawn a picture of the country he passed through, by looking out of the window of the carriage through a telescope; while a pencil fastened to his queue, drew the picture on the opposite side of the carriage. He died imbecile, after squandering his property. There was another patient, who said that a ride in the morning, and a warm parlour, with a pack of cards, in the afternoon, were all that life affords. He soon afterwards killed himself. Another gentleman told a friend he was tired of life, and was determined to quit it. His friend requested him to live till Saturday. He promised he would do so till four o’clock. His friend did not visit him till five, and found that the determination had been put in force an hour before. The two last were instances of *tedium vitæ*. A gentleman determined, that, in order to save his family from perdition, he would send them to heaven before they had committed mortal sin. He made an attempt on his wife’s throat; was confined, cured, and afterwards lived happily with his family for two years. The disease then returned; he solicited permission to enter an asylum, and died there. A gentleman told his medical attendant that, during the fit, he felt a strong desire to kill his children, and, being religious, ascribed it to the instigation of the devil.

A pretended madman will seldom escape the examination of medical men; though a crafty lunatic may. It is unfortunate that the trial of Belingham, for the murder of Mr. Perceval was hastened, for it was thought by some he was insane, and he was once in confinement. Public feeling was much excited against him.

3. *Dementia*.—In this variety of insanity there is a violent transition from different states, and from one thing to another. I have known patients repeat the names of animals, or of inanimate objects, without intermission for hours together. During the French Revolution, a young man saw his father murdered; he lost his speech and his reason, and attended only

to his physical wants. In dementia the judgment is scarcely exercised at all; it is characterised by sudden emotions of joy and grief; extravagant motions of the body; restless activity; a chaos of wild ideas; all transient and without design.

4. *Amentia*.—This form of insanity, which is also called idiotism, is owing to original malformation of the brain. If congenital, it is not susceptible of cure; but the patient must be kindly treated. Cretinism is a most remarkable kind of amentia, combined with goitre, or bronchocele. The latter is well known in Derbyshire. Dr. Traill had a servant from that part of the country, and, with the exception of the tumor, she was quite healthy. Cretins have generally large deformed heads. Some cannot walk till the period of puberty, and some can perform no voluntary motions but those of deglutition. They have no moral feelings. In some cases the genitals are large, and there is great salacity. If two intermarry their offspring is most helpless. If a cretin marry a healthy woman, the offspring is a cretin in the third degree. Saussure ascribes this disease to the stagnant air of the Alpine valleys. Others attribute the goitre to the use of hard water, which causes excessive glandular secretion.

Accidental idiotism has arisen from blows, the abuse of spirits, venery, &c. It often arises from disappointment. The patient sometimes repeats the same word frequently; perhaps from defect of memory occasionally; but generally from spasm of the muscles under the tongue, as in stammering. By a violent effect this spasmodic affection may sometimes be overcome, as in the case of a patient who could sing if liquorice was offered. Idiots generally fix themselves in a particular part of the ward, and if moved, return to it. One idiot had constantly a lascivious grin on his countenance; said only "yes," or "no," and if moved, or ordered to walk, expressed his anger by a grunt.

Mania from drinking sometimes gradually sinks into idiotism. One maniac was a great babbler of things without connexion. He was getting well apparently, when he fell down in a fit of epilepsy, became an idiot, and died. On examination, a hard tumour was found in the brain, and pus infused under the pia mater. Idiotism, of all the forms of insanity, is most difficult to cure; but Pinel says it is sometimes cured by an access of mania.

Mental alienation, is an alienation of

some of the powers of the understanding. Hence the derangement may be of various kinds. The first we shall mention is derangement of sensation. Hence patients often feel great heat in the abdomen, and this leads them to quit their beds, and to prefer the cold floor. High excitement leads to sleeplessness, and to great muscular exertion. But these are not always concomitant symptoms. If the disease has lasted long, there is generally a tendency to stupor. Sometimes an excessive quantity of food or drink is taken. This must be restrained, and not stopped altogether. The barbarity of keeping such patients on very low diet (which Pinel says is sometimes fatal) is now exploded. At the Bicetre, when the whole daily allowance of food was a pound and a half, served at one time, the mortality was sixty-two per cent. After the revolution, the quantity was increased to two pounds, served at twice, together with potage at night. The mortality fell to twelve and a half per cent.; but this was partly owing to other improvements.

Deranged sensations in the generative organs, lead to satyriasis. Women of the most modest habits, fall to a level with prostitutes; they complain of heat in the breasts and uterine region. In males this state leads to self-pollution, and even produces a tendency to worse crimes. Such patients you must seclude and restrain, by means of a strait jacket. Women give vent to their desires, at first only in whispers, but afterwards loudly, and by immodest gestures. After reason is recovered, modesty returns, and generally such persons have no knowledge of what has passed. Sometimes patients eat little or nothing, for fear of poison. One was so sunk in idiotism, that he would not eat unless food was put into his mouth.

Deranged perceptions of sight, are very common in delirium tremens. I knew a retired officer, leading a monotonous life, who used to see puny soldiers descend into the room, through a crack in the ceiling. Another patient who thought he saw in the yard a monkey with its young ones; they were in reality a hen and chickens. On his conceiving that the monkey came into the room, Dr. Traill pretended to catch it, and when the patient saw it in his grasp, without being able to feel it, he was cured of the delusion. In delirium tremens bleeding is not good. The best way of administering opium in such cases, is by opiate friction to the arms and legs.

Derangement of memory is very com-

mon, especially in dementia. A lady used to repeat words unconnected with each other for hours together. If her mouth was stopped with the hand, when the latter was removed, she began again with the word with which she left off. I have known idiots frightened on being threatened for a fault; and yet repeat the fault soon afterwards. This was owing to forgetfulness. One lady, who was kept apart from the other patients, in the Liverpool Asylum, on account of her howling, was very anxious to join the rest; but on obtaining her wish, would soon begin to howl again, having forgotten her promise to abstain from it. Sometimes, on the other hand, the powers of the memory are much increased.

One gentleman enjoyed, in the paroxysms, a kind of beatitude—writing poetry and being very malicious. Another filled quires of paper with poetry, little connected, but containing beautiful images. Sometimes a spot on the wall is transformed, in the imagination of patients, into a grinning countenance; a wreath of straw into a crown of diamonds; and a tattered cloak into a robe of royalty. Visions are very common, both by day and by night. One patient said his body was not his own, but belonged to Jane Johnson. Another said that his voice was that of a little man in his belly; another, that the head he wore was not his own, but that of a man who had cut it off; and a third, that he had changed bodies with his doctor, and insisted on feeling my pulse and prescribing.

The moral sense may be perverted, and cases the patient is not amenable to law for his actions. A mother cut off her child's head, and calmly told her husband of it—thinking she had sent her child to heaven. Pinel tells us of a peasant who was frightened into insanity, by a missionary's description of hell. He attempted the life of his wife, and actually killed his two children, and a person who was confined with him. He thought he was appointed to save the world by a "baptism of blood." He was put into the Bicetre for life, and thought he had escaped execution by the interposition of divine power. He then took it into his head that he was "the fourth person in the Trinity." After a confinement of ten years, he was allowed to go into the convalescent ward. He continued well for four years, but he then killed two persons and attempted the life of a third.

The most modest and refined women, have become immodest and obscene in

language and gesture; and more so than really loose women,—as if insanity prompted to conduct the most opposite to natural habits. If a gay person becomes suddenly melancholy, there is great danger of insanity, and the first symptom of convalescence will be a return to his natural disposition. If any of the patients in an asylum require more or better food than the rest, they should not be brought to table with the latter; for their companions will be sure to impute it to partiality. If patients will not take sufficient food, you must employ entreaty in the first instance, but if that fail you must force nutritious food upon them.

A young lady, afflicted with monomania, used to put up most fervent prayers for recovery; but yet expressed her conviction, every night, that she should die before morning. At last Dr. Traill laid her a bet of a pair of gloves, that she would be alive at his next visit. Accordingly, when he called again he claimed the bet, which she paid. These gloves he wore at all his subsequent visits, and whenever she began to talk in the old strain, a glance at the gloves silenced her. She gradually ceased to return to the subject, and was ultimately cured.

A man shot himself through the chest. The ball fractured the sternum and scapula, and was taken out behind. In the first instance he fired at his head, but the ball glanced from his forehead. He then discharged a pistol into his mouth, but the ball had fallen out previously. The balls, which are preserved, have the marks of the firing upon them; and when bullets fit tightly, there will also be a ring around their circumference. He appeared to be sinking from the wound in the chest, but suddenly became maniacal, and recovered. Some months afterwards, however, when on his passage to America, after dining cheerfully, he threw himself overboard. He sank immediately, having put cannon balls into his pockets.

The causes of insanity are various. The principal are hereditary disposition, melancholy temperament, various passions, nervous diseases, and injuries of the head.

1. *Hereditary Disposition.*—We know nothing of the nature of this cause, but its reality is not to be disputed. We are not certain, in such cases, that insanity must appear, but there is a predisposition ready to be called forth by any exciting cause. It has been known to pass over one generation and appear in the next. Insanity, when hereditary, most commonly breaks out at puberty, or at the

decline of life, and in females, at the cessation of the menses. In men there are no causes so common as excessive sexual intercourse, and indulgence in spirituous liquors. We cannot assign the proximate cause here, but it is probably some peculiarity in the structure of the brain; for why should not children resemble their parents in the form of the brain, as well as in that of other parts? The number of generations through which features may be transmitted is very great. A nobleman who, in the time of Cromwell, did penance for his gallantries, left behind him, in a village in Scotland, many copies of his remarkable Roman nose, which is still to be seen in his descendants there.

2. *Melancholy temperament.*—The French accuse us of this failing, and allege that melancholy and suicide are most common among us. If they mean *moping* melancholy, the allegation is not true; but if they mean, as Pinel says, the intense pursuit of one idea, it is rather a compliment to our national character. Insanity is sometimes ushered in by serious gravity, a disposition to study, hypochondriasis, and gloomy views of religion. Intensity of devotional feelings may lead to despair; from which there is but a step to suicide or an asylum. Sometimes the last spark of expiring reason, has been hailed by injudicious enthusiasts, as the perfection of religion. This is especially observable among those who delight to paint the Deity in glowing colours; but the most notorious drunkards and debauchees often end in religious ravings. People should also be warned against study of works of fiction, which inflame the imagination, present complicated scenes of distress, and favour a dreamy, indolent existence.

REVIEWS.

A Clinical Treatise on the Endemic Fevers of the West Indies intended as a Guide for the Young Practitioner in those Countries. By J. EVANS, Esq., M.R.C.S. London: J. Churchill, 8vo., pp. 309. 1837.

We hope we need not apologise to our readers for giving a third notice of this original and practical work on a class of diseases most formidable in their results, and very imperfectly described by preceding authors. The history of these diseases written by a careful observer will

be perused with interest by every medical practitioner. Impressed with this conviction we continue and conclude our review of this valuable work.

The author gives an ample clinical report of the diseases peculiar to the West Indies, and the histories of cases of intermittent neuralgic affections, intermittent inflammations, peritonitis, and simple and inflammatory agues—cases of endemic diseases and fevers. He next describes the pathology of the different organs and tissues, and then “The Seat and Nature of the Endemic Fevers of St. Lucia,” their connexion with yellow fever, the history of this last disease, and the different means employed for its treatment. It would be impossible for a weekly journal to give close analytical reviews of practical works of the kind before us, and therefore we must content ourselves with few extracts. We have, however, given sufficient to enable our readers to judge of the merits of the production before us. We shall now append a few important cases and take leave of our author. We need scarcely state after our lengthened extracts, that this work evinces extensive and faithful observation and deserves a place in the library of every medical practitioner resident in the West Indies.

Intermittent Peritonitis.—A. V., aged 25, of a nervo-sanguineous temperament, superficial veins very much developed; native of the West Indies, but has resided until within a few months in France. Plunged into cold water when the body was very much heated, and shortly after eating a copious breakfast; immediately felt a general uneasiness, and vomited his breakfast; he was then seized with colicky pains of the belly, which continued nearly the whole day; in the night these pains became continued, and fever was not long in making its appearance. The following morning I saw him: the patient complains of considerable pain throughout the whole of the abdomen, nausea, violent efforts to vomit, skin hot and dry; no evacuation of the bowels for two days; pulse full, and 100 strokes in a minute; no head-ache; urine high coloured, and small in quantity; the abdomen is very slightly distended, and extremely painful on pressure. V. S. $\frac{3}{4}$ xvi. statim, castor oil; hot fomentations to the abdomen. Evening; the patient seems nearly well; the skin is nearly moist, the pulse quiet, and the pain in the abdomen gone; he can bear pressure, though a little sensibility still remains; the bowels have not been opened; the castor oil was returned.—

To take calomel, gr. x. to-night, and a black draught early in the morning. 20th. Noon; I have again been sent for, as all the symptoms returned at ten o'clock this morning, after an intermission of twelve hours; skin intensely hot and dry; pulse 108, full and hard; abdomen extremely painful; the weight of the sheet is almost insupportable; vomiting of bilious matter; great thirst. Bowels have been freely opened. I must confess that I feel a great deal of astonishment, as I looked upon the disease as completely vanquished last night, and little dreamed of its return in so severe a form. I considered it a case of peritoneal inflammation, from hyperhemia of this membrane, consequent upon the sudden constriction of the cutaneous capillaries produced by the cold bath. The blood taken away yesterday was very sisy. Bleeding repeated; hot fomentations; barley-water. Evening, blood cupped, buffy. As the patient could not bear the weight of the flannels, his friends put him into a warm bath, which procured some relief; but he is still much in the same state as this morning, and there is now evidently a gastritis superadded; the tongue is red at tip and edges; great thirst; vomiting of bilious matters and mucosities, with effort; frontal head-ache, and dryness of the skin. Hirudines xxx. abdom. During the application of leeches the patient suddenly began to feel relief; the skin became moist, and the symptoms subsided rapidly. To take three grains of quinine every hour. 20th. The patient has passed an excellent night. There has been another intermission, but he has not taken any of the quinine; unfortunately his friends have thought proper to judge for themselves, and I was told that "*le sang est trop échauffé*:" he is now just like a person convalescent. There is a complete apyrexia, pulse soft, 80, skin moist; has perspired freely, and had his linen changed in consequence; but the abdomen is somewhat distended and sensible on pressure, though not much so, nor more than might be expected from the symptoms of yesterday. To take ten grains of quinine immediately, and to have them repeated in half an hour. Noon; all the symptoms returned half an hour after I saw him, and are now as violent as yesterday. To have a warm bath immediately. The disease being decidedly intermittent, I think it injudicious to repeat the bleeding, as we may expect another intermission to night. Nine o'clock, p.m. I have been obliged to repeat the bleeding. The symptoms

are more violent than ever; both the peritonitis and gastritis are most acute. Rep. hirudines. 21st. I have been up all night with this poor person. He has been again bled, and placed in a warm bath until fainting was produced, but the symptoms have made an awful advance. Has had one stool, about eight hours since, from the use of a syringe. From midnight until about two o'clock in the morning there was a partial calm, and quinine was administered in a clyster, but was soon returned. Since this period the symptoms have gradually but rapidly increased, and at present, one o'clock, p.m., 22d, he is in the following state: Drooping of the eye-lids, tears escaping on the cheek; extremities cold as ice; chest and abdomen burning hot: the latter distended, and so exceedingly painful as to make the patient scream with agony when moved. He insisted upon having cold water constantly applied, by pouring it from a vessel in which it is kept cool, but cannot support even a linen cloth. Tongue red at edges and tip, dry; pulse rapid and small; perfect consciousness, and aware that the result will be fatal. Rep. hirudines. Mustard to the inside of each thigh; stimulating frictions to the arms and legs. Evening; the friends have requested my opinion, and have begged me to allow them to do what they imagined they were able for the patient, who cannot outlive the night. He died at nine a.m., 23d November. Sect. cad., five hours after death. Body stiff but warm, abdomen meteorized. In cutting through the parietes of the chest and abdomen, the skin, cellular tissue, and muscles were dry; that is, no blood escaped from their divided vessels. About three quarters of a pint of fluid were discovered in the abdominal cavity; this fluid was what has been denominated sero-purulent: that is, serum in which molecules of albumen are suspended, giving it a wheyish appearance. Some of these molecules were of considerable size, resembling shreds of false membrane. The peritoneum covering the abdominal parietes red throughout almost the whole of its extent, and covered with a thin layer of fibrine, adhering in places to its reflections over the intestines, which are inflamed in patches to a great extent. The lower portion of the ilium of a dusky red, friable, and easily lacerated. Rougeur pointillée of the cul de sac of the mucous membrane of the stomach. This organ contained a small quantity of yellowish fluid. All the other organs healthy. Blood has undergone no change; colour-

less clot on the right cavities of the heart.

Gastro-hepatitis sub-acute.—G., Esq., native of England, some time in St. Lucia, of a nervo-sanguineous temperament, aged about 35, was taken ill two days ago with what he calls slight fever, which has continued ever since, but with a marked evening exacerbation. 2d December, 1833; skin hot, but very moist; pain in head, back, and extremities, but not severe; nausea; thirst; conjunctivæ yellow; urine high coloured, tinging the linen: it is opaque, but there is no sediment; abdomen slightly distended, but no pain on pressing any part of it; tongue yellow, and furred at the back; red at edges and tip; pulse quick, about 90; bitter taste in the mouth; tendency to diarrhœa; tenesmus; stools bilious and slimy. The patient says that just now he is comparatively well, and requests that I will return in the evening. He is anxious to take an emetic, but as I should wish to see the paroxysm uninterrupted or interfered with, I prescribed nothing more than barley-water and a most strict diet. Evening; paroxysm has begun about an hour; skin hot and dry; great thirst; whatever is taken into the stomach, even in the smallest quantity, is immediately rejected, mixed with yellow bile. He is now conscious of slight pain, or rather uneasiness, on pressing the epigastrium and right hypochondrium; head-ache increased, and the tongue more red at the tip; is still furred at the base; pulse upwards of 120; great uneasiness and anxiety from the nausea.—To take three grains of tart. antim. this evening, followed by gr. v. of calomel, and early in the morning castor oil in the juice of sour orange. 3d Dec. The patient is much better, and entirely free from his complaints of yesterday; the eyes are scarcely yellow; the urine clear, and has thrown down a lateritious sediment; tongue quite clean and pale. This patient remained well until the following day, the 4th, when at noon he again had general heat of skin, and quickness of pulse, and some thirst. The symptoms very slight, but still there is a complete state of pyrexia; with slight redness of tongue at the tip. Towards evening diaphoresis and return to health. Quinine gr. iv. ter die. 6th. Has had no return, and is perfectly well.

Remarks.—The symptoms which constitute fever are heat of the skin, quickness of the pulse, and disordered secretions, dependent upon a cause known or

unknown. This being premised, we might logically draw the following conclusion:—That these symptoms would bear a just proportion to the severity of the cause, that is, if the cause be a powerful one, the heat of the skin, the quickness of the pulse, and the derangement of the secretions would be very considerable, and *vice versa*. Experience daily proves its fallacy. In some of the most acute forms of gastritis which are to be found in the West Indies, the skin is cold and damp, and the pulse does not exceed eighty or ninety. The rigid inflexibility of truth daily subverts the most plausible arguments and the most subtle theories. Neither heat of skin, nor quickness of the pulse, bear any proportion to the severity of the disease. We daily see cases where the skin is intensely hot, and the pulse 140 pulsations in a minute, which are comparatively mild, and have the most favourable termination. What is meant by the general symptoms it would be difficult to express; they are so numerous, so various, and so different in each case, that it would be quite impossible to form a nomenclature of these diseases founded only upon them, without reference to the seat of the evil. If we study diseases we first ascertain the cause; the effects, or, in other words, the symptoms then become no longer difficult.

In the last four cases we meet with intermittent inflammations of different parts. In the seventh case the inflammation was seated in the parenchyma of the lungs. In the eighth in the fibrous textures of the articulations. In the ninth in the peritoneum; and in the tenth in the mucous membrane of the stomach, duodenum, and biliary canals.

That inflammation properly so called ever observes a purely intermittent type, has been, and still is, doubted by many; and the principal reason offered in defence of this objection is founded upon the treatment which these forms of disease require. But all the subtleties of logic cannot explain away a fact, and diseases similar to those above exist, have existed, and will exist, call them by what names we may. Except the last, I have carefully abstained from introducing any case in which the local inflammation was not marked, and clearly the cause of the general symptoms. These cases do not form a large proportion in the intermittent fevers of St. Lucia, I allow; but if we were to examine those of the more usual form, we must still admit the existence of inflammation as a point of departure

On the Nature and Treatment of Diseases of the Heart, with some new Views on the Physiology of the Circulation. By JAMES WARDROP, M.D. to King George IV., Lecturer on Surgery, &c. &c. 8vo., London, 1837. John Churchill.

The author of this work has long since established his reputation as a pathologist by his writings on Fungus Hematodes, on the Morbid Anatomy of the Eye, and as a biographer of Baillie. His work on Anæmism, on "Blood-letting," and his numerous tracts which have appeared in the Transactions of Societies and in periodical Journals during the last twenty-five years, have amply enabled the profession to judge of his practical talents, and on the work now before us will rest his character as a physiologist. He is indeed fully entitled to the appellation of original, being replete with a collection of facts and a chain of reasoning by which he has been able to explain many of the phenomena of the living body which had not even claimed the attention, far less an explanation, by the most celebrated physiologists. If, indeed, the views which Mr. Wardrop has given be correct, and their accuracy can scarcely, we believe, be disputed, a new and no less important field is laid open relating both to the physiology and pathology of the circulation.

The work is divided into two parts, the first of which only has appeared.

We shall allow the author to explain the nature of the work by quoting his preface:—

"The first part of this work contains preliminary observations on the structure and functions of the heart, with which are interspersed some new physiological researches on the circulation.

"The second part will give an account of the diseases of the heart, and those affections will be more especially treated of which are of common occurrence, and which we have the means of alleviating by medical treatment,—but comparatively little will be said of those morbid changes which seldom occur or over which the resources of medicine have been found to exercise little control.

"Whilst prosecuting some investigations concerning the diseases of the heart, and more particularly regarding their causes and treatment, the author's attention was directed to certain symptoms with which diseases of that organ are accompanied,—and, in seeking an explana-

tion of them, he was led to reflect on several natural phenomena connected with the circulation of the blood in the heart, and with the function of respiration, but of which no satisfactory explanation could be found, and to some of which even no allusion had been made in physiological writings.

"He was particularly struck with the influence of respiration on the action of the heart, and with the influence of the action of the heart on respiration, as well as with all the modifications of these functions, not only in diseases but likewise during the acts of weeping—sobbing—crying—laughing—in the giddiness experienced in turning round rapidly—in swinging, and in sea sickness.

"His attention was not less arrested when contemplating the influence, which the almost constant movements of the body exercise both on the respiratory and the circulating organs. He was led to inquire how the action of the heart and lungs is increased by violent exercise—how persons can by a process of 'training' acquire the power of using their muscles, until their muscular energy is exhausted, without causing breathlessness or a sense of suffocation—in what the art of diving consists—and finally, how diseases of the heart are caused by violent exertions and by mental excitement.

"Having arrived at the conclusion that these various phenomena are intimately connected with the great function of the circulation of the blood, further observations convinced the author that each of these different acts is employed for performing a specific purpose in the economy—some for increasing and others for diminishing the quantity of blood within the thoracic cavities, according as modifications in the quantity of blood are required, or an adjustment becomes necessary in the different organs for the due performance of their respective functions.

"In pursuing these investigations, the mind was conducted step by step to establish the existence of three important functions—functions connected with the circulation of the blood, which had hitherto been overlooked by physiologists.

First—That the muscles, besides being the active organs of locomotion, perform the important office of increasing the quantity of arterial as well as of venous blood, within the cavities of the heart.

Secondly—That the lungs regulate the supply of blood to the heart so as to prevent coagulation within the heart's cavities—and

"Thirdly — That the subcutaneous veins performing the office of a reservoir, prevent congestion of blood within the pulmonary vessels.

"By establishing these important functions—of the organs of active motion—of the lungs, and of the subcutaneous veins—several phenomena, both of the respiratory and circulating organs, admit of a satisfactory explanation; and we are enabled to account for some peculiarities in the structure of the vascular system, whilst we are, at the same time, materially assisted in the elucidation of many phenomena, in the diseases both of the circulating and respiratory organs.

"The second part of this work will give an account of the diseases of the heart and their treatment.

"From the supposed dangerous tendency of all diseases of the heart, we might have anticipated that the various affections of that organ would have been carefully investigated, even from a very early period in the history of medicine. But the erroneous impression of the limited powers of medical treatment, as well as of the fatal character of these diseases, would seem to have paralysed, rather than excited inquiry into this most interesting branch of medical science.

"Morgagni, Senac, Baillie, Burns, and others, had contributed much to advance our acquaintance with the pathology of the heart; but the subsequent researches of the French pathologists, more especially those of Corvisart, Laennec, Bertin, Andral, and Bouillaud, by pointing out the means of recognising, during life, those various morbid changes of structure which we had previously been able to detect only after death, materially contributed to the advancement of this department of knowledge. Still however it remains an important desideratum, to discover the means of discriminating diseases of the heart in their earliest stages, and before any of those formidable changes of structure have taken place, which it is not within the powers of medicine to relieve. It is quite evident that such changes of structure must be preceded by a train of phenomena, and by a series of lesser disturbances in the function of the heart, and the detection of these will enable us to apply remedial means, with a probability of achieving the same advantages, as in the treatment of diseases in other organs.

"We may also anticipate a great extension of our knowledge of curative means in the treatment of diseases of the

heart, since there is a class of medicines, which, from their specific influence on the organs of the circulation, may be advantageously employed in these various affections.

"Ipecacuanha, as is well known, acts upon the stomach—saline medicines on the small, and aloes on the large intestines—mercury influences the functions of the liver and salivary glands—cantharides and the various balsams operate on the urinary organs—narcotics act on the brain, and some even on particular nerves, as for instance belladonna on those of the iris. In like manner the preparations of antimony, of iron, of lead, and also some vegetable substances, as digitalis, colchicum, hellebore, and tobacco, have each a particular influence on the functions of the heart. It is not therefore too much to affirm, that the power of recognising diseases of the heart in their earliest stages, will, combined with the judicious exhibition of these various remedies, afford the means of treating the diseases of that organ as successfully as those of any other diseased viscera."

Our readers will observe that the explanations given of the circulation throughout the body, which simplify many obscure and hitherto unknown phenomena in the animal economy, are calculated to considerably modify and greatly improve practical medicine. The work evinces much originality, mature reflection, strong reasoning powers, and is replete with most important conclusions. It will add to the well-earned fame and high reputation of its distinguished author.

CLINICAL REPORTS.

No. I.

DISEASE OF THE BRAIN.

C. S., a girl, twenty years of age, was brought in insensible from a brothel, whither she had recently come from the country; and where, among other vices, she had been taught to drink. The following particulars were obtained from a girl who accompanied her. She had complained for some days of a pain in the left side of the heart, and yesterday fell off her chair suddenly, without sense or motion. A medical man was not called in till four hours afterwards. He bled her, and administered an aperient powder. No passage, however, had been obtained from the bowels. She now lies in a co-

matose state, with stertorous breathing, cold extremities, and pulse fifty-eight, and very weak. The pupils of the eyes, though much contracted, vary according to the light.

The head was ordered to be shaved immediately, and a blister applied to the scalp, together with twenty leeches to the temples. An enema containing an ounce of oil of turpentine, was directed to be administered immediately, and a drop of croton oil to be placed on the tongue every hour till the bowels should act. The feet to be placed in hot water.

All this was done. Her legs were immersed in very hot water; thirteen of the leeches fastened, and two drops of croton oil were administered. The pulse rose about ten beats in the minute, the pupils dilated a little; and the extremities became warm. She died, however, two hours after admission.

On separating the scalp some effusion of blood was found; owing, probably, to the fall. Very few red points were observed on slicing the brain. The anterior lobes of the cerebrum, adhered firmly to each other, and there was likewise extensive adhesion of the arachnoid membrane to the dura mater, over the middle lobe of the right hemisphere. The left corpus striatum was very soft, and of an unusual red colour towards its outer edge. Both the internal carotids were thickened as to their coats; and the left was hard and obstructed. Serum was found in the left side of the chest, the pleura of which exhibited old adhesions; but the lungs themselves were healthy. Fluid, containing a few flakes of lymph, were also found in the pericardium.

Clinical Remarks by the attending Physician.

When the convolutions of the brain are observed to be flattened, and its substance blanched (as in the present instance,) we generally find considerable effusion into the lateral ventricles. It was not here, however. I expected to find blood effused; but we are often deceived in this particular. Only a small quantity of effused fluid was observed; and that was confined to the left ventricle. There seemed to be an extravasation of blood in the sensorium; but I think it was only a projection of the sinus. It was the same on both sides. The mind of the patient does not appear to have been lost immediately after she fell down. The progress of disease in this case was not like that of ramollissement of the brain, for the latter is generally more slow in its progress,

going on sometimes even for years. In some cases the disease is local, but generally an extensive part of the brain is involved. The red colour of the left corpus striatum shewed that here we had inflammation in its acute stage. Brain, when softened, is generally yellow or cream-coloured. I think blood is often effused at first, and that the red tint lasts till removed by absorption. Contraction of the limbs is said to occur in ramollissement, but that is only in protracted cases, and is wanting in many even of them. In the present case one side was paralysed, while we had spasms of the other. This is very common, owing (to use an expression not understood) to irregular distribution of the nervous energy. We cannot depend on the previous history of this case. The only premonitory symptom mentioned was head-ache. This, and confusion of thought, sometimes make up the whole of the premonitory symptoms, and sometimes even those are wanting. This patient had led a dissipated life, and had been the subject of repeated inflammatory attacks. When she came in, treatment of a more active kind than that which she received was out of the question. I did not see her, but I consider her treatment to have been perfectly judicious. Nothing else on earth could have been done for her.

The plan I intend to adopt with our cases is, first, to detail the symptoms; then the conclusion which I draw from them; and, lastly, the measures to be pursued. Any change that may occur during the progress of the case I shall mention; and when it terminates shall notice if our judgment was right, and the treatment successful. We can seldom treat a disease from reasoning, but must act according to the symptoms, and afterwards endeavour to reason on them. In all fatal cases I shall endeavour to have the body examined before you. This often clears up difficulties and doubts, and will sometimes teach us how to treat similar cases. I generally prefer to admit acute cases, and severe chronic cases rather than slight. I am not anxious for monstrosities, but for cases that more commonly occur. Nor shall we expect to find these always agree with Cullen's Nosology, for many anomalies occur. We shall often admit cases we have no hope of curing; and we must therefore expect the deaths to be frequent; and, indeed, we shall admit those in which it is most likely to occur, for the sake of the dissection.

PROFESSORSHIP OF ANATOMY IN TRINITY COLLEGE, DUBLIN.

To the Editor of the Medical and Surgical Journal.

Sir,—Having read in your Journal of the 26th of August an editorial article, in which you assert that you have good authority for stating that Dr. Harrison is most likely to fill the vacant chair of Anatomy in Dublin, and in which, you likewise charge the Board of Trinity College with being governed by political feelings in the choice of their Professors. I think it right to make you or your informant acquainted with the constitution of the Act of Parliament for establishing the School of Physic in Ireland.

The Professorships when vacant, are directed by this act to be advertised three months previous to the election, and declared to be "open to Protestants of all Nations," and immediately before the electors (who in the present instance are the Provost and senior Fellows) give their votes, the President of the College of Physicians is to solemnly administer to each the following oath.

I A. B. do swear that I will, to the best of my judgment and opinion, and without favour, partiality, or prejudice, vote for such Candidate for the vacant Professorship as shall appear to me best qualified for the same—So help me God.

To assume therefore that Dr. Harrison or any other person can know how the Members of the Board will vote, until all the Candidates shall be ascertained, and their merits duly considered, is to suppose that the Board would act with "favour, partiality, or prejudice," a supposition that cannot be entertained for a moment, considering the character of the men and the nature of their oath, and one which is contradicted by the conduct of the Board of Trinity College, on all former occasions of election by oath, on which they have been known to act with purity, impartiality, and sound judgment.

I am, Sir,

Your obedient servant,

VINDEX.

APOTHECARIES HALL.

Mr. Johnson has been elected the Master, and Messrs. Mallin and Clapton the Wardens of the Company for the ensuing Year. Mr. Upton has been re-elected Secretary.

LITERARY INTELLIGENCE.

In a few days will be published, An ESSAY ON PYREXIA, or *Symptomatic Fever*; as illustrative of the Nature of Fever in general. By HENRY CLUTTERBUCK, M. D.

TO CORRESPONDENTS.

Justitia.—Application for the correspondence alluded to, with the House Surgeon, ought to be made to Mr. Richardson personally.

Inquisitor.—The Minutes of the Committee will be published by the Council.

North London Hospital Student.—The lithotriptic preparation is forthcoming, and has been claimed as the property of the hospital. The abnormal office is distinct.

R. Saville.—The working of the Anatomy Act, together with the pecuniary "appropriation clause," will appear in an early number. The burial expenses amount to 2l. 12s. 6d., including the perquisites.

Inspector.—Dr. Jones Quain will give the desired information.

Pugnax.—The assault ought to be particularly guarded against; it would render nugatory all future proceedings in a court of law.

T., of Dublin.—Many thanks for the intended communications.

A Richmond Hospital Student.—Yes, every justice shall be done him.

Scrutator of Brighton.—It will be disputed and dissipated into thin air.

T. S.—The communication must be authenticated.

B., of Dublin.—An early reply is expected—*Tempus fugit.*

X., of Shropshire.—Any bookseller can supply it—there is no excuse whatever.

An Inquirer.—Dr. Bright of Guy's, not of the Westminster Hospital.

A. T., of Hull.—A twelfth of a grain, twice a day.

T., of Newcastle.—He must favour us with his name confidentially.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by M.M. Cazenave and Schedel.

URTICARIA.

Urticaria is a non-contagious exantheme, and characterized by prominent patches, variable in form and extent, most frequently irregular, redder and whiter than the surrounding skin; in most cases very fugacious, and always accompanied by a very troublesome itching.

Urticaria, though sometimes acute, generally follows a chronic course, and its duration varies from two or three days even to months and years. That of acute urticaria is from eight to ten days; no limited period can be assigned to that of chronic urticaria. With respect to the duration of the patches it generally varies from a few minutes to twelve or twenty-four hours; however in some rather rare cases they continue for one or two weeks.

Causes.—Whilst this affection attacks all ages and both sexes, and appears at all seasons, it however more particularly attacks children, young persons, and females, and individuals of a sanguineous and nervous temperament. It is more frequently observed in spring and summer. Finally, there are individuals whose fine and delicate skin is so predisposed to it, that the slightest pressure or friction suffices to develop large patches of urticaria, similar to those caused by flagellation.

Urticaria may develop itself under the influence of direct appreciable causes. Thus it is produced by the leaves of the *urtica dioica*, &c. In such cases the

eruption, which is more or less local, is most frequently ephemeral and of short duration.

At other times, without our being able to discover the connexion between it and its probable causes, it appears to be developed under the influence of dentition, strong mental affections, indulgence at table, and especially the ingestion of certain kinds of food, mushrooms, almonds, honey, cucumbers, &c. But of all those which have in the highest degree the power of producing urticaria, are muscles, crawfish, certain shell-fish, certain smoked fishes, dried or salted. In these latter cases it is generally attributed to a greater or less degree of putrefaction in these animal matters; a thing however which is far from being proved: for among several persons who eat them one only may happen to be affected: we must then admit a certain disposition, which is sometimes so evident, that there are some persons who cannot, under any circumstances, make use of this food without invariably seeing urticaria developed. Mr. Biett in his clinical lectures has quoted cases of urticaria produced by the use of balsam of copaiba.

This eruption sometimes accompanies an intermittent fever of a quotidian or tertian type, or an irritation of some internal viscus. It may also co-exist with entirely different affections of the skin, particularly with *lichen simplex*. Lastly, it might be connected with some peculiar and unknown state of the system.

Symptoms.—The course of the eruption is extremely irregular: generally accompanied with general symptoms, most frequently presenting only those which are peculiar to it: it may, for a duration of some hours up to several weeks, disappear and return several times, leaving, however, but a short interval between its returns, so as ultimately to cease altogether: lastly, in a considerable number of cases

it ceases so as to reappear at more or less remote intervals, and by these irregular returns, it continues for months and even for years. Thus we have seen in M. Biett's wards several instances of chronic urticaria of more than a years duration.

According to its form, progress, and symptoms, Willan has divided urticaria into several varieties. They have been admitted by M. Biett, who has reduced them to the three following :

1st. *Urticaria febrilis*. (Urticarian fever properly so called). The eruption is preceded for some days by headache, nausea, fainting, epigastric pains, and anxiety: it is accompanied by some horripilations: it commences by a general sensation of itching with a feeling of heat over the entire surface; red or whitish elevations, surrounded by an areola of a bright crimson red, some make their appearance, especially on the shoulders, loins, inner surface of the fore-arms, and around the knees. They are prominent, sometimes circular, but most frequently irregular; their edge is hard, their extent variable; being sometimes very numerous and as it were confluent, they unite in several places: the extremities then seem as it were tumefied, and the skin presents a red tint which is almost general (*urticaria conferta*, Willan). An itching and a very troublesome sensation of formication accompany the eruption, and allow the patient but very little rest. The itching is principally increased by the heat of the bed. The eruption does not continue during the entire disease, which lasts from seven to eight days, including in this the period of invasion: it appears and disappears irregularly over almost all parts of the body, and its return, which in general takes place in the evening, is accompanied by a slight acceleration of the pulse. The patient may even by scratching himself make it return at pleasure over several parts. The duration of the patches vary from four, five, or six minutes, to one, two or three hours. In some still rarer cases the patches have a longer duration (*Urticaria perstans*, Willan). They may remain one, two, or three weeks. The predominant symptoms, during the course of the disease, are depression, anorexia, fever, and gastric irritation more or less marked. These symptoms gradually disappear, the eruption becomes imperceptibly less, it returns no longer, and does not occasion any other feeling than that of a slight itching; at last it ceases altogether, and in some cases when the exantheme has become very

marked and very general, a slight desquamation takes place.

This variety presents all the symptoms of intermittent fever; we have seen it return by regular accessions and disappear entirely with the fever, and reappear on the next day with it. In this case was the eruption but an additional phenomenon (epiphenomenon) or did it constitute the principal disease? It would be difficult to solve this question; but this is quite certain, that we have seen it yield several times, under such circumstances, together with the fever, to anti-febrile medicines alone, as for instance to the sulphate of quinine. It then often seems to be developed under some morbid state of the liver, and we have sometimes seen patches of urticaria of a very well marked jaundiced tint. In this case the itching was intolerable.

It is to this variety that the urticaria produced by the ingestion of the different substances already mentioned may be referred. It may then be developed at the end of some hours; but in general it is on the following day it is observed.

One or two hours after the ingestion of this food the patient generally feels a weight in the epigastrium, vertigo, nausea, general depression; the skin soon becomes hot, and the eruption appears. The symptoms are nearly the same as those already described, only they are frequently accompanied with vomiting and purging; the eruption is much more general, and it is then in particular that the patches become confluent, and that the swelling exists; the face is then often very much swollen, and the itching insupportable. In some cases the urticaria is complicated with erythematous patches of considerable extent. Lastly, this variety which in general diminishes in severity at the end of from thirty-six to forty-eight hours, and then soon disappears merely leaving behind slight traces on the skin for a few days, which under some circumstances are very few in number, may terminate in death. But in this case it is obvious that we should attribute it much less to the violence of the urticaria than to the deleterious action of the ingesta.

2d The *urticaria evanida* pursues an entirely chronic course. The eruption appears at irregular periods, sometimes in one point, sometimes in another; but it often attacks but one single region. It is not accompanied with fever, and in general disappears at the end of some hours. It is chiefly in this variety that the patches which are rarely of a round form, are

irregular, and bear some resemblance to those which might be the result of flagellation. They are not accompanied by any erythematous areola, and present no other symptoms except a very severe itching. The *urticaria evanida* generally lasts for several months, and it is often seen to continue even for entire years. M. Biett has seen it continue for seven years. It is often observed in women and in persons whose skin is very sensitive. Lastly, it frequently resists the most rational means of treatment, and in a great number of cases it appears closely connected with some change in the digestive organs, and chiefly in the stomach. Nothing, however, is more frequent than to see this disease in persons who enjoy perfect health.

In some cases the itching is replaced by a sensation of subcutaneous pricking which is very acute, resembling that which is occasioned by a needle sunk into the skin (*urticaria subcutanea*, Willan). This pain, the only appreciable symptom, is not accompanied by any eruption, except by some red points not much raised; and it is only at very remote intervals, that some patches appear. The *urticaria* which presents itself with these characters, seems to be chiefly produced by intense mental excitement, or by a sudden change of temperature. It is very uncommon. M. Biett has seen it but twice.

3d. *Urticaria tuberosa*.—In this last variety, which is also very rare, the urticaria presents itself with much more severity. It is no longer patches with a little prominence, but real tuberosities more or less extensive, deep-seated, hard, accompanied with difficulty in moving, pain and tension of a very acute nature. It appears chiefly towards evening and at night, on the next day it has entirely disappeared, leaving the patient dejected, weak, languid, restless, and complaining of general lassitude. It chiefly occupies the extremities, and the lumbar region. It sometimes presents itself with symptoms much more serious. Thus in the Hospital St. Louis, in a patient in M. Biett's wards, we saw it accompany a quotidian intermittent, and continuing for four years after, we found it to occasion, in consequence of swelling and great distension, ecchymosis, ruptures, and ulcerations: we have seen it, in many an accession, occasion general tumefaction, sometimes so great that the patient had actual attacks of suffocation: the movements were limited, the breathing was

short, the neck swollen, the face puffed and of a purple colour, the pulsations of the heart intermitting, sometimes even imperceptible; and death, which seemed impending, was frequently warded off only by copious bleeding. This patient, who had been in several hospitals, and with whom all the ordinary means had failed, was cured by Fowler's solution.

The *urticaria tuberosa* seems to be chiefly produced by excess in diet, and by the abuse of spirituous drinks. Its duration, which as we have seen, may be for several years, is ordinarily for several months.

Diagnosis.—The form and elevation of the patches, the presence of itching and the fugacious character of the eruption are signs sufficiently characteristic to prevent us from confounding urticaria with any other exantheme.

In the *lichen urticans*, which might be mistaken for some cases of urticaria, the papulæ are rounded, much less extensive, less prominent, their tint is deeper; they are more resisting under the finger; they never disappear spontaneously, and in fine they always present around them the elements peculiar to lichen, real papulæ which it is sufficient to have seen once in order never to confound them with the patches of urticaria.

The *urticaria tuberosa* might under some circumstances be confounded with *erythema nodosum*. The acute, continued, and persistent course of the erythema will suffice, in all cases, to distinguish it from this serious variety of urticaria, which presents itself with entirely opposite characters.

Urticaria sometimes exists in the same individual with other eruptions, with *erythema*, often with *roseola*, sometimes with *impetigo* and *lichen*.

Prognosis.—Urticaria in general presents no danger in itself. The *urticaria tuberosa* might alone, in some cases, become alarming; but it always constitutes a painful and serious disease from the itching and its obstinate duration.

Treatment.—The urticaria, which is the result of direct causes, does not in most cases call for any treatment. Acidulated local applications, one or two tepid baths, weak lemonade, would be the only means to be employed, should the eruption not disappear promptly. Lotions with acetate of lead diluted in water with a solution of sub-carbonate of potass, or even baths rendered alkaline by the addition of this salt, are sometimes necessary to appease the very severe itching,

especially when the eruption has been produced by the contact of certain insects (chenilles). The simple febrile urticaria readily yields to a strict regimen, to cooling drinks, and to some warm baths. Some purgatives are often useful. But when it is occasioned by the ingestion of certain kinds of food, we should hasten to excite vomiting, if it have not already taken place. Then, we should give a strongly acidulated drink (barley water with a drachm of sulphuric acid or nitric acid to the pint) sugared water, and every hour, from thirty to forty drops of ether on a bit of sugar.

Chronic urticaria is much more difficult to be eradicated; we must then chiefly insist on regimen, taking care to suppress every thing which appears to exercise any influence on the development of the eruption. In some cases it is good entirely to change the habits of the patient. A few bleedings, either general, or by the application of some leeches round the anus, might be very useful in young plethoric persons, and in women whose menstruation is irregular. Simple tepid baths, when the disease is of long duration, produce a less advantageous result than the alkaline or vapour baths, or even vapour douches, when the disease attacks a part by way of preference. Acidulated drinks, gentle laxatives, are the means most suitable in most cases, to be added to the preceding. When the urticaria accompanies an intermittent fever, the latter affection must be combated by suitable treatment. Thus we sometimes obtain some success from the sulphate of quina; the febrile attacks cease, and most frequently with them the eruption disappears. Lastly, if the quina had failed, and the intermittent urticaria presented itself with the serious symptoms mentioned, we have above seen that we have recourse to Fowler's solution, with some chances of success.

It is always improper and dangerous to use any local means to repel this eruption which might rapidly induce fatal metastasis to the brain, lungs, &c.—R. [The hydrargyrum cum creta with rhubarb in small doses is one of the best remedies in the urticaria of children.—R.]

VESICLES.

(*Vesiculæ*)

The diseases ranged under this order are characterized by small elevations of the epidermis formed by the collection of a serous and transparent liquid. These

elevations have received the name of vesicles. In some cases the vesicles ultimately lose their transparence and assume a yellowish tint. The serum may be re-absorbed; most frequently it is effused over the surface of the skin, where it sometimes forms whitish scales, at other times thin crusts, of a yellowish colour and lamellated appearance.

These diseases may follow a different course; some are essentially acute: *varicella*, *miliaria*. The others sometimes present themselves in the acute state, but more frequently their course is chronic: *eczema*, *herpes*, and *itch* (gale).

Their duration varies from some days only to one or two weeks, some months, or even to years.

Symptoms.—Vesicles, which are sometimes preceded in their appearance by general symptoms, as in the species essentially acute, succeed to rough surfaces, of greater or less breadth, often almost imperceptible, in the centre of which the epidermis soon becomes elevated. Sometimes, on the contrary, they are developed without being preceded or accompanied by any other symptoms than a more or less annoying itching.

In their course the vesicles sometimes rest on a red and inflamed surface, or they do not present the slightest inflammatory areola.

They may be small, acuminate or globular; or broader, projecting and irregular, or else flattened. In some cases they are discrete; in others they are agglomerated, and form large surfaces which appear roughened (*hérissées*) as one might say, with an immense number of small white points, of a silvery hue.

With respect to form they most frequently cover surfaces irregularly circumscribed, and of variable extent; they sometimes form bands of greater or less breadth, in the form of demi-cincture, or else they are regular rings.

Seat.—The vesicular affections may attack all the parts of the body; they often cover it entirely, as occurs in the acute species, *varicella*, *miliaria*, and sometimes *eczema*; in certain cases, even the itch may attack almost simultaneously the entire skin. Generally speaking, however, *eczema*, *herpes*, and the itch are limited to one or several regions, and often occupy but a very circumscribed extent.

Causes.—Among the vesicular affections the itch alone is contagious; the others result from an inappreciable disturbance of the system, and may be developed, in

some cases, under the influence of an external cause.

Diagnosis.—The presence of vesicles, independently of the characteristic symptoms which appertain to each species, will almost always suffice to prevent any mistake in the diagnosis; and though, in some cases, certain vesicular affections appear at first view, capable of being readily confounded with pustular inflammations, there still exists between them a well-marked line of demarcation, if it be considered that the one always commences by vesicles, and that if they sometimes lose their transparency, they never contain any thing but a sero-purulent liquid, that they are constantly accompanied by transparent vesicles, and lastly that, in concreting, the sero-purulent liquid never gives rise to any thing but squamæ, while the others always commence by small collections which are really purulent and are accompanied by a more severe inflammation, and give rise not to squamæ, but to thick crusts, &c.

Prognosis.—Vesicular affections are in general not dangerous; some of them (the *acute eczema*, for instance), might sometimes become so by their extent.

They may terminate in resolution; the liquid which raises the epidermis is re-absorbed, and a slight desquamation is set up. It is the termination of *miliaria*, and sometimes that of *eczema*. At other times the fluid becomes concrete, and lamellated crusts are formed of a yellowish colour. This is what is observed in *eczema* and *herpes*. In other cases the liquid is effused over an inflamed surface, which becomes excoriated, and exhales a serum more or less copious (*chronic eczema*). Sometimes again, real ulcerations are formed (*zona*).

Treatment.—Vesicular affections, in general, require but a very simple treatment. Antiphlogistics are the best means to be employed with those which put on an acute form. With respect to those which are chronic, they sometimes require a particular treatment, and oftentimes a very active one which, however, they may obstinately resist for a considerable time.

MILIARY FEVER.

(*Sudamina—Miliary Fever.*)

Miliaria is characterized by the eruption of vesicles of the size of a grain of millet, spread in variable numbers over a greater or less extent of surface, and which almost always accompany some other affection of much more severity.

All parts of the body may be the seat of these vesicles, but they are principally observed on the trunk, either anteriorly or posteriorly. They also are developed on the extremities, but less frequently on the face. The eruption is almost always limited to surfaces of greater or less extent; it seldom occupies the entire body.

Causes.—The appearance of miliary fever always coincides with greater or less excitement of the tegumentary envelope, and with sweats more or less profuse. It comes on, as a concomitant symptom, in a number of gastro-intestinal affections, and its development generally coincides with the paroxysms. It is frequently observed in puerperal fever, particularly when several serous membranes are simultaneously affected. It also accompanies the sweating sickness, certain cases of rheumatism, and sometimes scarlatina. In some cases of epidemic gastro-enteritis, miliary fever has been observed as one of the constant symptoms.

This disease may generally be considered as symptomatic of a much more serious affection. There are cases, however, where it is, one might say, idiopathic, when it is developed, for instance, in persons in good health, after violent exercise, during great heats in summer.

Miliary fever is then accompanied by a sensation of heat and very troublesome itching; the number of the vesicles is sometimes very great, but the eruption is ephemeral, and everything is again right in the space of twenty-four hours.

The symptomatic miliary may be developed in all stages of the diseases which it accompanies, and may even present itself once, or oftener, while they continue.

Symptoms.—It is not preceded by any particular symptom, except an exacerbation of the principal disease. In general, the appearance of the vesicles is accompanied by sweats, more or less copious, and by a sensation of heat, and itching which is very troublesome where it presents itself. The vesicles are seldom confluent, but they often form patches of variable extent, where they are grouped together and more or less approximated. Their number is very variable; sometimes a considerable part of the body is covered with them; at other times they are only here and there.

The vesicles, at first very small and transparent, are often developed over an intensely red surface, and this tint is then very visible through the vesicles (*Miliaria rubra*). In the space of from

twenty-four to thirty-six hours, the vesicles are increased in size, and then inclose a milky fluid, which gives them a pearly appearance (*Mil. alba*). This is particularly striking in scarlatina, when a great number of these vesicles cover large surfaces of a raspberry-red colour. They are flaccid to the touch, and promptly disappear, either by the absorption of the contained fluid, or by its escape externally. Sometimes the miliary ceases when the vesicles desiccate; sometimes successive eruptions prolong its duration for one or two weeks.

In certain severe cases of entero-colitis, accompanied with general depression, the miliary eruptions which are often developed, during the night, in the paroxysms, present on the next day a state purely vesicular, and the skin which they cover is not unusually red; one would say that an immense number of small drops of limpid water were spread over its surface. These vesicles disappear in the space of about twenty-four hours, and a small epidermic exfoliation takes place over the parts which it occupied.

Eczema is the only disease with which miliary fever might be confounded: it differs from it in the circumstances under which its appearance takes place, in its rapid course and its short duration. Besides in eczema the vesicles are very confluent; they are found in great numbers, collected together in a very circumscribed space, whilst in miliary, the vesicles almost always isolated, are larger than the vesicles of eczema.

The prognosis of *Sudamina* is not unfavourable; it is proportioned to the severity of the disease which they accompany, and the appearance of this eruption usually announces very considerable excitement, without however our being warranted in considering it alarming in itself.

Miliary fever requires little treatment; it is the general affection, whatever that may be, which must be combatted; and we feel ourselves warranted in stating that it is the antiphlogistic treatment which it is expedient to employ. [*Miliaria* may appear in cases of typhus and other fevers, purpura, rheumatism, and other diseases, and may be purely symptomatic. In such cases, the primary disease requires most attention, and the treatment must be modified according to the nature of the disease.—R.]

LECTURES ON SURGERY.

BY JOHN HUNTER, F.R.S.

OF ADHESIVE INFLAMMATION.

Although inflammation is an action produced for the restoration of the most simple injury in sound parts that exceeds union by the first intention, we must still look upon it as one of the most simple operations of nature. It is to be considered only as a disturbed state of parts, which require a new but salutary mode of action to restore parts to that state in which the natural mode of action will be necessary. But this same operation can and does vary, and is often carried much further than union, according to circumstances; and is often attended with disease, and that of various kinds, by which it becomes more and more complicated. It becomes therefore necessary to begin by describing it in its most simple form, and with its most general effect, and to particularize further as we go on.

I shall call everything inflammation that produces the following local effects, viz., pain, swelling, and redness, all depending on one cause, and occurring at the same. Out of inflammation arise many other local effects, which may be called secondary; such as adhesions, suppuration, ulceration, and even death or mortification in the part, and universal affection, such as sympathetic fever, and universal death.

The act of inflammation is, as I have said, most probably in the smaller vessels. What the action is, or in what it differs from the common action of these vessels, is not easily ascertained; for we are better able to judge of the immediate effects than of the immediate cause.

Hitherto I have only shown that this inflammation takes its rise, and is capable of uniting parts, when preternaturally divided; but we shall find that it is capable of arising from very different causes, and that it is capable of producing adhesions in whole parts, or in natural separations, such as common cellular membrane, large circumscribed cavities, joints, &c., and these effects will be found to answer very important purposes.

As the adhesive inflammation precedes the suppurative in every particular, excepting the outlets, and the suppurative the ulcerative, the propriety of following this order of nature in treating of them will appear evident.

Adhesive Inflammations.—If the actions of adhesive inflammation were allowed to extend themselves, it would prove more hurtful than any good that could arise from it; hence there are natural obstructions to its extending, which we shall first consider.

Natural Causes of the limiting of Adhesive Inflammation.—I have already observed that exposure of internal surfaces becomes the immediate cause of inflammation; that when it extends further than the exposed surface it is by continuous sympathy; and that when a whole cavity is wholly exposed, the whole would take on inflammation. We may now observe, that whenever a cavity is opened, the simple contact of its sides, or even the simple contact of these with any other living part, will set bounds to the immediate cause, which is the exposure.

To explain this further, we may observe that there is no such thing in an animal as an empty space in any of the circumscribed cavities of the animal body, exclusive of the outlets or reservoirs, which are imperfect, not being circumscribed. Every other part of an animal is either connected by the cohesion of one part with another, or by simple contact. This holds good too in the cellular membrane as well as the circumscribed cavities; for if a wound is made into either, we find that the surfaces of both, beyond the cut edges, are entire, and generally in contact with one another.

To explain this position, let me instance a case. If we make a wound into the cavity of the belly, in a sound state of those parts we shall find every viscus is in contact with some other viscus, and that the whole inside of the peritoneum is in contact with the viscera, so that no space is unfilled. If this wound is not allowed to heal by the first intention, still we find that no inflammation will take place, or extend further than the attachment of those parts to the cut edges, excepting what is owing to continuous sympathy. If this were not the case, every part of the cavity must inflame, because every part would be equally exposed; and if the contact were removed at the time of receiving the wound, or at any time afterwards, the whole cavity must inflame, every part being in the same predicament as regards exposure.

The same thing would happen in the cellular membrane, if those cells were not in a natural state in contact, and inflammation would as readily extend over the

surfaces of each cell as air does when blown into part.

Inflammation, then, takes place at the edges of the exposed parts in order to preserve this contact, as well as to serve as a basis for future operations: and in cases of spontaneous inflammation of circumscribed cavities, we find that where this contact is completest the inflammation and its consequences are the least; as in the belly, in cases of peritoneal inflammation, the inflammation is greatest in the angles between the viscera, where the parts are not so well in contact.

The effect of simple contact, in excluding the irritation from extending, was well illustrated in a woman who had the Cæsarian operation performed. After the child was extracted, the wound could not be brought together well, therefore so far gave rise to peritoneal inflammation; but the belly closing and falling in on its contents, the whole came in contact as before. The woman lived twenty-six hours, which gave time for the inflammation to take place. After death, it was found that the intestines were united to the peritoneum all round the wound, for above half an inch in breadth, and the surface of the intestines, which lay unattached at the bottom of the womb, was inflamed, while every other viscus, as also the peritoneum beyond the adhesions, were free from inflammation.

The adhesive inflammation seems to be nearly of the same nature, whether it arises from the constitution, from a particular disposition of the part, or from some violence inflicted on the part; the final intention being nearly the same in all these cases, for in all it is an effect that has a tendency to repair an injury, as is evidently shown in many cases of violence, though it may not in all. Its utility is most obvious in those cases which arise from the constitution, or from disease in a part. When the adhesive inflammation arises from the constitution, it may be from some disease of that constitution, and, if so, it may be supposed to be of service to it, especially if it should be supposed to be the termination of an universal irritation in a local one, and by that means relieving the constitution of the former, as in gout. But where it is only a simple adhesive inflammation, I am rather apt to think that it is rather more a part of the disease than an act of the constitution, or termination of the disease. When it proceeds from a disposition in a part, it must be considered to arise from a disease of that part.

Although in all cases and in all parts the adhesive inflammation is not absolutely necessary and preparatory for the suppurative inflammation, yet if it is in the cellular membrane or a circumscribed cavity, then its effects will prove salutary. It may indeed be considered absolutely necessary to prevent greater mischiefs, for very bad consequences would arise without it. The object of it in these parts is to unite the parts together for their future benefit by means of the coagulable lymph and serum thrown out, by which the extension of the suppuration will be limited.

It would appear from observation that some surfaces of the body have a much stronger disposition to throw out coagulable lymph than others; or we may view this effect in another light, that some surfaces of the body do not so readily unite by exudation of the coagulable lymph as others do, and therefore on such surfaces there is commonly a much larger quantity thrown out than probably would have been if union would readily take place. Thus we see in inflammations of the heart that the coagulable lymph is thrown out on the external surface in vast quantities, while at the same time the heart shall not adhere to the pericardium. This extravasated matter is always of the same nature with that of the parts which produced it, which is a curious fact. If the disposition of the part is cancerous, the extravasated coagulable lymph is a poison, for on being absorbed it contaminates the absorbent glands, producing cancer; and probably the same takes place in every poison that is capable of irritating to inflammation and extravasation.

Appearances of adhesive inflammation.

—The part inflamed becomes redder than common, and redder and redder as it advances; the red being of a scarlet hue when the inflammation is healthy. The part becomes apparently more vascular in a natural state, and most probably is really so, both from new vessels being set up in the old parts, and from the adventitious uniting substance becoming vascular. These new vessels become of use both in the state of adhesion and of suppuration; in the first to give powers of action to this new substance which assist in preventing suppuration, in the second to form a basis for the future granulations. In consequence of this extravasation the parts swell, which is generally in proportion to the inflammation, the swelling being probably most where the inflammation is greatest, that is, at the point of irritation,

and it is gradually lost in the surrounding parts. The whole swelling appears like a part of the body a little changed, without containing any extraneous matter, and indeed is simply formed by extravasation of fluids, without their having undergone any material visible change.

Such inflammations as approach to the skin often produce vesications, which are filled with serum and often coagulable lymph, both which are sometimes tinged with red blood. This arises from the violence of the inflammation producing an apparent degree of weakness, approaching to a death, in the connexion between the cuticle and cutis, the life being in this part very weak, for in the beginning of mortification and of the putrefaction of dead bodies it is produced. This connexion of the cuticle is more or less destroyed in every inflammation of the skin. We seldom see an inflammation attack the skin but the cuticle comes off sooner or later. We generally observe it peeling off in flakes after the inflammation has subsided.

The pain attending inflammation would not appear to be in all cases very acute, for many have very visible inflammations which do not give very much pain. However, this will vary according to the violence of the inflammation, or rather according to the quickness of its progress and its approach to suppuration; for when there is a quick dilatation of the vessels, and rapid extravasation of the juices, the sensations arising from such will be increased; but in cases where its progress is slow, as from indolent tumours, the mind is hardly sensible of its progress. That it must sometimes be very trifling is shown by the fact that on opening dead bodies we often find strong adhesions where the friends of these persons had never heard during life of a single complaint. We also see cases in which this inflammation arises from violence, where it gives very little pain. A man shall be shot through the abdomen, and, if none of the contained parts are materially hurt, the adhesive inflammation shall take place in all the internal parts contiguous to the wound, yet no degree of pain is felt from this process. In many bruises and in simple fractures the pain from the inflammation is very trifling, although there may be much laceration of the parts.

Of the Uses of Adhesive Inflammation.—This inflammation may be said to arise in all cases from a state of the parts which they cannot remain in; therefore

an irritation of imperfection takes place. It may be looked on as the effect of wise counsels proceeding from a consciousness of imperfection: nature is taking all the defensive precautions possible, for in all cases we shall evidently see it answer wise purposes, such as checking the suppurative inflammation, by making parts adhere which must otherwise fall into that state; and where this effect does not fully take place, it acts as a check to the extent of it, as we see in circumscribed cavities. In the tunica vaginalis, after the operation for hydrocele the parts often collapse and unite to other parts of the same sac by adhesive inflammation, which prevents the suppuration extending over the sac, so that partial collections of water again take place. In still larger cavities, as the abdomen, where partial inflammations often take place, as after child-bearing or wounds of this cavity, we find this adhesion takes place, which either prevents suppuration altogether or unites the parts around it, and as the abscess enlarges the adhesive inflammation spreads, and thus excludes the general cavity. The same thing happens in inflammation of the pleura or surface of the lung. The cellular membrane everywhere in the body is united exactly in the same manner; the sides of the cells, as it were, sweat out the uniting matter, which, coming into contact with the opposite surfaces, joins them into one mass.

The lungs are subject to two modes of action in inflammation; being so circumstanced as to partake of the character of both orders of parts, the circumscribed cavity, and the secreting surface or outlet. The cellular membrane of the lungs readily admits of adhesive inflammation, like the cellular tissue elsewhere; but the inner surface of the air-cells, like the urethra, passes directly into the suppurative inflammation, and the matter which is thus formed is obliged to be coughed up. It is, perhaps, impossible to produce inflammation of the one without the other, which is, perhaps, the reason why inflammation of these parts is treated with such bad success.

We cannot give a better illustration of the use of the adhesions arising in consequence of this inflammation than to contrast it with the erysipelatous. How far this disease is to be ranked amongst inflammation I will not at present say; but it has some of the characters, as swelling, redness, pain, &c. The swelling arises, not from extravasation of coagulable lymph, but from serum: and it has other

peculiarities, as being generally superficial, and spreading along the surface with an abrupt edge, which is, perhaps, owing to its specific character being always confined to the part affected. It has nothing of the adhesive character attending it which was not necessary; because this inflammation being confined to the skin seldom produces suppuration. But it sometimes happens, when erysipelatous inflammation attacks deeper-seated parts, that it suppurates; and when it does so, it appears often to be a forerunner of mortification.

A man was attacked with an inflammation on each side of the anus. It had such an appearance as might have been expected from the suppurative and erysipelatous inflammations joined: it had an oedematous appearance. He was bled, and the blood appeared very sily: he took physic, and was fomented. The next day the inflammation had reached the scrotum, where a fluctuation, with a gurgling of air, was felt. I now made an opening near the rectum, and in the scrotum, and let out a quantity of dirty-coloured matter. It continued to spread over the loins, scrotum, bottom of the abdomen, &c., where I made openings, and out of which the cellular membrane hung like wet tow. In this case, the suppuration was diffused for want of the adhesive process preceding or accompanying it, by which means it would have been limited.

Adhesive Inflammation sometimes imperfect—Sometimes it happens that the adhesive inflammation is so imperfect that it cannot set bounds to itself, and still less to the suppurative. This may be owing to two causes; first, the violence of the inflammation and quickness with which suppuration ensues, that is, before the parts have sufficiently united; secondly, the inflammation may be, as I suspect it is, of the erysipelatous kind, especially when there is a tendency from the beginning to mortification. This mixture of the suppurative with the adhesive, or hurrying on of the suppurative, I have often seen in the abdomen of women who have been attacked with peritoneal inflammation after child-birth; and when these circumstances become the cause of death, we find matter mixed with coagulable lymph, as if formed together.

The adhesive inflammation also takes place in cases where it is impossible it should produce the same good effects; as in wounds which are not allowed to heal by the first intention, as a stump after

amputation, and many other parts. But it is one of those fixed and invariable principles of the animal machine, that, on all such irritations, the uniting process should be produced, although, like many other principles in the same machine, it cannot always produce the same salutary effects. So that although the wound is not allowed to, or cannot, heal by the adhesive inflammation, yet the parts go through the common actions consequent upon being wounded; first, they throw out blood, as if to unite the parts by the first intention; and then, the vessels contracting themselves, coagulable lymph, with serum, is thrown out, which has the effect, even in such wounds, of preventing a great extension of the inflammation, while the contraction of the vessels prevents the inflammation from running along their inner surfaces.

Effects of adhesive inflammation on the Constitution.—These effects are very slight, even when the inflammation arises from violence; but the effects of those inflammations which are indolent in their progress are still more trifling in the constitution. This arises from the slowness of the alteration produced in the part, as it were, insensibly stealing on the constitution.

We know that one effect of adhesive inflammation is the uniting of parts not intended by Nature to be united, and which must thus be made less moveable on one another; in fact, they must at first have little or no motion on one another, as occurs in the cellular membrane and circumscribed cavities: but it happens that motion is again obtained after a time by the elongation of the connecting part, which is effected by the repeated endeavours for motion. These uniting media are seen to become vascular. They are perhaps often the cause of many indescribable sensations, which cannot be called pain. In the heart they are the cause of palpitation, &c.

On the resolution of Inflammation.—Since an animal body can be made to act improperly by impression, we can see no reason why, when acting improperly according to such impressions, it should not be made to act properly by the same mode, namely, by impression.

The cure of inflammation is resolution, and an attempt towards it, when in the adhesive state (for this is intended to prevent suppuration taking place), must be in general made only under the following circumstances, namely, when inflammation arises constitutionally, or from dis-

ease of the part. In cases of accident where there is no exposure, as also where there is, but that exposure is removed in time by bringing the parts into contact, and where the life of the parts has not been destroyed, in all such cases we find that resolution will readily take place.

It is commonly supposed that there are a great many local inflammations which should not be resolved. An inflammation arising from a preceding indisposition in the constitution, commonly called critical, has always been classed amongst those which are not to be resolved; it has been insisted on that the inflammation should rather be encouraged, and suppuration produced. But in such treatment it is always under the idea that the inflammation is in such parts as will readily admit of cure when suppuration takes place; for if the disease is otherwise situated, the cure of the constitution by suppuration will be a mode of cure which will reflect back another disease on the constitution, under which it will sink; therefore resolution in such situations should, if possible, be brought about. Many deep-seated inflammations, if allowed to suppurate, will, of themselves, most certainly kill: gout also, in the head or stomach, should always be resolved, and left to settle in some other part less connected with life. If inflammation is really a concentration of the constitutional complaint, and if, by not allowing it to rest there, the same disposition would really be diffused over the whole animal again, and would be liable to affect some other more important part. Still it does not appear necessary that it should suppurate, for suppuration is only a consequence of inflammation; not an immediate effect of the original constitutional disease, but a secondary one. As suppuration, therefore, is only a thing superadded, and as we shall generally find that inflammation subsides as suppuration comes on, I see no reason why inflammation should not in the present case as well subside by resolution as by suppuration. It may, however be supposed, that as this suppuration is not a natural or immediate effect of the disease, yet as it is a continued local action, that it is capable of diverting the disease to the part. I hardly know an instance where inflammation from violence may not with propriety be resolved, and prevented from going into suppuration, except where it relieves the constitution from any prior disease. Thus, Mr. Foote was cured of a violent pain in his head by amputation

of his leg ; but he afterwards died with a different complaint in his head. Might not the first diseased action in the head be altered in this case, and an action of a different kind induced, which proceeded to the degree of effecting his death ?

THE MEDICAL JURIST.

No. 2.

INSANITY.

3. *The Passions.*—These, if indulged in, become habitual, and the state of mind which they induce is then little removed from frenzy. Children should be early taught to control the impetuosity of their temper. Undue severity, however, creates duplicity and cunning. The most injurious effects may be produced on a child of sensibility, by making a favourite of another. If there be great pride, such conduct may only induce dislike to home, but in some cases the sleep is disturbed, the spirit broken, and idiotism is the ultimate consequence. I knew a young man, says Dr. Traill, who was not acquainted with his father till he came of age, and a particular circumstance prevented the latter from receiving him as a son. His reason gave way. He is still alive, though it is twenty years since.

Anger produces flushing of the face, or if it be more violent, an ashy paleness with a glaring eye, dilated pupil, clenched hands, and quivering limbs. All these symptoms evince a tendency to congestion of the brain, and are dangerous in those who are subject to apoplexy, epilepsy, and other diseases of a similar nature. In a man, subject to fits of anger, whose head is bald, you can see the blood, during the paroxysm, gradually mounting over the scalp. Mental alienation sometimes shews itself, for the first time, in a fit of anger.

Sudden despair, fright, or horror, will sometimes produce insanity. Pinel says it sometimes occurred, during the French Revolution, in young persons, on witnessing the butchery of their parents. Dr. Traill saw a case of idiotcy from terror. The circumstances were the following :—some young persons in the country, talking in the evening of superstitious fears, a young lady declared so vehemently the impossibility of her being made to feel them, that the others determined to try. They accordingly borrowed a skull from a medical student ; put a cap on it ; and

placed it in her bed. When she retired, they crept up stairs to await the result. They heard no noise, and went to bed. Next day she did not appear at breakfast. They became alarmed ; and, on going up stairs, found her sitting up in bed, playing with the skull, and with the grin of idiotcy on her countenance. She never recovered.

Intense joy is sometimes a cause of insanity. I knew a gentleman, says Dr. Traill, who by some uncommonly lucky speculations, became suddenly affluent. He became excited, and thought he had discovered a plan, by which the naval superiority of England might be secured for ever. On my visiting him, he said he would make my fortune ; and wrote me an order on the Bank of England for ten thousand pounds, as an earnest of what he would do. He showed me an address to the prime minister, containing a plan for paying off the national debt. Some time afterward my poor friend died in a madhouse. Another gentleman had a passion for rare books, though he never read any. He also purchased the most expensive furniture and plate. The case went on to weakness, paralysis, and complete insanity at last.

Hope may cause insanity. Dr. Traill has known it produced by the anticipation of marriage.

Love, even without despair, has been known by Dr. Traill to produce insanity in both sexes ; and where the parties were of such excellent moral dispositions, as to make it evident the cause was mental and not physical excitement. Excess of sexual intercourse will sometimes produce it. A baronet married a lady of great personal charms, and soon became debilitated and epileptic from sexual excess ; absence from home, and the use of tonics, restored him. One of the most violent cases Dr. Traill ever saw, was from disappointment in love ; but in that case there was an hereditary taint in her constitution. Jealousy is a more frequent cause than love. A friend told Dr. Traill of a case, in which a woman cut off her husband's penis, as he lay asleep, in order to disappoint his ideal mistress.

Exposure to cold while heated, will sometimes produce insanity ; probably from repelling the blood from the surface of the body to the brain. Hence it is sometimes produced by catching cold during menstruation. This was the case with a young lady who drank cold water, and sat on the damp ground after a long walk, while the menses were present,

Her insanity became worse as the next menstrual period drew near; but after a while the flux returned, and she recovered. In another person the same cause might have produced apoplexy.

Hysteria long continued, sometimes degenerates into idiotism. The influence of the uterine system in this disease, is evident from the liability of females to insanity after parturition; especially if the lochia be suppressed. At puberty, and "the change of life," there is a determination of blood to the head.

Intemperance is the most common of all causes; especially intemperance in the use of spirituous liquors, which produces insanity in all its forms. Generally the first visit of person affected from this cause to an asylum is short; but they are soon brought back again, and the case ends in mania or idiotism. The story of the sailor who "treated resolution with a glass," is a common illustration. Instances of adhering to resolutions of abstinence, are very rare, though Dr. Traill has known several. He told a lady who indulged in secret drinking, that it would end in insanity. She thanked him with tears, and took nothing stronger than tea till her death. A man, who became suddenly rich, thought of nothing but eating, though without indulging in wine or spirits. It settled into a complete monomania.

Insanity has been sometimes produced by the large bleedings which were at one time much practised. Epilepsy and injuries to the head are also causes. Dr. Traill knew one man who went mad from vanity.

With regard to the treatment of insanity, we shall first consider the subject of asylums. One of the first objects to be attained, is sufficient ground for the buildings, and for separate yards for the different classes. These yards should not be overlooked, for exercise ought to be taken free from observation. The Glasgow Asylum is the best we have seen, but that at Perth is said to be a perfect model. There should be separate wards for convalescents, for epileptics, for dirty and noisy patients, and for persons of a better class. There should be long galleries, with sleeping rooms opening into them on one side, each furnished with a window, and with a ventilator above the door, to be shut whenever circumstances might require. These sleeping-rooms should never be called *cells*. At the Liverpool Asylum, Dr. Traill succeeded in banishing iron-bars from the windows; the

frames being made of cast-iron, with panes of glass only twelve inches by seven. These windows opened with a swing-sash, with a stopper to prevent their opening too far. The windows of the galleries should overlook only the yard belonging to that particular department. Each gallery should have a separate staircase, but they should all communicate, by doors kept locked, with the governor's apartment. Every gallery should have a room for eating and reading; and by putting convalescents in charge of the rest, it makes them very quiet. At Liverpool every gallery is provided with a bath, a scullery, and a water-closet. Water descends from a high cistern to a lower room, where it is warmed by passing through a boiler of hot water by means of a pipe bent into the form of a worm, which pipe afterwards rises into a room not so high as the cistern from which it originally descended. After the water has been once raised into the cistern, it finds its own way into the bath-room. Here the pipe should terminate in a cock, not to be turned by hand, but by the keeper's key. Cold water should be conveyed by another pipe, and thus a bath may be had of any temperature, and the patients will have no access to the fire.

If you can get a patient to work in the garden, or at anything else, it will be a promising symptom of recovery. Dr. Traill has a beautiful set of drawings executed by a patient, who had several relapses before they were finished, and one day threw them at the doctor's head.

The best form for an asylum is that of a St. Andrew's Cross. In Bedlam, which is of a rectangular form, the governor is at a great distance from many of the patients. The horrible abuses brought to light by the Parliamentary Report of 1815, were not confined to private asylums. All should be under the control of an active committee, and a good code of laws. Good temper, activity, and a stout frame, are indispensable for a governor. The beau ideal of a governor, says Dr. Traill, was the one at the Liverpool Asylum. I have often been surprised at his presence of mind when struck, or during sudden anger; and have always found him at his duty, at whatever hour I called; often reading to the patients, or playing draughts with them. His name was Owen. In that asylum a male never entered the female side, without the presence of a nurse or the matron. This is a necessary precaution; for in Yorkshire

several females became pregnant by male keepers and male patients. A nurse or a keeper ought never to be allowed to strike a patient. Dr. Traill often dismissed them at Liverpool because they could not restrain their temper. They were ordered to hold the offending patient fast, assisted by others, till the ward-bell brought the governor. Insubordination is generally offensive to the other patients, but sometimes conspiracies are formed. It is better not to require the assistance of patients; but in one case Dr. Traill would have been overpowered, had not the other patients secured the one who struck him.

Maniacs are not now kept, like wild beasts, in dark subterranean cells, chained, lying on straw, without change of raiment, and wallowing in their excrement. If any one should think this not to be a true picture, let him look at the parliamentary returns. Chains have been long abolished at the Liverpool Asylum, and instead of them leathern manacles are used for the wrists and ankles, when necessary. If it was necessary still further to confine the hand, a muff was employed. The strait-jacket is not used there now. If the patient is apt to strike, a leathern strap passes from the manacles to the back, which only allows the hand to reach the face, and this should always be permitted. If the patient kicked, the legs were joined together by a strap, which allowed him to take only short steps. The best way to prevent violence, is always to allow as much liberty as is consistent with safety; and especially to allow the patients to walk in the yards instead of confining them to the house.

Patients often reproach their friends with imaginary crimes. One used to upbraid his wife, when she visited him, with having put him into the asylum, in order that she might enjoy his property with her paramour. She was a woman of exemplary character.

Change of habits will sometimes cause insanity. One man, of very large size, says Dr. Traill, on turning baker, was so overcome by the heat of his oven, as to become maniacal. Owing to his attempts to injure the other patients, I ordered his hands to be secured; for which he owed me much ill-will. One day, while sitting on a bench, I observed him approach me sideways, till he was directly before me. His object was to seat himself suddenly on my thighs, and thus injure them with his great weight; but I slipped on one side, and bruised his buttocks on the seat. Had I expressed any irritation, his malady

would probably have been increased; but when he saw me sitting quietly by his side unhurt, he looked very foolish. we were ever afterwards good friends. He recovered, went on board a vessel as mate, and on one occasion, by his prudence, saved it from being wrecked.

In one asylum, the plan of which has been approved by parliament, there are to be sleeping-rooms on each side of the galleries, but this will cause the latter to be dark, as they can only be lighted at one end. The panes of glass in the windows are small, for the patients are apt to throw their shoes, and other articles, through them; and if the panes are large, the mending of them becomes expensive. At Liverpool they cost only one and two-pence each. In the water-closets the water should not be at the command of the patients. In one case, where the water was let in by a hinged seat, a patient was observed amusing himself by exhausting the cistern, by alternately rising and setting down. The basin should be deep, and furnished with a "stink trap;" and the keeper, by means of a key, should let the water through it, every three or four hours. The pipe which leads from the basin should not be large, for if so, patients are apt to stuff their clothes down it; and an instance occurred of a patient's making his escape through the water-closet; so that an iron bar was obliged to be put across it.

The scullery is to allow the patients to wash their hands at pleasure, which is very desirable after exercise, &c. If a patient be so manacled as not to be able to wipe the nose, or the perspiration from the face, he complains of it bitterly, if of cleanly habits; and it is only in a few cases of mania that it can be necessary. If a patient be very violent, he should be put to bed. The bedstead should be made of deal, six feet three inches long, by four feet two inches broad, sloping towards the middle, where there should be a leaden gutter, leading into a vessel to contain the urine. Let him lie on straw, over which a blanket and sheet are thrown, or one of either. There must be staples at the sides, flush with the surface, to receive straps from the manacles and leg-straps. If they attempt to abrade the skin over the sacrum, by raising the buttocks frequently, Mr. Owen keeps the latter down, by a strap passed over the thighs. Spring-locks are better than buckles, being fastened more quickly. They should be opened only by the keeper's key. The strait jacket makes the

patient hot, oppresses the breathing, and prevents his wiping away the perspiration. If the patient requires to sit up, put him on a bench or chair, with a strap passing round the middle. When Dr. Traill went to the asylum at Liverpool, he found a young lady mad from disappointed love; and so furious, that she was kept strapped on a close-stool, where she sat laughing and drumming with her heels. If let loose, she butted with her head, and attempted to bite. Three nurses were required to put her to bed. She liked one girl who fed her. They gave her a ward to herself, and let her loose, with her arms confined by a muff. She at first butted against the Doctor's stomach, and then blew a feather along the floor for an hour. They left her alone, upon which she went to the window, and seemed amused by the passengers. She soon left off butting with her head; was allowed, at the end of a month, to associate with the rest, and through kind treatment, and the removal of restraint, became quite decorous. She is now removed to the house of her friends, and though quite an idiot, walks about, and takes her meals with the family.

Dr. Traill never tried the whirling-chair, which he does not consider safe, on account of its causing determination to the head, and sensations like those of seasickness. Pinel recommends the douche, and the French employ it very much. It suddenly confounds the patient, and stops his violence, and is therefore a valuable remedy in maniacal excitement. Fear cannot be recommended as a means of quieting patients, for we have no means of proportioning its violence. Pinel, however, gives many cases of good effects produced by it, and these might be obtained perhaps, if we had better means of regulating the degree of it.

Without classifying the patients, there can be no hope of curing them. The parliamentary returns show that up to 1818, some asylums annually bled and phsyicked the patients, a ward at a time. This was routine of practice with a vengeance, but it is alleged of a celebrated practitioner. When a patient requires to be secured, it should be by an overwhelming force at once, and without noise or anger. If he should refuse to eat, and has not been accustomed to drink out of the double-spouted mug, he will smile at the idea of making him swallow, and you must then put that measure in force. He will generally open the mouth, after holding the breath a long while, if

not, it must be prized open with the key. It is never necessary to break a tooth, and the operation is so disagreeable to the patient, that he will generally avoid it in future. Sometimes the governor must be peremptory and indignant, but never in a passion, or it will ruin his influence with the patients. The medical attendant should treat him with great respect, as should also the servants. Uncontrolled power, however, should not be left in the hands of any man; and the official visitors, or the committee should enquire into all the details, and the conduct of the officers. The servants should be under the entire controul of the governor, as they are apt to be very troublesome. They should not be allowed to subject the patients to any restraint. It is of great advantage to employ convalescents in household occupations. Patients are seldom cured at home, and the visits of friends have often made them agitated, and increased their delirium. Sometimes after having remained quiet for months in an asylum, the mania has returned in two or three days after their being at home.

EPIDEMIC DYSENTERY AT TAUNTON.

To the Editor of the Medical and Surgical Journal.

Sir,—The town and neighbourhood of Taunton have for some weeks been visited with an epidemic, more widely extended in its assaults, and at the same time more fatal, than has occurred within the memory of the oldest inhabitant, and, according to its degree of severity, and as this or that portion of the intestinal canal was affected, assuming the character of cholera, diarrhoea, or pure dysentery—this latter being the more frequent form. It is my intention to draw up as concise and accurate an account of its rise and progress as it is in my power to do, indulging in as little speculation as may be; and if you agree with me in opinion that such an epidemic should not pass without being recorded, you will oblige me by inserting it in your widely circulated journal.

Solitary instances of bowel complaint appeared as early as May and June, and throughout July, but these for the most part yielded readily to medicine, and it was not until the beginning of August that the disease became so frequent as to be regarded as an epidemic, or so fatal as

to attract much attention. At this time children and elderly persons were the principal subjects of attack, but after the first fortnight all ages and both sexes were equally affected. Children and the aged, as might be expected, sunk most readily: the former frequently on the second and third days. The ordinary duration of the disease was ten days or a fortnight, but relapses were exceedingly common, and several who were considered convalescent, and sitting up, were suddenly seized with faintness and rapid sinking of the vital powers. All classes seemed to suffer indiscriminately; but of course the bad clothing, poor food, and wretched habitations of the lower classes aggravated the character of the disease in them, and the sthenic, the usual type, was in them more frequently converted into the asthenic, and bore a striking resemblance to the epidemic which prevailed in Dublin in 1826.

I have heard of no sufficient evidence that the disease was communicated from one person to another, but I can easily imagine that the extremely offensive effluvia from the evacuations may have produced it in some; as in my own person the examination of an evacuation almost caused vomiting, and did in the course of an hour or two act on my bowels as fully as a large dose of castor oil usually does, but there it stopped.

In most instances the complaint commenced suddenly, without premonitory symptoms, like a common diarrhoea; the stools being copious, feculent, and their discharge attended with griping pains; these continued a few days, and in many cases constituted the whole disease. More frequently, however, the demands to stool became more urgent, with most distressing tormina and tenesmus, and with a fixed pain in the iliac regions, and along the arch of the colon, increased on pressure. The stools now contained little more than a jelly-like mucus, mixed with blood, the latter often in great quantity; the skin was hot, especially over the abdomen; the pulse increased in frequency and hard; tongue coated, with red tip and edges, but in the worst cases it had a red and raw appearance; the thirst was excessive, and the urine scanty, high-coloured, and passed with pain and difficulty; languor and depression of spirits. In the more advanced stages of the severe cases, shreds of membrane were frequently seen amongst the fæces, dark and very offensive,—in one instance which fell under my observation to so great an extent, that a large portion

of the canal must have been denuded of its mucous coat, and the fætor was altogether gangrenous. All the symptoms of the complaint exhibited periodical exacerbations, and in a few there were perfect intermissions.

Although the pathological condition on which the symptoms of diarrhoea and dysentery depend is now pretty well known, namely, vascular congestion and inflammation of the mucous membrane of the intestine, it is much to be regretted that out of the numerous deaths during the late epidemic not one post-mortem examination has yet been made; we can only therefore assume that the ordinary appearances would have been observed here; these, however, the symptoms during life pretty closely indicated. The fact of many cases having yielded at once to stimulants and tonics does not at all disprove this position; for, as by these means states of chronic inflammation are often removed, so also by the same means incipient stages of inflammation are frequently cut short, or rather I should perhaps say, states of vascular engorgement bordering on inflammation, are removed, but this mode of treatment, I apprehend, will not often be ventured on.

As to the cause of this epidemic we continue in much the same state of ignorance as we ever have been with regard to epidemics in general. We may remark that it was preceded by an unusually hot and dry July; but here we must rest. During its continuance we had every description of weather, and the wind from all points of the compass; as to the existence of noisome smells, or other changes in the atmosphere appreciable by our senses, they are not sufficiently constant to be attended to.

The disease is now evidently on the decline, few fresh cases comparatively having occurred for some days. It is not possible to ascertain the exact number of persons who have been attacked, but we shall be able to form a tolerably correct estimate from the number of deaths which have been registered in the different registry offices, and then ascertaining the average mortality in the practice of the different medical men. Proceeding on this principle it would appear that upwards of two thousand persons have been affected with this disease. This, however, is obviously understating the number, for there were a great many who, from being only slightly affected, or other causes, did not apply to any medical man for advice. There have been registered in the St.

Mary's and in the Trull districts up to the present time seventy-two deaths, sixty-eight of which occurred in the former. I have endeavoured, though without success, to obtain from the registrar of the St. James's district, the number registered by him; but I have reason to believe that they, at least, amount to twelve, in all, therefore, eighty-four. The concurrent testimony of all the medical men with whom I have conversed leads me to fix the average mortality at one in twenty-five. This would give 2,100 as the number affected with this disease; if we suppose that four hundred, which is not probably beyond the mark, have not applied for relief, then 2,500 have suffered; affording sufficient evidence of the widely spread influence of this epidemic. I shall exhibit the ages of the victims in a tabular form at the foot of this paper.

In the treatment of this epidemic many and opposite modes have been pursued. Astringents, sedatives, and the more strictly antiphlogistic system, have each had a trial; and, as might have been expected, specifics have, in not a few instances, been looked for, and said to be found; but I apprehend that it will be nearer the truth to admit that, in most cases, (that is, those amounting to dysentery,) the disease held on a certain course, the symptoms only being mitigated by the treatment adopted.

Astringents have been largely tried, and if not injurious they certainly did not expedite the cure; when given in simple cases of diarrhœa in the very onset, and followed by the strictest attention on the part of the patient to diet, confinement, &c., they were not unfrequently successful.

The treatment by opium and its salts has been, perhaps, that most frequently had recourse to, and this probably as much because the practitioner had observed the tendency of the disease to run a certain course, as from the relief it afforded to the sufferings of the patient. To one who had been ill many days, passing very dark and horribly offensive stools, full of shreds of membrane, with a raw, red tongue, small, frequent pulse, and excruciating pain over the whole abdomen, I gave first three, and afterwards two grains of solid opium every second hour, with great benefit; all the symptoms improved, and this patient, as bad or worse than any I have seen, will, I think, eventually recover.

The acetate of lead has been frequently and largely exhibited both by the mouth

and injected into the rectum, and, undoubtedly, in many cases with much relief: but wherever I have prescribed it, I have rather attributed its beneficial operation to its sedative than astringent powers; the frequency of the calls to stool was much lessened, but I always found that after its use, very large and dark evacuations took place. It seemed to me to allay the irritability of the muscular coat of the intestines, and thus to allow of their retaining the secretions poured into them, not to lessen or restrain the secretion or exudation of the fluids.

Mercury, to produce its specific effects, has not been much used, and contradictory estimates of its powers have been formed. Dr. Kinglake informs me that it is the only remedy which has appeared to him to modify, or in any way affect the course of the disease; while another practitioner says that he has carried it to salivation in two cases without benefit. I have only given it in small doses where I suspected derangement of function in the liver.

The treatment which I have myself pursued has had a strict reference to what I believed to be the pathological condition of the parts concerned, determination of blood to the mucous membrane, and not seldom inflammation, and I have not been disappointed in the result. In the slighter cases, confinement to bed, small opiates, with ipecacuanha, and occasional laxatives, castor oil, with a few drops of laudanum, and the lighter food, were all that was required; when there was fixed pain, leeches and blisters were applied; but wherever the symptoms from their violence indicated, blood was taken from the arm, which, both in my experience and in that of others, was always buffed. For the relief of the violent paroxysms of pain, which often assumed a cholicky character, sinapisms or turpentine epithems were very successful. Anodyne enemata did not, in my experience, afford that relief I expected.

I cannot conclude, without expressing my thanks to my medical brethren here for the readiness with which they have imparted to me their observations on this epidemic, and for their testimony that the above sketch coincides with their experience.

CLINICAL REPORTS.

EDINBURGH INFIRMARY.

MERCURIAL DISEASE

M. R., is the wife of a looking-glass maker, whose duty it is to "silver" the mirrors, as it is called, with mercury. Her father's trade is the same, and from her earliest years she has been accustomed to assist in the business. Four years ago, after sleeping in a damp bed, she was attacked with pain in the head, back, and all the large joints; but the only parts in which they are now felt are the knees and legs, where their severity is very great, but is not increased on pressure or motion. Various remedies have been tried without benefit. For the last twelve nights she has taken every night an opiate draught, together with a quantity of spirits, amounting latterly to several glasses. This practice has much injured her stomach, and she is now troubled with nausea, vomiting, flatulence, pyrosis, anorexia, and other symptoms of indigestion. On the head, shoulders, and legs are the cicatrices of ulcers, which broke out six years ago, and continued open for two years. (On the forehead are two or three prominences, which feel soft to the touch. She has constantly a bad taste in the mouth; her teeth are rather black, and the salivary secretion is sometimes increased, but never to any great extent. The gums are sound, and were only once sore from some pills which were prescribed while the ulcers remained open.)

This patient stayed in the hospital only ten days. The treatment consisted of a warm bath every other night, a pint of compound decoction of sassa-parilla daily, a scruple of Dover's powder every night; slight perspiration was produced; the pains were somewhat alleviated, but she went out of her own accord, not materially relieved.

No. 24.

Clinical Remarks by the attending Physician.

This patient has been exposed to the fumes of mercury, by which her health has become affected, and her bones diseased. The prognosis is very bad. She has cough, and though she has no other symptom of phthisis, we fear it is commencing. It is very apt to occur in such cases. She has dyspnoea, but only occasionally. It is of an asthmatic nature, and we meet it, when it occurs, with an antispasmodic. The pains follow the course of the long bones, on which irregularities are felt. One of the tumours on the forehead has burst, and the bone is felt to be rough at the bottom of the wound. In the manufactory in which she has worked, two other persons are similarly affected, and in other manufactories many more. Whether the ulcers which burst out six years ago were mercurial it is not possible to say, but as they were very numerous it is probable they arose from the constitution being diseased; and such a constitution may unquestionably be produced by mercury, as is seen when it is used for the cure of other diseases. These ulcers were very obstinate, for they continued open for two years, which is another proof of a bad constitution. Some people think they cannot take too much mercury for syphilis, and they continue it too long, which is very apt to give rise to an affection of the bones. But this is widely different from banishing mercury altogether. Before it came into uses syphilis robbed many people of their noses. In the case before us disease did not take place till the patient caught cold from a damp bed. Without this primary cause the secondary cause (the injury which the constitution had sustained from the mercury,) would not have been sufficient. If similar combinations of causes were taken into account in disputes it would draw the teeth of medical acrimony. Some, for instance, affirm that certain diseases are contagious, others that they are not. I believe that they are so sometimes, and that a predisposition is necessary to their being communicated. Cases of small pox frequently occur which we cannot trace to exposure to the virus, but we do not doubt that such exposure has really taken place.

A humour was found in the neck, which I thought might be connected with the disease of the scalp. I therefore ordered the head to be shaved, and it was found to be covered with small tumours. From

3 c

these matter had been absorbed, and had given rise to swelling of the glands in the neck. I fear the bones of the head are hopelessly affected. We are giving sarsaparilla and nitric acid, both of which are recommended for disease of the bones, and likewise for syphilis. The pain and frequent attacks of dyspnœa we relieve by opiates. She was too fond of the latter before admission, and washed them down with whiskey, though she has not the appearance of a dissipated character. Last night she was seized with so severe an attack of difficulty of breathing, that the surgeon was sent for to perform tracheotomy. He did not think it proper, however, to do so, and no doubt he was right, for the dyspnœa in this case is not produced by a cause which demands that operation. Where organic disease exists of a nature to interfere with respiration, the patients are liable to spasmodic attacks, and then we must not trust to their going off spontaneously, for in two such cases the patients died suddenly, when they might have been saved by tracheotomy.

We have given diaphoretics to determine to the skin, but we have not a mere febrile state of a general nature to deal with, for there is evident determination to the chest. We have applied leeches, and are now trying tartar emetic ointment, which is a form of issue. Before I resorted to this ointment I used to apply repeated blisters in such cases, for I prefer them to issues. I have here no hope, however, of curing the lungs. Tubercles probably are already formed, from repeated inflammatory attacks, and these attacks were probably occasioned by tubercles already existing.

MADRAS NATIVE INFIRMARY.

Communicated by W. Rose, Esq., Assistant Surgeon to the Madras Army.

My dear Sir,—To the kindness of my friend Mr. Lawder, who always feels sincere pleasure in communicating to the Junior Medical Officers of the army, the results of his long and scientific career, I am indebted for extracting, from the Records of the Madras Native Infirmary, this and several other cases equally interesting, which I shall feel much pleasure in forwarding to you from time to time.

With the case I send you a preparation of about ten inches of the ileum, which

you will find perfectly filled with lumbrici, I have the honour to remain,

My dear Sir,

Yours very truly,

W. ROSE.

[We have received the preparation from our valued correspondent, M. Rose, and consider it a very valuable one. We are also much indebted to him for his instructive clinical reports, which are ably drawn up, and show Mr. Lawder to be a most judicious and scientific practitioner. Mr. Rose is also entitled to much praise for his transcription of the cases, as well as for his original reports, which we shall publish.]

TETANUS FROM WORMS.

Pungan, native of Madras, aged fourteen, of a thin spare habit of body, was admitted into the Native Infirmary, under the care of J. Lawder, Esq., Surgeon to that institution, at two o'clock, P.M., on the 15th June, 1835, complaining of severe griping pains in the abdomen, accompanied by very frequent and spasmodic contractions of the muscles of the lower extremities, which rendered them so extremely rigid that flexion of the joints was impossible. He lay with his legs extended, the abdomen was very tense, and presented a considerable convexity; the spine much incurvated during the paroxysm; the whole weight of the body supported by the occiput and heels, exhibiting a strongly marked case of *Opisthotonos*; so much so, as to leave considerable space between his back and the bed. The spasmodic contractions of the muscles of the upper part of the trunk were very severe, particularly those of the jaws, which were firmly closed. However, as soon as the paroxysm subsided, he could immediately open his mouth, and the temporal, masseter and buccinator muscles were before very rigid and tense, now became perfectly relaxed and natural. Tongue white and furred; thirst urgent; constant sickness of stomach; bowels obstinately constipated for the last fourteen or fifteen days; urine scanty and high coloured; skin hot and clammy; respiration hurried; pulse frequent and small.

The previous history of the case could not be satisfactorily collected from the parents, but from what I could ascertain, this poor lad had been gradually pining away for some months; the paroxysms, which were at first rare and mild, have latterly become frequent and much more severe, and the abdomen has been for several days tense and painful.

From these symptoms, and more especially from the relaxation of the muscles of the jaws during the intervals of the paroxysms, from the long time that elapsed between the commencement of his illness and his admission into the hospital, from the absence of that violently shooting pain from the Ensiform cartilage to the spine, indicating the spasmodic contraction of the diaphragm, which invariably attends idiopathic tetanus, from the absence of that peculiar perspiration, which is generally present in true locked-jaw; and from having before observed one or two similar cases since I have been placed in charge of this hospital, I am led to think that this is not a case of genuine tetanus, although represented to me as such; on the contrary, I suspect very strongly, that worms in the intestinal canal is the sole cause of this disturbance.

Tinct. opii. m. l.

Aq. ment. pip. ʒss. m ft haustus omni hora repetendus nisi stupor superveniat.

16th, 7, A.M.—Bowels opened during the night; a quantity of slimy mucus appears in the evacuations, which is an additional proof of the existence of worms; slept a little; spasms continue the same.

Rep. haustus and enemata—et perop-time infricetur abdomini Linimentum infra prescriptum.

Ung. hyd fortioris,

Tinct opii, aa ʒss. m.

11 o'clock, P.M.—Continues in the same state; bowels opened by the medicines; some indurated feces together with slimy mucus appear in the evacuation.—Rep. med.

Half-past 12, P.M.—Spasms continue and increase in frequency; countenance ghastly; eyes sunk and hollowed; intervals between paroxysms very short; bowels opened twice; evacuations same as before. During the visit a violent paroxysm came on, which attacked the muscles of the entire frame, and lasted but a short time, nature sinking in the

struggle, and death relieved the unfortunate boy from his sufferings.

Autopsy six hours after death.

Limbs much wasted; abdomen very tense; the arched form of the back very apparent; muscles exceedingly rigid, and on cutting through the common integuments, appeared more florid than usual; the small intestines presented a very peculiar appearance, and were arranged in several longitudinal folds, with slight indentations between them, and communicated to the finger a sensation as if they were filled with small cords. On slitting open a portion of the jejunum, it was found actually distended with lumbrici coiled together several of which were six, seven, and eight inches long, and filled up the whole length of the small intestines so completely as to render it impossible for anything to pass except fluids, which were actually filtered through them.

The natural contraction of the intestine only tended to produce a greater impediment to their passage by forcing them downwards one against the other, and then producing a mechanical obstruction to their expulsion. This was particularly observed at the valve of the colon, through which I endeavoured to force some of the worms, but failed in the attempt, showing to a demonstration that no medicine could have accomplished their evacuation per anum.

The large intestines were in a collapsed state.

This is a case of peculiar interest, proving how readily a disease of this kind might be confounded with true or idiopathic tetanus.

J. LAWDER.

The London Medical

AND

Surgical Journal.

INFLUENCE OF THE MEDICAL PRESS.

THE lives of public men, even the most virtuous and the most exalted, are not exempt from censure, neither do they escape the voice of calumny or reproach: this is

he boon to which they must submit, and the man who voluntarily exhibits himself before the public, whatever be his calling, or he who becomes a servant of that public, may glut his ambition, or gratify his vanity; but he must also be fully aware that he cannot, at the same time, avoid public censure. It is from this freedom permitted and sanctioned in the discussion of the characters of public men that the "Liberty of the Press" has had the happiest influence on society, upholding what is praise-worthy and what is good, exposing and condemning what is base, unprincipled, and corrupt.

The Press has been a powerful engine, and it is not to be wondered at that the public journals have been, and ever will be, the objects of terror and of hate to those individuals whose public conduct will not endure the light of truth. Our Houses of Parliament, our Courts of Justice, daily exhibit the salutary influence of public animadversion on the conduct of members of those bodies; and it is impossible to deny the beneficial influence which censure, especially that which emanates from the press, has on the conduct of public men, especially those in the atmosphere of political life, where the most hideous and selfish passions of human nature are so much excited. With this "freedom of the press," and with its well known influence in this country on men in all departments of public life, it appears almost paradoxical that it is only of late years the conduct of those members of the medical profession, who hold official situations in our public charities, should never have been the subject of public animadversion, until the publication of the *Lancet*. Before that memorable epoch, surgeons and physicians of our hospitals might not only have been guilty of gross neglect of duty, but experiments might have been made on any

number of the sick poor, and which might have been even the cause of death, without the slightest notice being taken of such conduct by the governors of these charities. There were then no Courts of Conscience, no Courts of Justice, no "Guardians of the Poor," no Committee of Governors to protect the sick against the most monstrous abuses. Since the interests, comforts, and even the lives of the sick poor, and the portal of our public hospitals have been guarded and protected by all the vigilance of a literary Argus, not only have some of the most formidable abuses been remedied, but an incalculable benefit has arisen to medical science by the junior branches of the profession being enabled to profit by the errors and blunders of their seniors. So much so indeed have the changes in the discipline of our metropolitan hospitals been within these few years, that a student of the present generation would scarcely credit any account, however faithfully narrated, of what the charitable institutions of the metropolis were thirty years ago.

We have been led to make these remarks in consequence of the proceedings which are now taking place at the North London Hospital, a Committee of the Professors of University College being occupied in the investigation of a case which not only deeply involves the interest of that school of medicine, but which involves the honour and integrity of one or other members of that body, as well as our veracity as editors of a public journal.

In a former number we gave an account of an operation of Lithotomy, which was performed by Mr. Liston, on Monday the 26th of June last, the patient having been admitted only on the preceding Saturday; the short time allotted for the necessary preparation of the patient, urg-

ing us to point out, especially to the junior members of the profession, the great danger of operations when a careful and protracted system of previous treatment had been neglected. We also stated, that the percussor entered with a sudden *jerk*—that two stones were found in the bladder, which were broken down, and only small portions removed,—and it has since been proved, that the fluid which was injected into the bladder to facilitate the operation, did not make its exit by the urethra. We further stated that the patient died on the fourth day after this operation—that the dissection of the body, contrary to the established rule of the hospital, was performed *privately*, and the contents of the pelvis were removed, by Mr. Liston's special directions, to his private dwelling. Whatever opinions may have been entertained of the death of the unfortunate patient, and whatever murmurs and whispers may have been made by the students, in their anxiety to know the real cause of the patient's death, and the appearances on dissection, yet day passed away after day, and week after week, without the slightest notice of this highly important case having been taken by that Journal where the puffings of Mr. Liston have always found a ready welcome, until Mr. Liston delivered a Clinical Lecture on the 19th day of August, the operation having been performed on the 26th of June, an abstract of which was sent by him to the *Lancet*, and published in that Journal, having for its title "*LITHOTRITY—MIS-MANAGEMENT WITH A CATHETER—DEATH.*" The account of the case published in the *Lancet*, and the account given by Mr. Liston in his Clinical Lecture, give such a very different statement of the circumstances connected with this operation and subsequent history of the case, that in order that our readers might

form a just estimate of the conflicting statements, we ventured to copy from the *Lancet* Mr. Liston's own words.

The imputation which Mr. Liston's statement contains on the character of the student who had been acting as House-Surgeon, did not fail to excite the attention of the members of University College as well as the medical officers of the Hospital, and we have much satisfaction in stating, that they have considered it their duty to institute an inquiry, and endeavour to ascertain by an impartial examination of evidence, all the facts connected with this mysterious affair.

We will not farther allude to the important truths which have been elicited by the examination of the different witnesses, though the minutes of the committee are open to public examination. But in justice to the individual for the protection of whose character the Committee especially met, as well as for the reputation of their College, we shall merely state that our account of the operation has been proved by that evidence to be in every respect correct, and that the Committee have compelled Mr. Liston not only to produce the preparation before them, but they have also claimed it as the property of the Hospital.

We stated in our Number for August 19th that we should refute Mr. Liston's calumnious attack on the veracity of our report, and we might have done so at the moment, had we not thought it wiser to allow the Committee of the Hospital to do so and spare us a disagreeable duty. We now leave him to his own reflections on the matter; but beg to assure him, that fearless of his attacks in his clinical lectures for recording truth, we shall continue to publish his unfavourable as well as favourable cases, just as we do those of every other hospital surgeon in London, as examples of the present state of

operative surgery in this metropolis both for the instruction of our junior readers, and the edification and admiration of all surgeons both at home and abroad.

The liberty of the medical press, shall not, so far as we are concerned, be troubled by Mr. Liston or any one else.

REVIEW.

Histoire Des Maladies Observées A la Grande Armée Française, Pendant les Campagnes De Russie en 1812 et D'Allemagne en 1813. Par le Chevalier J. R. S. DE KERCKHOVE. Anvers. 1835. History of the Diseases observed in the Great Army of France in Russian and German Campaigns of 1812 and 1813.

The work of which we here present a sketch to our readers, is from the pen of De Kerckhove, or De Kirchoff, who held one of the highest and most responsible appointments in the Medical Staff of the French Army, under Napoleon. Its object is to detail the history of those diseases which prevailed in the great army of France during the campaigns of Russia in 1812, and of Germany in 1813. The favourable reception it met, and the high character of the book, are fully attested by the fact of its having run through three editions. The author has divided the work into two parts; the first containing general considerations both of a historical and medical character, and a fund of information of a most interesting description, relative to events which have exercised the most powerful influence over the destinies of Europe, and have produced changes of the most extraordinary and unexpected character in the moral, physical, and political state of the principal kingdoms of the civilized world. In this part of the work the reader will find a most satisfactory account of the commencement, progress, and melancholy termination of the disastrous expedition to Russia, "which contributed to hurl that man of prodigies, Napoleon, from a throne attained with too much bloodshed, sustained with so much glory, and forfeited through so much infatuation, a degree of infatuation so glaring and so palpable that, to the dispassionate and cool reflector, it now appears to have been actually infused through the immediate in-

tervention of Divine Providence itself, justly incensed at the outrageous and wanton sacrifice of human life which this extraordinary man hesitated not to make for the purpose of indulging and gratifying that inordinate and all-grasping ambition which, not satisfied with so many and so sanguinary victories over his fellow-creatures, aspired to the terrific undertaking of warring against the very elements, and which ultimately overwhelmed him, "when the meteor of conquest allured him too far."

The author's chief aim is to render himself useful to his professional brethren by detailing the most important observations collected by him during this disastrous war, a war which equals the most surprising and extraordinary expeditions of antiquity.

He set out from Mayence on the 6th of March, 1812, as Army-physician attached to head quarters. When he arrived at Posen, he was sent as physician to the head-quarters of the third corps, commanded by Marshal Ney; with this corps he entered Moscow on the 14th of September of the same year, and left that place, with the same corps, on the 19th of the following month.

On his return to Berlin in the commencement of February, 1813, the third corps being disorganized, he again entered head-quarters. On the 4th of June he received another appointment at Gortz, being attached as physician to the head-quarters of the second corps, under the command of Marshal Victor, which he joined at Grunby, in Silesia. With this corps he re-passed the Rhine after the battle of Hanhan, and quitted it at Mayence, to take the hospitals of this place in charge. From this active service we must be inclined to receive with more confidence the communications and observations contained in his work, than if they were the mere reveries of speculation in the closet. The author states that in presenting to the public in this work the result of the experience obtained by him in the field of battle as well as in the hospitals, his chief care is to draw up his cases and remarks with zeal and fidelity. He also makes a statement to the justice and importance of which every practical physician will readily subscribe, namely, that the medical practitioners should profit as well by his errors as by his success; and should as near as possible conform to the precept given by Baglivi:—*Neque ab antiquis, neque a novis sed ubi veritatem colunt et sequor.*

"The medicine, or clinical medicine, of observation is," he says, "the true medicine; the more we deviate from the rout traced by the fathers of medicine, the more liable are we to fall into error. Zimmermann was right in saying that medicine took its rise from observation, that it is observation which conducts it to perfection, and that it is for the want of it, that it is sometimes nothing but a mere unmeaning jargon. To proceed successfully in practice, we should not lose sight of the physical and moral constitution of the patient; we should direct attention to the character, course, and causes of the disease; we should assist nature instead of wishing to direct her. Fortunate it is, if soundness of judgment and simplicity of method direct the therapeutic means of the physician. We should adhere to those principles, the correctness of which is immoveable, and be upon our guard against the spirit of system. Nor should we be led away by the fascinations of novelty, nor abandon ourselves to the enthusiasm which such novelty so readily gives rise to, and which accounts for the ardour with which every new theory, however absurd it may be, is generally received by so many proselytes. Nor should we be the blind followers of those systems engendered by an excited imagination, but should always hold in remembrance the maxim of one of our great masters in the art of healing, *ars medica tota in observationibus*."

Our author gives a caution here applicable in all countries, and of which all medical practitioners would do well to profit by, namely, not to imitate the example of those physicians who have a medicine for every symptom, and vary their prescriptions every hour in the day, and also to beware of the practice of those who, without paying any regard to climate, and without establishing distinctions between diseases, sexes, ages, temperaments, and constitutions, adapt their treatment to some particular routine system which may be in vogue at the time; whilst others again begin the treatment of every disease indiscriminately by giving an emetic or purgative mixture, followed by some enemas, under the ridiculous pretext of *clearing out the body*. "It is," says our author, "to such practitioners, who have but one treatment for all diseases, that the satirical descriptions of Pliny, Moliere, Rousseau, &c., will justly apply, not to the genuine physician. Initiated in the sanctuary of Epidaurus, and capable of studying the mysteries of

nature." I have invariably perceived," continues our author, "and it cannot be repeated too often, that to see medicine shine with *eclat* and with all its advantages, we must, by carefully investigating the constitution of the patient, the causes, nature of the attack, character, and progress of the disease, aim at simplicity in the treatment. Nothing is so true as the assertion, that by going through the hospitals we are sure to find most success in those, where the practitioners, studying nature in diseases, adhere to simplicity in their prescriptions. . . . The physicians should place hygienic means in the first rank, and not forget that in many cases, particularly in fevers, prudent expectation often succeeds better than the employment of drugs, as most frequently the cure is the work of nature. This assertion is sufficiently proved by the frequent example of the poor and destitute, who recover without doing anything, and that in the midst of circumstances the most unfavourable." Whilst we are ready to go a certain length with our author in these views, and to agree with him to a certain extent with respect to the advantages to be derived from observing simplicity in the treatment of disease, we would not be understood to advocate indiscriminately the method of expectation in the practice of medicine. We know full well that the sthenic and active diseases of our climate, as well as the habits and robust constitutions of the people, would by no means admit of it. In concluding the introductory part of his work our author wishes it to be understood that, in maintaining that the medicine of observation is the true method, he has not the least intention of denying or disparaging the utility of the sciences with which the healing art is connected, and which are tributary or ancillary to it; it is, he acknowledges, absolutely necessary to cultivate them in order to observe with advantage, as they assist us in accounting for the phenomena which present themselves in the nature of man, and they serve as a guide to conduct us through the darkness of therapeutics. It is necessary that the physician should establish the basis of his experience and observation on the knowledge of anatomy, physiology, chemistry, materia medica, and pathology. However, he says, whatever be the relations of medicine properly so called, with the different sciences connected with the knowledge of man; whatever be the aid which it borrows from the sciences with which it communicates; whatever be the lights which it may have

obtained, or may now obtain from them, it will still be certain that practical medicine rests essentially on the direct observation of diseases.

We shall not attempt to follow our author through the first part of his work which is far more adapted to historical detail than medical analysis. We shall therefore proceed forthwith to the second part, which treats of *Disease*; and first, of what our author calls (chap. i.) *embarras gastrique*. This was a very frequent affection in the French army, owing to the coarse and bad quality of the food, and to the irregular manner in which the army was fed. It presented in general the following symptoms.—loss of appetite; lassitude, and sometimes wandering pains in the limbs; a feeling of general illness; a feeling of constriction or of pain in the precordial region; head-ache, more or less severe; bitter taste in the mouth; tongue covered with a whitish or yellowish coat of mucus; borborygmi and flatulence; nausea, sometimes vomiting, sometimes diarrhoea, colic, and tension of the abdomen: this gastric disturbance was connected with a more or less marked affection of the liver; the tongue was then covered with a greenish-yellow coat, and the patient had bilious vomiting. This gastric disturbance was considered as an accumulation of saburral matters in the stomach; but it would now be regarded as an irritation of the gastric mucous membrane, and the head-ache and affection of the liver which accompanied it would be regarded as the result of the sympathetic transmission of this irritation to the suffering organs.—*Treatment*. Tartar emetic, so useful more particularly in treating the diseases of soldiers who are so liable to use coarse and unhealthy food, was the principal remedy employed with the view of evacuating the *primæ viæ*. Nothing appeared so essential as clearing the stomach of the alimentary or other matters which it might contain. If this treatment were neglected, diarrhoeas and bilious fevers were observed to follow in a great number of cases, or else the duration of the gastric disturbance was prolonged to an indefinite period. Our author observed as a general fact that when the gastric affection was not accompanied with redness at the edges of the tongue, or with red points, we must have recourse to the employment of emetics, powerful remedies when seasonably administered. He remarks here, that the use of tartar emetic has been too much neglected of late years. He considers that

it deserves to hold a very high rank in the materia medica from its great utility in many diseases. When the system is assailed by morbid causes, the stomach is frequently the first to feel it; it becomes disturbed in its action, whilst the appetite still more or less continues; the alimentary matters then used not undergoing the natural change of digestion, it becomes necessary to evacuate them, otherwise they produce a local irritation which destroys that equilibrium between the functions so necessary to the existence of health; and the more this equilibrium is interfered with the more serious are the diseases which arise from it. Sydenham states that he has frequently observed that at the termination of acute diseases diarrhoeas come on from the omission of tartar emetic; and the authority of this great master of medical observation is well deserving of consideration. Sometimes, however, after the action of the emetic, when the gastric disturbance still continued and seemed to depend on irritation of the liver, our author administered purgatives, such as senna, rhubarb, manna, sulphate of magnesia, &c., from which he always obtained good effects when the irritation of the liver was slight or chronic; this is accounted for by the derivative and stimulant effects of purgatives on the intestinal mucous membrane. If after the employment of tartar emetic there was observed any appearance of exhaustion or sinking of the vital powers, he put the patient on nourishing diet, such however as was easy of digestion, and also administered bitters combined with aromatics.

CHAP. II. *Gastritis*. Inflammation of the stomach holds at present a very high place in the nosological cadre scale. With the exception of Morgagni and Hoffman, the old physicians from not sufficiently appreciating the important office of the stomach in the animal economy, paid but little attention to it. This inflammation when acute was generally confounded by them with other abdominal inflammations, and when chronic was altogether overlooked by them. But at the present day physicians devote themselves more to the study of pathological anatomy, which has given them more accurate notions with respect to the seat of diseases. It is to these, and chiefly to M. Broussais, that we are indebted for our more intimate acquaintance with its nature and diagnosis.

Our author feels satisfied that gastritis acted the most considerable part in the production of several diseases which prevailed among the French troops; the mor-

bific causes to which the soldier was exposed rendered this opinion extremely possible; but at the period of Napoleon's wars gastritis received but little attention from medical men. The symptoms of gastritis are—Fixed pain: burning heat; weight or tension in the precordial region; sensation of fulness in the stomach; increase of epigastric sensibility on pressure, or on the injection of food, drink, or medicines; wandering pains between the shoulders or under the sternum; headache, dizziness, lassitude in the limbs; sudden sinking of the vital powers; trembling; faintings; cold of the extremities; increased dry heat in the epigastrium and on the forehead; alteration in the features; oftentimes fever, more or less marked; cold sweat; pulse small, hurried and contracted, oftentimes unequal, sometimes intermittent, seldom hard; dryness of the mouth and throat, in which the patient sometimes experiences a sensation of burning; great thirst, desire of cold and acidulated drinks; anorexia, or sometimes an increase of appetite; sour eructations; disposition to vomit, or actual vomiting; the stomach rejects everything the patient swallows; constipation; urine red, concentrated, and scalding, often diminished and occasionally suppressed; breathing more or less difficult; restlessness, anxiety, &c. These symptoms are developed in proportion to the intensity of the disease and the individual habit of the patient; but it should be remarked that in the most severe gastritis the sensibility is as it were abolished; that the pain is little or not at all felt, and that the pulse becomes slow and almost imperceptible. When it has attained an extreme degree, it is often accompanied with spasmodic contraction, extinction of the voice, hiccup, delirium, and other cerebral phenomena. It may be observed that redness and retraction of the tongue, or redness of the apex and edges of this organ, symptoms generally considered as pathognomonic of inflammation of the stomach, do not always exist in this disease. There have been cases of gastritis, when the tongue was entirely pale, and presented no change, except that it was covered with a mucous coat.

The combination or co-existence of all these symptoms is not necessary to constitute gastritis. The author adopts M. Broussais division of the disease into two species, the phlegmonous, and erythematous or erysipelatous, the former being that wherein the entire substance of the organ was involved, and the latter being

that which has its seat in the gastric mucous membrane.

Gastritis may attack the entire stomach, or affect it only partially. It may be idiopathic or symptomatic. It is usually communicated to the small intestine, and this pathological state is now called gastro-enterite. It may be transmitted sympathetically to the liver, and so excite hepatitis and jaundice; to the bladder, to the lung, to the mucous membrane of the pharynx and larynx, to the eyes, to the brain, &c. and to give rise to inflammation of these several organs.

The author after this very graphic description of the symptoms of gastritis, next passes on to the causes which, under ordinary circumstances, may excite it; the detail of which we shall not here present to the reader, as, though excellent, it contains nothing very particular in it. With respect to the particular causes which occasioned gastritis in the French army at this period, he enumerates them as follows: privations, fatigue, sudden transitions from the heat of the day to the cool of the night; icy cold drinks taken when the body was bathed in sweat; the burning thirst which was suffered for want of water; the gross food and irregular manner in which the soldiers were fed; the abuse of spirituous liquors and the indigestible or unhealthy food they used, and that after having been for a long time fasting, often at a time when they were worn out with fatigue, hunger, heat, and cold. After detailing the prognosis and several terminations of the disease, in which, however, there is nothing very uncommon he proceeds to the

Treatment.—The first indication is to destroy the causes of the disease. If the presence of acrid substances in the stomach be suspected they should be discharged as soon as possible, vomiting being excited by some mild tepid drink. Warm water with butter, oil or fat, are adapted to this purpose. If the disease be occasioned by poisoning, the treatment is obvious.

In cases of gastric distention caused by coarse bad food taken by the soldiers, our author found advantage from emetics of ipecacuanha; after this, some days rest and attention to diet, keeping up freedom of the bowels by lavements, demulcent drinks, and sometimes derivatives applied externally, sufficed to perfect the cure in several cases observed in the French army, in which it was not necessary nor expedient to have recourse to bleeding, except rarely and with extreme caution.

When the inflammation was well established and severe, local bleeding by means of leeches to the epigastrium was employed. If the inflammatory action was very violent, it was found necessary to have recourse to general bleeding. The bleeding should be adapted to the age and constitution of the patient. The physician should not allow himself to be imposed on by the weakness or smallness of the pulse, as it generally becomes full after bleeding.

When the pulse sinks very much, it is necessary, before taking blood to endeavour to excite reaction by a moderately warm bath, by frictions to the surface of the body, by the application of sinapisms to the extremities, &c.

After leeching, constipation should be removed by means of lavements. The epigastric region should be covered with emollient cataplasms. Warm pediluvia rendered irritating by means of salt or some other substance; hot cataplasms spread over with mustard, if the re-action is not strong, should be applied to the extremities, as also blisters or sinapisms to parts remote from the seat of the disease, as along the back or to the thighs, provided, however, there be not a state of general irritation: the patient should be restricted to the use of cold mucilaginous drinks. After the disappearance of the fever, and of the acute stage of inflammation, purgative lavements should be employed so as to produce derivation to the large intestine.

After the disease has lost its acute character, there frequently remains great sensibility of the stomach, which occasions pain and vomiting at intervals. Narcotics, improper at the commencement, are then indicated. They should at first be given in very small doses, nor should the dose be augmented unless with great caution. The author preferred, in such cases, the external application of narcotics, namely, gentle frictions over the præcordial region with the watery extract or tincture of opium, or with the extract of stramonium, or belladonna. He sometimes used poppy-lavements, sometimes mucilaginous lavements, with some drops of tincture of opium, more especially should the patient labour under exhausting diarrhæa. The author makes an observation here with respect to the comparative strength of opium administered internally and externally, namely, that in an equal dose it acts more powerfully when given in lavement than internally. We believe that it was the late Baron Dupuytren who first

remarked this fact; and if we remember aright, the reason assigned by that distinguished physiologist for the effect was, that when the substance was administered in lavement, it was not within the limits of that part of the canal endowed with digestive faculties, and consequently all elements were taken into the system whole and entire.

Here we shall pause for the present, and resume our analysis in next number. In the mean time we have given ample evidence of this most interesting and instructive volume. The author is evidently possessed of a profound knowledge of medicine, and is a physician of great practical experience and judgment. His work is destined to become classic, and will be one of reference and authority.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

LIVERPOOL—MONDAY NIGHT.

The seventh annual meeting of this association commenced here this morning. Every necessary arrangement to promote the comfort and convenience of the members visiting Liverpool has been adopted by the Local Committee. The various institutions, public, commercial, and other buildings, manufactories, &c., and everything worthy the inspection of the curious, have been thrown open for gratuitous inspection.

Among the distinguished visitors already arrived, or immediately expected, are—Prince Esterhazy, the Marquis of Northampton, president of the association, and the Earl of Burlington, president-elect, Lord Nugent, M. Gay Lussac, M. Fresnel, jun., Earl Fitzwilliam, Lord Milton, Hon. Mr. Fitzwilliam, Lord de Tabley, Sir B. Taylor, Sir P. G. Egerton, M.P., Earl Balcarras, Viscount Sandon, M.P., Viscount Cole, M.P., Marquis of Downshire, Earl Howe, Lord Radstock, Earl of Leitrim, Lord Bloomfield, Viscount Lismore, Marquis of Westminster, Lord Curzon, Earl of Charlemont, Earl of Glengall, Earl of Ormond, M. de Vernueuil, M. Dufresnoy, Baron Dupin, Professor de la Revé, Professor Leisbig, Joseph Schloefield, Esq., M.P., Mr. Guest, M.P., Sir H. Watson, Col. Hull, Col. Sandworth, Professor Faraday, Professor Powell, Professor Whewell, Mr. Jerdon (editor of the *Literary Gazette*), Mr. De la Beche,

Mr. Dolland, Sir Thomas Brisbane, Sir David Brewster, Sir Wm. Hamilton (astronomer royal of Ireland), Sir W. Hooker (professor of Botany in the University of Glasgow), Dr. Lloyd (provost of Trinity College, Dublin), Professor Buckland, Professor Peacock, Messrs. Wield and Bryan (secretaries of the Royal Dublin Society), Dr. Orpen, Dr. Apjohn, Sir R. Bateson, Mr. Kingsley, Dr. Evanson, Mr. Verstraete, Mr. Cooper, M.P., Captain H. Vernon, Hon. A. Trevor, M.P., William Fielding, Esq., M.P., Professor Henslow, Professor Miller, Professor Johnston, Professor Daniel, Professor Graham, Sir O. Mosley, E. Fleetwood, Esq., M.P., Sir J. Riddle, Bart, Dr. W. C. Taylor, Dr. Lardner, Dr. J. Johnstone (Birmingham), Dr. Granville (author of the "Spas of Germany"), Dr. Roberts (St. Asaph), Dr. Warren (Boston), Dr. Holland (Sheffield), Dr. Copeland (author of the "Dictionary of Medicine"), Mr. S. Hare (Leeds), Mr. W. Walker (Edinburgh), Mr. Brett, F.R.S., Dr. Carlisle, Dr. Rees, Dr. J. Black, Dr. John Reid, Dr. O'Beirne, Mr. J. G. Simpson, Dr. P. H. Madden, Colonel Sykes, Mr. Porter, Mr. Ashworth, Mr. W. Greg, Mr. Remington, Mr. Kingsley, Mr. Russell, Mr. Henwood, Mr. Hawkins, Mr. Williams, Mr. J. W. Lubbock, Mr. Burt, Colonel Gold, Mr. Cunningham, Mr. Osler, Mr. Golding Bird, Mr. R. Kane (Dublin), Mr. Geo. Crane, Professor Sedgwick, Dr. Traill, Mr. Gray, Rev. J. Reade, Rev. J. Hope, Mr. J. Ball, Mr. Wheatstone, Mr. Delwyne, Mr. Llŵellyn, Mr. Bateman, Mr. Fannin, Dr. Pollexfen, Major Williams, Major Clerke, Mr. Ashburne, Mr. Darthex, Dr. Carmichael, Mr. Lyne, M. Capdevielle, Mr. Bovill, Mr. Crane, Mr. Graham Hutchinson, Sir John Hilton, Mr. Franks, Mr. Pemberton, Mr. J. Luke, C.E., General Brown Clayton, Mr. R. E. Drunsend, Mr. Solomon, Mr. Cotton, Dr. Williams, Colonel Farquharson, Mr. Dixon, Mr. Montgomery Martin, &c.

The various sections were allocated according to the following plan. The arrangements were efficient and satisfactory—

A. Mathematics and Physics—Mechanics' Institute.

B. Chemistry and Mineralogy—Ditto.

C. Geology and Geography—Ditto.

D. Zoology and Botany—Royal Institution.

E. Medical Science—Medical Institution.

F. Statistics—Saving's Bank.

G. Mechanical Science—Mechanics' Institute.

A public breakfast took place at the Adelphi Hotel at nine o'clock. At eleven the various sections met.

Section A. (Mathematics and Physics.)

—Sir David Brewster presided, and papers were read on the following subjects:

—By Mr. Lubbock, on tide observations; Mr. Burt, on aerial currents; Colonel Gold, on telegraphic communication; Mr. Cunningham, on magnetism; Professor Whewell, on an anemometer; Mr. Osler, on ditto; Professor Powell, on dispersion of light.

Section B. (Chemistry and Mineralogy.)—Dr. Apjohn presided in the absence of Mr. Faraday. Mr. George Crane read a paper "on the smelting of iron by anthracite coal," in which he shewed that iron of a very superior quality could be manufactured at a much less expense than at present, by using anthracite coal. Mr. Golding Bird read a paper on the subject of the crystallization of metals by voltaic action. Mr. R. Kane read one on pyro-acetic acid.

Section C. (Geology and Geography.)

—Professor Sedgwick presided. A report "on the relative levels of land and sea," was submitted by Professor Whewell. Rev. T. Yates read a report "on mud in rivers," and also "on fossil vegetables in new red sandstone of Worcestershire." H. G. Strickland read one "on gravel." Capt. H. M. Denham, R.N., resident marine surveyor of the port of Liverpool, produced an elaborate report, illustrated by drawings and diagrams, of the tidal capacity of the Mersey at its separate stages of high-water, springs, and neaps. At low-water, springs, and neaps and at the half-tide level—(which he proved most clearly was a level applicable to every tide at three hours before and after each high-water period), especially noticing its progressive velocity, and giving in detail the amount of salt and insoluble matter contained in every cubic yard of tidal water at various depths, and at every half-hour of flood and ebb, showing the predominant portion on the ebb, and the consequent effect upon the banks and channels in Liverpool Bay, which quantity Captain Denham curiously and most interestingly proved agreed with the cubical increase found in the region of deposit. The hypothesis, thus deducted into practical results, was received by the association with rapturous greetings and a most animated discussion, when the gallant captain re-

ceived the public thanks of the president, the Marquis of Northampton, the president of the geological section, Professor Sedgwick, and the most gratifying compliments of Mr. Greenough, Mr. De la Biche, Mr. Manlihan, &c. Indeed, when we perceive an officer adding such mental and bodily exertions in the cause of practical science, whilst conducting a system of local navigation so ably, that out of 29,000 vessels entering the port in the last two years, but nineteen wrecks have taken place, we would if possible add to the justly due eulogium of the association which have seconded such eminent services to the state; for we must recollect that Liverpool is the second emporium of the kingdom, and almost primary in contributing to the revenue.

Section D. (Zoology and Botany).—An exhibition and slight notice of *argus persicus*, the poisonous miannet of Persia, by Dr. Traill; result of Mr. Children's repetition of Mr. Cross's experiment on the reproduction of insects from the solution of silica, by Mr. Gray; on the solid materia's of plants and animals, and the effect of their subsequent addition to the crust of the earth, by the Rev. T. Reade; a communication of Sir Thomas Phillips's method of destroying insects which attack books and manuscripts, by the Rev. F. Hope; on *erica mackayana*, with an exhibition of live specimen, by Mr. John Ball; exhibition of *Victoria Regina*, a new water-lily sent from British Guiana by Dr. Shomburgh, by Mr. Gray, a description of which has already appeared in the paper.

Section E (Medical Science).—George Holland, M.D., 1. Cause of death from a blow on the stomach, with remarks on the means calculated to restore animation suspended by such accidents; 2. Inquiry into the influence of the brain on the heart, and other organs in health and disease; H. Carlisle, M.B., TCD., on the formation of the sacrum in man, and some of the lower animals; G. O. Rees, deputy committee, on the analysis of glands and their secretions; J. Black, M.D., account of the late influenza at Bolton, January, February, and March, 1837; M. Brett, F.R.S., remarks on experiments on expectoration; Dr. John Reed, on the functions of the 8th pair—experimental inquiry; Dr. O'Beirne, letter as to report—brain and nervous system; J. G. Simpson, on the evidence against the contagious propositions of cholera, &c.; Dr. P. H. Madden, experiments on the connection between

nerves and muscles. Dr. Roget, on taking the chair, stated that, owing to the absence of professor Clark, who was expected shortly to arrive in this town, he was acting as president. In all the meetings of this section, at which he had been present, the proceedings had always been conducted harmoniously, which he had no doubt would be so on the present. The secretary would state the heads of the papers to be read. They were furnished by Dr. Holland, Mr. Carlisle, Dr. Rees, Dr. Black, Mr. Brett, Dr. O'Beirne, Dr. Macnitosh, Dr. Simpson, and Dr. Madden.

Dr. Williams then read the report of a sub-committee appointed at the last meeting to inquire into the sounds and motions of the heart, and their causes. The sub-committee commenced their labours by ascertaining the sounds produced by physical agencies in electric tubes; and proceeded, secondly, to examine if they found a parallel in the organs of life, the heart, and arteries. A series of interesting experiments were now detailed, showing the sounds caused by currents of water and more dense fluids, impeded and unimpeded in their course, in electric tubes. The result gave deductions showing that water, in straight elastic tubes, and unimpeded, uttered no appreciable sound; but but an interruption caused by a bend or an angle in the tube, by its contraction at any point, by knots or projections in the canal, and by foreign substances introduced, as thread and knotted thread, caused the utterance of sounds, as murmur, humming, hissing, rasping, and musical sounds accordingly. At the extremities of the tubes in the openings sound was detected. Dr. Williams then stated that the second division of this subject had not yet been satisfactorily terminated by the sub-committee, who would continue their labours if the meeting approved of it; but sufficient was done to show that the application of these physical laws to life were justifiable, some of which were enumerated, and were highly interesting, some very delicate, and some of practicability.

Section F. (Statistics).—This section met at the Savings Bank, Bold-street. Colonel Sykes presided.

The President read a paper drawn out by himself, in pursuance of a resolution passed at the meeting of the association, held at Dublin last year, giving a statistical return of the four collectorates in the Deccan, under the Bombay government. The paper gave an outline of the

country—its rivers, roads, geology, climate, atmosphere, state of the barometer from six years' observation thereof, quantity of rain fallen within a certain time, the hot winds, whirlwinds, and hail, and observed the only time ice was ever seen in that country was in the hottest part of the year; it was generally preceded by high winds, heavy thunder, remarkably vivid lightning, immediately followed by a heavy fall of hail, which was generally succeeded by a heavy and continuous rain. The gallant colonel also stated that the salubrity of the climate was such, that in six months only one death had occurred in the Poonah districts, and that a child; that the average of sickness was one in fifty-five, and if the cholera was included, which was a European disease, it was one in forty. Of the botany of the districts, he stated that there were 45 roots cultivated, and 22 wild; of fruit, there were seven very fine species of grapes, six of which he had introduced into England within the last twelve months. (Of the agricultural produce of the country, he stated there were two harvests in the year—the rainy and the dry, and that there were twenty-two kinds of grain produced; that the hilly part of the country produced chiefly rice; that some of their productions were very prolific, as much as 61,380 having been known to be produced from one seed, and others as much as 16,960; corn, barley, peas, and sugarcane—of the latter there were four kinds produced. The garden produce was very considerable, as vegetables formed the chief diet of the natives, not so much from choice as from necessity—their poverty being such that they could not afford to obtain any other kind of food. Edible roots were very numerous, and were divided into fruit vegetables and leaf vegetables. There were many wild plants and flowers used as greens, and the tender twigs of the bamboo were used for a similar purpose. Of the grapes of the country the most valuable was a native of Cornwall. The inhabitants made no hay, but allowed the grass to remain on the ground until it was dry, when they cut it with sickles; there were several wild tanning plants, as well as some very powerful kinds. Few European seeds were cultivated.

The reading of different portions of this paper drew forth the admiration of the association.

The Colonel stated that it was compiled from twelve large MS. vols., the fruits of his labours for many years, and that for

the benefit of the association he had condensed it to about two hundred MS. folios. The association were unanimous in a vote of thanks to the colonel for his valuable services. During the reading of the paper the chair was occupied by Dr. Taylor.

Mr. Porter read a brief memoir on the "state of trade between England and America," which was followed by

Mr. Ashworth reading an interesting report upon the state of education at Bolton.

The business of this section was terminated by Dr. Taylor reading an abstract of the annual report of the regents of the University of New York, on the progress of national education.

Section G. (Mechanical Science).—This section met at the Mechanics' Institution. Professor Robinson in the chair.

In the absence of Mr. G. Remington Dr. Lardner read and explained that gentleman's paper on the railway balance lock; the object of this was to do that upon railways which is accomplished on canals by means of locks—namely, to raise the trains to any given height according to the inequality of the surface.

The next paper was from a Mr. Williams, on what was denominated a "trof-fos pump." The alleged improvement was, that his pump would allow the water to flow in a continuous stream, while the well or spring might be at a considerable distance from the operator.

Mr. Russell read a paper giving a variety of interesting information relative to the motion of steam-vessels in shallow water.

Mr. Kingley exhibited a model of a new description of drawing board, which, as it contains most of the implements and instruments used in geometrical drawing, is calculated to facilitate the operations of the draughtsman.

THE DINNER

At five o'clock five hundred members of the association sat down to dinner at Lucas's Repository. The Marquis of Northampton presided. The dinner was provided by Mr. Radley, of the Adelphi, and Mr. Lynn, of the Waterloo Hotels. On the removal of the cloth,

The noble Chairman rose and said that that meeting, although not a political assembly but a scientific one, yet he was sure there was no one present but would respond to the toast he had the honour to propose, "Her most Gracious Majesty the Queen"—(cheers).

"The other members of the Royal Family" was the next toast.

The Chairman afterwards proposed—"the Mayor and Corporation of Liverpool."

The Mayor returned thanks.

The Noble Marquis, in proposing propriety to the British Association, said he rejoiced exceedingly when he looked round the room and saw such a brilliant assembly; that he, as their viceroy, might consider himself as dining in great state, surrounded as he was by such a body of distinguished gentlemen. That was his "last dying speech," and in the evening he was to be "turned off," and to give his sceptre into more worthy hands; they would then say, "the king is dead—long live the king."

The "Health of the President elect," Lord Burlington, was then drunk with acclamation.

His Lordship returned thanks, observing that from the flattering manner in which they had been pleased to receive that toast, he found it impossible to acknowledge the compliment in such a way as would be satisfactory to him. When he looked around and saw the spirit which pervaded—which animated—the vast assembly—composed of men from all parts of the country, where no feeling of party or bitter spirit was permitted to appear, but where they had one object alone—that of the advancement of science and the benefit of mankind—at heart, he could not feel otherwise than gratified. It was impossible to reflect on such a scene, and not to contemplate the great moral benefits that must arise from that association. In conclusion he begged to say that he should emulate the conduct of his noble predecessor in the chair, whose health he begged to propose—(cheers).

The Marquis of Northampton returned thanks. He afterwards said that although the greater portion of the British Association, whom he had the honour of addressing, were natives of the British dominions, yet there were others among them from foreign parts. It was extremely delightful to see foreigners amongst them; and he begged to propose "The health of Professor Mholl and the distinguished foreigners who had honoured the British Association with their presence."

Professor Mholl responded to the toast; and, as foreigner, trusted they would make large allowances for the difficulty in which he was placed in having to address them in any than his native tongue. He begged to thank the worthy noble chairman for the honour he had done

foreign science. Associations like that—without party-spirit or jealousy—not only contributed to the advancement of science, but also operated as a tie, bringing nations together. If they went on a few years longer, bringing in contact persons known only to each other by their writings, soon all those jealousies and party national feeling would be done away with. He concluded by expressing an ardent wish and hope that the British Association might become a common tie, binding nation to nation—(cheers).

A general meeting of the association took place at 8 o'clock in the evening, at the Royal Amphitheatre, when the Marquis of Northampton resigned his office of chairman in favour of the Earl of Burlington.

The annual report, which was very elaborate, was read by Dr. Traill, and a statement of the finances of the society was made by the treasurer, by which it appears that the society have a balance in hand of upwards of 5,000*l*. A large addition is expected to the funds from the number of tickets sold, which even now greatly exceed the number sold in Bristol last year.

THE ANATOMIST.

THE LARYNX.

Besides the muscles, vessels, nerves, and mucous membrane which enter into the formation of the larynx, there are four cartilages and one fibro-cartilage.

The *thyroid cartilage*, the largest, presents anteriorly a prominent angle called *pomum Adami*, which is formed by the meeting of its *alæ*. Each *alæ* is of a quadrilateral form and presents posteriorly two *cornua*; the superior *cornu* is the longest, and is connected to the great *cornu* of the *os hyoides* by the *thyro-hyoid ligament*; the lesser, or inferior *cornu* being connected to the side of the *cricoid cartilage* by *synovial membrane* and *ligaments*.

The upper margin of each *alæ* is connected to the *os hyoides* by the *thyro-hyoid membrane*, the inferior margin being connected to the *cricoid cartilage* by the *crico-thyroid membrane*, which is of a yellow colour and elastic; the outer surface of each is rough and divided unequally by an oblique ridge, the inner surface being smooth and covered by *mucous membrane*.

The *crioid cartilage* is next in size and forms a ring, it is narrow before and deep behind, its inferior edge is connected to the first ring of the trachea, its superior edge, anteriorly, is connected by the crico-thyroid ligament to the thyroid cartilage, and posteriorly it supports the arytenoid cartilages; its inner surface is covered by mucous membrane, and its outer surface is rough and presents posteriorly a vertical ridge for the attachment of muscles.

The *arytenoid cartilages*, two in number, are the smallest of a triangular shape: the apex of each is surmounted by a small moveable cartilaginous appendix, the base concave, to move upon the cryoid cartilage; the posterior surface concave to lodge the arytenoid muscles, the external edge convex for the attachment of muscles, and the inner edge is flat. The apex of each is connected to the epiglottis by a fold of mucous membrane called the *aryteno-epiglottidean fold*, and the base is connected to the cryoid cartilage by synovial membrane and ligaments.

The epiglottis, resembling in form an artichoke leaf, is connected by a stalk-like process to the angle of the thyroid cartilage; anteriorly to the body of the os hyoides by cellular tissue and mucous membrane, and to the base of the tongue by three folds of mucous membrane, the central one of which is called *frænum epiglottidis*, and posteriorly by the aryteno-epiglottidean folds of mucous membrane.

The *glottis* is the superior opening of the larynx, it is of a triangular form, its base being anterior, formed by the epiglottis, its apex posterior and inferior formed by the appendices of the arytenoid cartilages, and its sides formed by the aryteno-epiglottidean folds.

The *rima glottidis* is also of a triangular form and placed beneath the glottis: the base is posterior, formed by the bases of the arytenoid cartilages, the apex anterior corresponding to the angle formed by the apex of the thyroid cartilage, and the sides are formed the chordæ vocales.

The *chordæ vocales*, two on either side, arise from the anterior aspect of the arytenoid cartilages, and approaching each other, are inserted into the angle formed by apex of the thyroid cartilage: the superior is semilunar, the inferior horizontal, and between the vocal chords of either side is a small oval fossa, called the *ventricle* of the larynx.

THE THYROID BODY.

Of a reddish-brown colour, consists of two lateral lobes and a connecting middle lobe. The lateral lobes are placed by the sides of the trachea and larynx, and the middle lobe rests upon the anterior aspect of the second, third, and fourth rings of the trachea. Each lateral lobe is of a pyriform shape, the base inferior, and the apex ascending to the thyroid cartilage; both lateral lobes overlap the carotid vessels, the thyroid artery, and the recurrent nerve; and are covered by the sterno-hyoid, sterno-thyroid, omo-hyoid, and platysma-myoides muscles, the cervical fascia, and the integuments. This body or gland is supplied with blood by the superior thyroid arteries from the external carotid, the inferior thyroid arteries, from the thyroid axis, which is a branch of the subclavian artery, and sometimes by an artery from the arteria innominata, or from the aorta itself, called the middle thyroid artery; its blood is returned by the thyroid veins, which descending on the anterior aspect of the trachea empty themselves into the left vena innominata. No excretory duct has been discovered emerging from this body.

MR. WARDLEWORTH'S OBSTETRIC CASES.

To the Editor of the Medical and Surgical Journal.

Sir,—Should you deem the following cases of sufficient practical importance, and worthy of a place in your widely-circulated Journal, your insertion of them will oblige

Your obedient servant,

S. H. WARDLEWORTH, Surgeon,
Cross-lane, Perleton,

Sep. 13, 1837. near Manchester.

I was desired, some years ago, to attend Mrs. L., aged twenty-four, in labour of her first child. On my arrival I found, on inquiry, that she had been in labour for two days, and that the waters had come away some hours previous to my arrival. On examination I found the os uteri fully dilated, the head presenting naturally and entering the true pelvis. The pains had been strong and frequent, but now the uterine action was suspended, and I was told that she had had no pains since the waters came away. I gave her ʒj of secale cornut. in ʒvj of

tepid water immediately. About five minutes after its administration the uterus began to act freely, pains strong, and without any evident intermission. In about a quarter of an hour after taking the ergot, a very fine girl was born alive. The uterus still continuing to act as violently as before, led me to suppose that that organ was contracting spasmodically upon the placenta, and immediately after securing the funis, ran my finger along the umbilical cord, and found, at the entrance of the os internum, the head of another child presenting naturally—this was also expelled in a short time, and also alive. The uterine action now ceased altogether. I desired one of the attendants to apply firm pressure, with the hand over the region of the uterus; and, after waiting a short time, and no recurrence of pain, I made an examination and found, to my astonishment, a third child lying snugly within the uterus, and also in the natural position—the os uteri was soft and dilatable. I gave her another 3j. of ergot, as before. About twenty minutes after its administration a third daughter was born alive. The secundines came immediately away, and no unfavourable symptom occurred after.

Mrs. S., aged thirty, her fourth labour. Was summoned in a great hurry to attend her, on account, as the messenger stated, that the person was dying. On my arrival, I found the woman laid on the bed, to all appearance dead; pulse not perceptible at the wrist; extremities cold. On enquiry, was told she had parted with large gushes of blood during each pain, and that she had been in labour for several hours. On examination I found the os uteri dilated to the size of sixpence, and thin; the membranes ruptured, and the head presenting naturally; the placenta was not placed in any way over the os uteri. Taking into consideration the low state of my patient, as the vital powers appeared almost extinct, I immediately gave her *secale cornut.* 3j. in 3iv. of rum, which had the effect of bringing on re-action, together with strong uterine contractions, and the os uteri began to dilate, and in thirty minutes after the administration of the ergot, she gave birth to a fine lively boy. The placenta came away naturally, and in two months after she had acquired her usual state of health and vigour.

Remarks.—I have been induced to send the above cases, which I think prove beyond a doubt, the power of *secale cornutum* in producing uterine contractions.

Knowing that this effect is doubted by many medical men, and that the ergot is supposed to be injurious and sometimes fatal to foetal life. In the above cases the children were all born alive and vigorous. I could adduce many more cases to the same effect, as I have been in the habit of administering the ergot frequently, and found the use of it attended with no bad results either to mother or child.

TO CORRESPONDENTS.

Lithotrity.—The case is not unique. Where the fatal symptoms could no longer be concealed, we see no impropriety in the surgeon's leaving town.

University College Student.—The committee of the hospital is for the purpose of regulating the affairs of that institution alone. The committee of discipline is for the purpose of watching the conduct of the students of the college, but they have no control over the moral conduct of the lecturers. The election of professors is made by the council, which body has also the power of expelling. The council are elected by, and are under the control of the body of shareholders. All appeals from the committee of discipline and hospital, or from the council, are to a general meeting of shareholders and governors.

The Rejected should without any hesitation place himself under the tuition of any of the established MOLARS. We opine a three months grind will be required.

Gracchus. The Biographical Sketch alluded to was written by Erinensis in his best style, and will be found in the *Lancet*.

Medicus.—Doctor Bull, Doctor Hogg, and Doctor Lamb, are members.

A Student.—The practice of the Charing-Cross Hospital is not recognised, nor is there the least likelihood of its being so. Dr. Golding is still Director.

G. S. Southampton must ere this, have seen that his wants have been supplied.

J. R. He has recanted his former doctrines.

Publicola.—News from Dublin will be acceptable, but must be authenticated.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE
SKIN,*Annually delivered in Paris,*

By M. BIETT,

Reported by MM. Cazenave and Schedel.

VARICELLA.

Varicella is a non-contagious disease characterized by an eruption of vesicles more or less numerous, the appearance of which is preceded and accompanied by constitutional symptoms, and the desiccation of which generally occurs from the fifth to the eighth day.

Questions of great importance have been raised in latter times with respect to varicella, and we deem it right before giving the description of this disease, to enter into some details on this subject.

The name of varicella, or flying small-pox (*petite verole volante*), had been given, at first, to slight affections of a purely vesicular character, to distinguish them from small-pox properly so called, to which they were found to bear considerable resemblance, and of which they were regarded as varieties. At a later period these diseases were completely separated, as well in reference to the symptoms as with respect to the causes. Never, it was said, are the symptoms of varicella those of variola; nor is the cause of variola ever that of varicella. Differences so considerable were sufficient to trace a well-defined line of demarcation between these two affections, and according to those who established these distinctions, nothing was easier than to distinguish these affections from each other. Experience has not, however, demonstrated the truth of these assertions; for we see that in the lengthened debates on inoculated variola, very skilful prac-

titioners give the name of varicella to affections, which, according to others, were real instances of variola. Far from being decided by the discovery of vaccination, these dissensions on the nature of varicella became still greater, and even in our own time, the conclusion of practitioners is not generally established with respect to this very important question.

Among the authors who have paid particular attention to this subject, some, as Thomson, Berard, Delavie, &c., maintain that varicella should not be distinguished from variola, of which it is but a variety; for, according to them, the cause of the two diseases is the same. Others, as Luders, Abercrombie, Bryce, &c., while they admit that certain variolic affections have been incorrectly designated by the name of varicella, maintain, that the latter should be distinguished from variola, and that it constitutes a distinct affection, as well by reason of its symptoms as of its cause.

Let us now take a rapid view of the facts and arguments advanced by these authors in defence of their opinion. We shall then assign the reason which has determined us to describe varicella as a disease distinct from variola.

M. Thomson having observed that in variolic epidemics, vesicular eruptions bearing an entire resemblance to varicella, became simultaneously developed, and under the influence of the same causes as variola, both in vaccinated individuals, as well as in individuals who had already had variola, was naturally led to conclude that these eruptions having one and the same cause, should be considered as varieties of one and the same disease.

In these epidemics as well as in those which we had an opportunity of observing some years since in Paris, the different eruptions might be divided into three groups: 1. Variola, properly so called. 2. That which is called the *varioid* dis-

case, or modified variola; 3. An eruption, purely vesicular, presenting all the appearances of varicella.

One sole cause, the variolic contagion, seemed to develop these different eruptions: they were observed in the same districts, in the same streets, and in the same houses. Should the disease attack a numerous family, some were affected with variola, some with varioloid form, and some with varicella. There was one striking circumstance in every case, and that was the mildness of the disease in persons who had been vaccinated, and in most of those who had already had variola; the eruption in these individuals presented all the characters of the *varioloid* form, a name imposed in consequence of its striking resemblance to variola, and Dr. Thomson had no difficulty in proving that it was nothing but variola itself modified by the influence which either vaccination, or a previous variola had exercised on it.

But the Edinburgh professor went still farther, for he advanced that the varicella itself was nothing else but modified variola, sustaining his assertion on the following grounds:—

1st. On this circumstance, that on the one hand, persons placed in contact with other individuals actually affected with varicella had contracted variola, and that on the other hand, the contagion of this latter affection had developed varicella.

2. On this circumstance, that there never exists an epidemic variola without varicella, and *vice versa*.

3d. And lastly on this circumstance, that varicella is only developed in those individuals whose constitution has been modified by the previous existence either of the vaccine inoculation or of variola.

This opinion of M. Thomson is far from being generally adopted. It has even been combated by physicians who entirely concur in his opinion with respect to the variolic nature of the pustular eruptions observed during the epidemics of variola, and designated by the title of *varioloid* diseases.

In answer to the arguments advanced by M. Thomson in support of his opinion, they observe:

1. That in a variolic epidemic, it is very difficult to determine precisely whether the development of this affection in persons placed in contact with others labouring under varicella is rather the result of this communication than of the variolic infection which then develops the disease on all sides.

2. That the vesicular varicella properly so called is not transmitted by inoculation, and never develops variola.

3. That the persons who consider varicella as contagious have confounded this affection with the *varioloid*, or modified variola.

4. That varicella is developed in persons not vaccinated, and who have never had variola, where, therefore, it cannot in any way be looked on as a variola modified by the previous existence either of this disease, or of vaccine virus.

5. That vaccination performed a short time after the disappearance of varicella, follows its course in the most regular manner, which never happens when vaccination is employed after variola.

6. That variola often prevails epidemically without being accompanied by varicella, and that, on the other hand, this latter affection may also prevail epidemically without being accompanied by the former.

Finally, that the characters of the eruption, and the symptoms of varicella differ essentially from those of variola.

These objections have been met by M. Thomson; but the question remains still undecided; accordingly it still appears to us indispensable to follow the rout already traced, and still to describe varicella among the vesicular diseases and as an affection distinct from variola.

Varicella is, as we have said, an affection characterized by an eruption of vesicles more or less numerous, presenting a certain size, and becoming dry in the space of from five to ten days. These vesicles are at first transparent and afterwards become opaque. Their appearance is preceded and accompanied by constitutional symptoms: they are distinct and most frequently attack the entire body, but in successive crops.

Two varieties of varicella are distinguished: in the one, the vesicles are small and but slightly elevated, and contain a limpid, colourless fluid; in the other the vesicles are large, globular, soft, broader in their body than at their base. The contained fluid which is at first transparent soon becomes turbid, and assumes a milky appearance.

Of these two varieties the first is called by English writers by the name of *chicken-pox*, and the second by that of *swine-pox*.

Both may be developed in the same individual at different periods, and present the same symptoms, whether they occur previous to or after vaccination or variola.

Varicella often prevails conjointly with a variolic epidemic. According to some authors some epidemics have been observed where varicella alone prevailed. It is chiefly developed in the commencement of the year, and during spring. It ordinarily happens that the same individual is affected but once in his life, though he may be affected several times. The disease is principally observed in young persons, though it may attack adults.

Varicella is preceded, for twenty-four, thirty-six, or forty-eight hours, by depression, general indisposition, thirst, loss of appetite, and constipation. There is frequently nausea, sometimes vomiting and pain in the epigastrium; the skin is hot, the face injected, the pulse rapid, and there is a tendency to sweat. These symptoms, more or less severe, may be very slight. In general they do not cease at the time of the eruption, but they continue for two or three days. The eruption usually commences on the trunk, sometimes, however, on the face, and continues to come out for several days in succession.

In the varicella with small vesicles (*the chicken-pox* of the English), there are observed, from the first day, small elevations of a red appearance, irregularly circular, in the centre of which a small transparent vesicle soon points out. These vesicles increase in size during two or three days; some are pointed, others flattened. On the second or third day, the fluid which they contain, from being transparent becomes milky; the patient is very much troubled with itching; the vessels become flaccid, and seem flattened. On the fourth day some of them are encompassed by a red areola. Towards the fifth, desiccation commences, and from the sixth they are succeeded by small brownish scales. These small thin crusts dry from the circumference towards the centre, and fall off on the ninth or tenth day. As successive eruptions of vesicles take place during two or three days, different periods of the eruption are observed simultaneously in the same person, and the duration of the disease is prolonged to the eleventh or twelfth day.

The varicella with globular vesicles (*swine-pox* of the English), is preceded by the same symptoms, and is developed in the same manner. The red points are soon succeeded by large vesicles containing a transparent fluid, which becomes turbid after the second day of the eruption. The vesicles have then attained

their maximum size; they are soft and flaccid to the touch; they are of a pearl white colour, and their circumference, which is surrounded by an inflammatory areola, extends beyond their base.

After the third day the vesicles become depressed; they are shrivelled, and the contained fluid becomes thick, and assumes a yellowish tint.

As there is, at the same time, considerable itching, it often happens that children open the vesicles by scratching them, which occasions an additional degree of inflammation in these points, and also the formation of a yellowish pus, which is more or less thick. This happens chiefly on the face. The crusts that succeed these pustules continue for a longer time, and leave behind them small cicatrices. The same phenomenon may also occur in the preceding variety.

The vesicles, after being depressed, open before the end of the fourth day, and are succeeded by small lamellated brownish crusts. These crusts dry from the circumference to the centre, and fall off in the space of four or five days, leaving small red surfaces behind them, which gradually disappear.

As the vesicles come out successively during two or three days, the eruption is observed simultaneously and in the same person, in different degrees.

Diagnosis.—It is very easy to distinguish varicella from decided, or even from distinct variola, by means of the regular course, and gradual development, of the variolic pustules, which also contain a whitish thick matter, the development of which precedes the supuration, and was pointed out long since by Ashburner, an English physician. But it is not so easy to distinguish varicella from the modified variola.

In this latter affection the precursory symptoms are, in general, very severe; which never happens in the case of varicella. In the modified variola, the eruption is pustular. The pustules are small, circular, and most frequently depressed in the centre. Frequently after the fall of small scaly crusts, small tubercles are observed, which disappear slowly. In varicella, the vesicles, at first transparent, afterwards contain a sero-purulent fluid; they are never succeeded by small tubercles, as the modified variola. We shall further remark that varicella is not contagious, whilst the modified variola may be transmitted by inoculation, and even, in certain cases, may develop a rather severe variola.

The treatment of varicella is very simple: a regulated temperature with a free circulation of air, tepid drinks, and confinement to bed, are the only means required, even in the most severe cases.

ECZEMA.

The term eczema comes from the Greek *ἐκζέω, effervesco*. Willan has adopted it to designate one of the genera of the vesicular affections.

This genus is characterized by vesicles which are ordinarily very small, collected together in great numbers, and most frequently occupying very extensive surfaces which are irregular and not circumscribed.

Eczema may present appearances entirely different, according as it exists in such or such a state; which circumstance has no doubt induced Willan to divide eczema into *E. solare*, *E. impetiginodes* and *rubrum*. M. Biett, in his clinical lectures has been long in the habit of dividing it into acute eczema and chronic eczema. This method we have adopted.

Under the acute *eczema* we rank:—

1. The *eczema simplex*, which constitutes a very distinct variety by its slow progress, but one very different from that of the chronic eczema, which succeeds the acute eczema. 2. The *eczema rubrum*; and 3. The *eczema impetiginodes*.

1. *Eczema simplex*. This variety presents itself under the form of extremely small vesicles, which are very crowded and close to one another, and developed, without the least inflammatory areola, over a surface, the colour of which does not differ from that of the surrounding skin.

Eczema simplex appears without the slightest precursory symptom; the patient feels a slight itching, and is very much surprized at seeing an eruption of greater or less extent. The vesicles which constitute it are numerous, very much crowded, transparent, small, and free from pain; they present a shining appearance; the small drop of serum which they contain is turbid, and takes on a milky appearance; the liquid is soon re-absorbed, the vesicle withers and falls by an imperceptible desquamation, or else it opens, and there forms an extremely small thin scaly disc, which soon becomes detached. In no case does the eruption occasion those inflamed surfaces, that exhalation of serum, and that renewing of the scales observed in the other varieties; it does not leave the slightest trace behind it.

These different stages take place slowly, and the disease is generally prolonged by

successive eruptions, which causes its usual duration, to vary from one to two or three weeks, and sometimes even beyond that period.

The *eczema simplex* may be general; but it is usually limited to a surface of more or less extent. Among other places it is observed rather frequently on the arm and fore-arm; very often in the space between the fingers, and being sometimes confined exclusively to this part, it may be mistaken for the itch. It is not accompanied by any other symptoms than an itching, which is sometimes severe, more particularly when the eruption is general.

This variety of eczema appears most frequently in young persons, and chiefly in females. It is frequently observed to develop itself after irritating frictions and lotions. It is this eruption which is most generally occasioned by those medicines sold by quacks to drive out the itch. We have very often observed it in persons obliged by their trade to continue all day near a furnace or very hot fire.

Lastly, it is sometimes the result of causes not easily appreciated; thus it often appears between the fingers in women after accouchement.

The *eczema simplex* is a slight disease which is never accompanied by constitutional symptoms; it often complicates them, being ordinarily produced by the means employed to combat it; it sometimes exists with lichen.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

Of the Resolution of Inflammation by Constitutional means.

If the inflammation is of the true adhesive kind, the only thing to be done is to lessen everything that has a tendency to keep it up, because we know of no method that will entirely quiet or remove the inflammatory disposition, or mode of action; there is no specific against inflammation that we are acquainted with. Whatever will lessen the power or disposition will lessen the effect.

There appears to be three means which tend to remove inflammation: first, by weakening; secondly, by producing temporary weakness; thirdly, by lessening or soothing the irritability.

That which absolutely weakens is bleeding, purging, quietude, and low diet. The temporary weakness is produced by

sickness at the stomach, faintness, &c. The soothing effect may be produced by sedatives, antispasmodics, &c., such as many sodorifics, anodynes, &c. The first will have the greatest, most immediate, and most lasting effects; the second and third act as auxiliaries; the second probably will come nearest to lessening the cause, while the other will assist so far as irritation is a cause; they should go hand in hand, for wherever we lessen the power we should at the same time lessen the disposition for action. But neither bleeding, sickness, nor purging can possibly lessen the original inflammatory disposition: by lessening the power of action of any disposition you only lessen or protract the effects, which, however, will be of singular service, as less mischief will be done, and will often give the disposition time to wear itself out.

Bleeding, then, at first may be necessary; but this must be done with some restriction. If inflammation arises from real powers, then bleeding freely is absolutely necessary; but if from too great action of weak parts, bleeding should be no more than what will lessen the violence of the blood's motion, or remove the feeling in the part inflamed of too much to do. The quantity, therefore, must be according to the symptoms and other circumstances, that is, according to the visible indications. The indication for bleeding is, first, according to the violence of the inflammation, joined with the strength of the constitution; secondly, according to the disposition to form blood; thirdly, whether the disease is in a vital part; fourthly, its situation, whether near the heart or not; fifthly, according to the duration and the extent to which it has affected the constitution.

With respect to the first kind, in which the constitution is strong and the inflammation is violent, bleeding largely is proper, and in many cases bleeding near the part will answer better than from the general habit; less may be taken away in this way with an equal effect on the part inflamed, and of course with less effect on the constitution, as bleeding from the temporal artery, or the jugular vein, for complaints of the brain, or cupping or applying leeches near the part, as, for example, to the temples in inflammation of the eyes.

The same mode of practice is to be followed with regard to the second, third, fourth, and fifth. It seldom happens that one bleeding will be sufficient in a considerable inflammation. The first blood

taken affords a symptom of the disease; if it is buffy, thick, and considerably cupped, future bleedings may be used with less caution. On the other hand, there may be indications for bleeding sparingly; first, from there being too much action with weakened power; secondly, from a disposition to form little blood; thirdly, from the part being far from the source of the circulation.

A gentleman had a violent inflammation of the eye; the blood was sizzly, but though sizzly the coat was exceedingly tender, and so slight as not to bear its own weight when raised up. He was bled plentifully several times, without any good. Here was not, then, much power, the blood putting on the sizzly appearance in consequence of there being increased action in the vessels of this part of the body.

A lady with inflammation of the tonsils was bled; the blood was sizzly, but loose; and after three bleedings the blood became so loose that the bark was given, which did service. The disorder returned again, and the same mode was used; the blood was sizzly only in the first bleeding: the bark was obliged to be given again.

In such cases bleeding is very seldom necessary. Where it is necessary, it should be as near the part as possible, in order that it may have the greatest effect on the part with the least damage to the constitution. If local bleeding be used, leeches will answer best, because but little inflammation follows their bite; however, this can only be put in practice in inflammations which are pretty much external. In many cases we cannot take it immediately from the part, and must be content to go as near as we can, as in bleeding from the temporal artery or jugular vein, in affections of the head. Sometimes of course even this will be impossible, as in inflammations of the liver and stomach.

Too much action with small powers may often, if not always, be classed with the irritable, and bleeding here should be performed with very great caution. When inflammation is far from the source of the circulation the same precaution is hardly necessary, as in general it can be taken away from the part.

We cannot depend on sizzly blood alone as a proof of the propriety of repeating the bleeding; we must take into consideration also the strength of action.

The pulse is a great indication for bleeding in inflammation, but is not

always to be relied on. In inflammations that are visible, the knowledge of the kind of inflammation is in some degree ascertained, in which cases it has been supposed that we go on surer grounds in our indications for bleeding. But all inflammations are not visible; therefore we require some other criterion. If we could ascertain the pulse peculiar to certain appearances in visible inflammations, and were sure that universally the same pulse attended such appearances, we should then suppose we had the true indicative criterion to go by, and be able to apply it to invisible inflammations, and judge of these by the pulse. But when we consider that the same kind of inflammations in every part of the body will not produce the same kind of pulse, but very different pulses, not according to the inflammation, but according to the nature of the parts inflamed, and many of these parts are invisible, we see that we at once lose the criterion of the pulse as a guide. There may be every symptom of inflammation and the pulse be soft, and not quicker than usual, and yet the blood when taken away will be sisy and cupped.

A lady had this kind of pulse (soft and not quick), and at the same time had a violent cough, with tightness of the chest and stitches in the side; bleeding was ordered, when the blood was found sisy, &c.; nor did the illness subside till the sixth bleeding.

A hard quick pulse is generally an indication for bleeding, being frequently accompanied with sisy blood; but even these signs are not always to be depended on as furnishing a criterion. The kind of blood is of consequence to be known, for although it should be sisy, if it is not firm in its texture, but lies squat in the dish, bleeding must be performed very sparing.

As the pulse simply, independently of all other considerations, is not an absolute criterion to go by, and as a sisy and strong coagulum is only an afterproof, let us see if there are any collateral circumstances that can throw some light on this subject, so as to enable us to judge, *à priori*, whether it is right to bleed where the pulse does not of itself indicate it.

When speaking of inflammation of various parts, I took notice of the pulse peculiar to each part, which I may now be allowed to repeat. First, I observed in inflammation of parts not vital, or such as the stomach did not sympathize with, that if there was great power and not much irritability, the pulse was full, frequent, and hard. Secondly, on the con-

trary, in inflammations of the same parts, if the constitution was weak, irritable, &c., that then the pulse was small, frequent, and hard, although, perhaps, not so much so as when, thirdly, the inflammation is in a vital part, as the stomach or intestines, or some part with which the stomach readily sympathizes; then the pulse is quick, small, and hard.

Now in the first of these dispositions bleeding is absolutely necessary; but in the second, where the pulse is small and frequent, bleeding should be performed with great caution: though the person may be of strong constitution, yet in inflammations of these parts the constitution appears to be more irritable, and to have a greater sense of weakness. We should bleed to two or three ounces by way of trial, which could do no harm.

The urine will throw some light on the disease; if high-coloured, and not much in quantity, it may be presumed, with the other symptoms, that bleeding will be of singular service; but if pale and copious, though the other indications may be strong for bleeding, it may be necessary to do it with caution.

Bleeding, however is a remedy of so much importance that it should be employed in all cases with great caution; yet not more than appears really necessary.

I cannot perceive why bleeding should have such an effect on inflammation as it often has. We cannot account for it simply on the mechanical principle of lessening the quantity of blood, because this can never remove the *cause* of inflammation.

Medicines—Medicines which have the power of producing sickness lessen the powers of life universally, because every part of the body sympathizes with the stomach; and when they are intended to produce this effect they should not be given in doses sufficient to produce anything more than sickness, for the act of vomiting is rather a counter-action to that effect, and I believe has rather the effect of rousing, as few are so weak as not to be able to bear sickness. Purges have been much recommended, under the idea that there were humours to be carried off; such practice answers best in the cases in which bleeding is useful. In irritable habits, where inflammation becomes more diffused, greater caution is necessary, as nothing tends to weaken the habit more. A single purge has been known to produce death in dropsy. In such cases bark may be required to bring the constitution into a proper state, either for

resolution or suppuration, by increasing the powers and diminishing the action; and thebaica may be a good assistant as a soothing or sedative with the bark.

Modes of Resolution by external applications.—Whether we have any external applications which have really a tendency to resolve an inflammatory disposition, is not well ascertained. We are in possession of many that can weaken, so as to lessen the powers, (most of which appear to be of the soothing kind,) and thus lessen the action, though the cause may still exist; by which means the effects are lessened, and the inflammation is either cured or protracted, until the disposition wears itself out. Perhaps cold is one of the greatest weakeners, but it should not be used too freely, as it may produce a worse disease, which is indolence. Lead is supposed to have considerable effects in this way; but I believe much more is ascribed to it than it deserves. Its properties appear to be to lessen the powers, and therefore it should not be used except when the powers are too strong. Applications to weaken should not be applied to irritable parts; on the contrary, the parts should be strengthened, which can only be done through the constitution.

Whatever power external applications possess, they must act in one of four ways: first, which is the immediate or truly local; second, by repulsion; third, by revulsion and derivation; fourth, by sympathy, which is probably the same principle in the animal economy as revulsion and derivation.

The first, or local effect, may be of two kinds: 1st. simply such as is an antidote to the action of the part, as cold, sedatives; 2nd. such as destroys the first irritation, by exciting a second. This is most applicable to specific diseases, as the action of mercury in a venereal sore: but all specific diseases will not allow of it; a gonorrhœa in a scrofulous habit is an instance of this. In some cutaneous cases this mode of cure is very useful. Sedatives are less useful as local applications than counter-irritants, but both of them may have another effect, viz. repulsion or derivation, which must be from a constitutional affection, such as I have called an act of the constitution, as in gout. If the constitution is determined to have a local complaint, by which she throws off a constitutional disposition, then these revulsions do not rid the constitution of the disposition. It is difficult to say what will merely repel and what will

cure. Repulsion, however, is a cure of the part, whatever effect it may have on the constitution. Surgeons were formerly greatly afraid respecting repulsion. They were even afraid of curing a gonorrhœa, lest they should drive it back into the constitution and produce a pox; but they did not consider that it does not arise from the constitution, and has nothing to do with it.

Revulsion and derivation appear to me to depend on the same principal in the constitution as sympathy, and, like the latter, have the greatest effect in habits which are irritable or nervous, and in diseases which are nervous, as cramp; not in such as change the structure of parts. I knew a nervous girl cured of pain in one arm by rubbing the other. These terms were used under the idea of removing humours by inviting them from other parts, as making an issue to remove eruptions. They probably act by causing an irritation in one part to cease when an irritation in another is excited; and this latter may be made greater than the original one, though in a part less dangerous, and where it can be more easily cured, as burning the ear cures the toothache; vomiting, the swelled testicle; blisters, pleurisy, &c. In some of these, as the vomiting to cure the testicle, no new disease is excited, but only the action of the part. The cures performed by these modes are in many preferable to those by means of local applications, and they will succeed where the others fail; thus, vomiting will cure hernia humoralis, when other applications have had no effect. The cure by revulsion, or sympathy, is in some respects the reverse of that by derivation, yet it is probably from the same consent of parts, but from a different action. In these a remedy is applied to a sound part to cure a diseased, which is either contiguous, continuous, or remote, and the action is either similar or dissimilar. The cure of continuous parts by similar sympathy is by the application of such remedies as we suppose would cure if applied to the part. That of remote parts by dissimilar modes of action, is by stimulating a part in such a way as that the sympathy shall act in the same way, and yet the action in the diseased part be not at all similar to that in the sound part: suppose, for instance, a part in any mode of action, a medicine applied to it would increase that action. but by applying it to another part it will remove the first. The contiguous is different from the two former, and can only be applied to surfaces, as a blister to the scalp to remove head-

ache. These may be either stimulating, or soothing, or specific.

Treatment of Adhesive Inflammation when Suppuration must take place.—The treatment must, in some measure, be the same as in the foregoing in accidents where the powers are very great, and the inflammation violent, namely, bleeding, purging, sickness, &c.; but when the constitution is irritable, bark, &c., as before directed. In cases where there is considerable sympathy, sudorifics, as Dover's powder, seem desirable, as they tend to keep up the harmony between the skin and the stomach. Opium in peculiar constitutions increases irritability; but in others, where there is not this peculiarity, it is highly useful in soothing and diminishing irritability.

Different applications have been made to the inflamed parts, as fomentation, washes, poultices, &c. The mode of applying heat and moisture by fomentation appears more efficacious than in the form of a fluid; it certainly gives ease at the time of the application, but the symptoms generally recur between the times of using it, and with nearly the same violence. How far the application of a medicine for fifteen minutes out of the twenty-four hours does good, I hardly know.

Washes are fluid applications, and are more commonly used to inflamed internal surfaces than to the common integuments. I am afraid we are not much acquainted with their true specific virtues, the use of them being very vague. For inflammation of the eyes we use astringents, as alum, vitriol, &c. For inflammations of the throat with port wine, vinegar, &c.; yet how absurd it would be, in the opinion of any surgeon, to use the latter applications to the eyes; and yet if the two inflammations are the same I do not see why we should not use the same remedies to both parts. These like the former, have only temporary effects.

Poultices are constant applications, and may be either simple or medicated; their effect is greatest locally, but it extends likewise to surrounding parts by sympathy. They may be medicated with lead, opium, &c. Simple poultices are the best application where we have no particular object in view.

THE MEDICAL JURIST.

No. 3.

INSANITY.

After the time of Pinel, the allowance of food to patients in the asylum under his charge, was reduced one-fifth, and great mortality ensued. One keeper was executed for starving a patient to death. Maniacs require a large quantity of food, owing to the violent exertion which they undergo, and the loss of strength from perspiration, &c. The diet should be plainly, but well cooked; and, to convalescents, served up neatly. At the Liverpool Asylum there are four rates of board; and the diet, of course, differs in such; but if the physician orders it, the poorest patient gets a dinner of the best. The four classes dine separately; the meat is all cut, and therefore no knives and forks are used by the patients, who eat with a spoon. They all pay, or their parishes for them. The kitchens are fitted up with all the modern improvements.

Amusements are too often scandalously neglected. Occupation withdraws the thoughts of the patients from the subject of their malady. The best model of an asylum in this respect, is in a bad country, at Saragossa, in Spain; there are large gardens, in which the convalescents may occupy themselves; and those of different habits are employed in other ways, either in the house or in workshops. From its neatness and the regularity of all its arrangements, it has the appearance of a military asylum. The patients have among them a wealthy association for the cultivation of olives, and other patriotic objects. Aristocratic patients in general disdain labour, and are less frequently cured on that account. In towns, with the exception of skittles, fives, see-saws, and others, no games out of doors can be pursued; but some can work as joiners, and at other trades: the usual reward for working (and they generally seek it with avidity) is a little better diet, or a better ward. For convalescents, newspapers, books, draughts, the piano forte, and (for females) the mending of clothes, afford pleasing occupations. One of the best books for this purpose is the Penny Magazine. Those who make the beds, wash the cups, clean the rooms, and perform other domestic services, get better sooner than others. In Amsterdam there are only a few servants in an

immense establishment of poor persons, the latter performing most of the work. If the patients have previously had a taste for the fine arts, their cure will be facilitated by cultivating them. If they are fond of music, for instance, when their attention can be drawn to it, their convalescence is begun. Always allow it, unless the hallucination should happen to relate to it. At the Bicetre, and Salpêtrière, there is a large cobbler's shop, and those who work in it obtain a small premium on their discharge.

A slight must never be shown to the feelings of patients. Convalescents are sometimes thrown back by denying them the materials necessary for their work, or not allowing them to go work at the usual time: they are often very sensible to galling words, or anything like contempt or indignity. Such treatment will often produce the most violent excitement. You should never break your promise, even when made while the patient was maniacal, for persons of moral feelings often retain a great regard for their word. A gentleman, says Dr. Traill, was brought into the asylum at Liverpool, in so violent a state of excitement as to require confinement in bed. As he had been at my house a few days previously, he considered me to be the author of his "imprisonment," as he called it; and on that account had a violent antipathy to me. By moistening one of his hands with urine, he made the manacle so soft, that he slipped his hand through it, and then, with a piece of glass which he had taken from a window he had broken, and had secreted in his mouth, he cut all the other straps. On looking through the aperture opening into the gallery, I saw him standing quite naked, his body smeared with excrement which he had taken from the close-stool. He had very nearly torn away the window-frame; and we afterwards learned that his intention had been to precipitate himself out of it; which was of a height of three stories. The governor rushed in with me, but before we could secure him, he struck us each a blow in the face; the governor pinned him in his grasp; I laid hold of his legs, and we laid him on the floor. The manacles brought by a keeper were too small; and while the governor went to look for others, he was left in charge of the keeper and myself. He then asked me why I held him on the floor. I replied that he had struck the governor and me; but we allowed no striking in the house; that I knew he was a man of his

word, and would let him rise if he would promise to be quiet. He promised accordingly; and though the keeper remonstrated, I ordered him to leave the room, and not to interfere with my patient. We sat down quietly on the edge of the bed, and talked quietly of the weather, and other matters, till the return of the governor, when he held out his hands for the manacles, and we were ever afterwards good friends. All this was owing to my having betrayed no fear, and shown perfect confidence in his word. I have sometimes made great sacrifices of time, rather than break a promise. I once listened for two hours and a half to a written statement, and the patient was then satisfied that I was not one of the conspirators, as he thought I had been; and he told the governor so.

Lunatic asylums are not now made exhibitions as they formerly were, and which must often have had a very injurious effect upon convalescents. In Great Britain, and in many places on the Continent, they cannot now be seen without an order from the governors, or the medical men attached to them.

You must endeavour to calm the maniac; to soothe the melancholic, &c. Till they are nearly well, however, they cannot listen to long arguments, and therefore should be short and pithy. They must be treated as children in winning, restraining, correcting, &c. Some, however, are very witty and shrewd, and detect any inconsistency in words and actions. In their excitement they sometimes remember former kindness. They are very susceptible of taunts. Dr. Traill once said to a patient, he was sure he was not goose enough to believe such nonsense; but he remembered the taunt in all subsequent paroxysms, and asked the doctor if he thought him a goose now, or that he could only talk nonsense. The habit of seeing people rise, eat, &c., at regular hours, and the obedience of other patients, has the best effect. There was, not long since, an investigation into the treatment which a distinguished naturalist met with from menials. He was kicked by them, and received every indignity, though he had not lost all recollection of his former condition. A gentleman informed Dr. Traill, that at an asylum where he lived as an assistant, about the end of the last century, the doctor used to arm himself with a whip, *in terrorem*, before entering the yard.

Maniacal explosions, as Pinel says, are only automatic impulses, at which it is

not rational to be angry. If much excited, the patient cannot listen to argument; and if dangerous, he must be restrained. For this purpose a bed with straps is preferable to a strait-jacket, for how carefully soever it may be put on, the action of the patient generally makes it press on the neck; where, by impeding the passage of the blood through the jugular veins, it increases the determination to the head. Conspiracies have sometimes been formed to seize the keepers and get possession of the keys. Some persons are aware of the approach of a paroxysm, and beg to be confined. One gentleman used to go to the Liverpool Asylum, about every nine months, and request admission; but this could not be granted without the order of a medical man. A woman used to request confinement for a few days, and used then to spit copiously about the room and walls, and on all who approached her. The first thing she did, on recovery, was to clean the room and the bed. There should be a few rooms allotted for noisy patients, but they should not be far from the governor, for such persons require much attention.

Monomaniacs have very disturbed rest. Some abstain from food in consequence of rash vows. In such cases, some medical men resort to the stomach-pump, but it is liable to do harm. In one case, where a long tumour in the neck prevented deglutition, Dr. Traill supported a patient for three months on injections containing eggs.

If religious people become insane, you must avoid all religious books and conversation, and keep them from the other patients, as their spirit is contagious. You must employ solicitous treatment, gentle exercise in the open air, and occupation. There is a great tendency in monomaniacs to suicide. A case occurred in France, in which a patient hung himself from a key which had been left inside the door. He suspended himself by means of a shred which he tore from his shirt, and sitting down on the floor he managed to kill himself. In the daytime you may allow such patients to mingle with the rest, and at night confine them, hand and foot, to the bed. Some patients of this kind are apt to dash their head against the wall, and in some asylums there is a room for them with the walls padded. It is very common for patients of this class to cut their throats. If the wound be inflicted on the trachea below the larynx, and is not closed, the voice is lost. This fact has been fre-

quently shown on a pig. One man thought he was ordered to amputate his penis, in order to obtain salvation. He did so about the middle, with a razor; injuring the scrotum at the same time. He recovered after sometime, and Dr. Traill often saw him as a servant; but he avoided any tokens of recognition, as he seemed anxious to avoid it.

Some disapprove of asylums being furnished with chaplains. Pinel disapproves of public religious services for the insane, and Dr. Traill has generally found them worse after the visit of the clergyman. The question is still *sub judice*; but the very best effects have recently followed the introduction of public religious services into some lunatic asylums in Edinburgh.

The following is an instance of moral power exercised over a patient;—I once, says Dr. Traill, went into a room, where there was a patient disposed to be violent. He immediately fastened the door, but at this I was not disconcerted, for the governor was on the outside with a key which would open it. I sat down by him on the bed, when he asked me if I was not afraid. "Afraid," I replied, "of what?" He said, "Afraid of me! I have the strength of ten men in each arm!" I smiled, and told him that strong as he was I had a spell which could master him, and that, if I pleased, I could tie a knot upon him, and throw him out of the window. The extravagance of this boast evidently astonished him. He gave me his hand, and afterwards told the governor that Dr. Traill was a wonderful man, and had "immortal strength."

We must sometimes be cautious in giving liberty to maniacs who appear quiet. There was one, says Dr. Traill, who I thought might be allowed to sit up in the chair. Two or three days afterward he asked me to look into his eye, as there was a speck there. While I was doing so he made a bite at me, on which I coolly observed, that we never allowed biting in the house, since it was inconsistent with the rules of good society, and that if any one attempted to bite, we put him to bed. He replied, "Is it so?" and never afterwards made any attempt of the kind.

One man refused to eat, because he thought he had the devil in his stomach, and he wished to starve him. Dr. Traill told him that the devil, if not supplied with food, would eat him, which induced him to take food. An emetic, given to expel the devil, hastened his cure. An-

other man thought he had received a command to beat out his brains out with a cobbler's hammer, and had actually commenced a spot of the frontal bone before he was discovered and taken into the asylum.

With respect to the medical treatment of insanity, but little of value may be learned from the ancients. Celsus recommends stripes, and other barbarous measures. A better system was begun in Saragossa during the last century, and Pinel was the first to introduce an improved system into France. Willis was not a physician; his treatment was too severe, and it was wrong to allow the keepers to return blow for blow. If blows are allowed as a punishment, it either assumes that the patient is a moral agent, or it is a needless barbarity. It always excites the patient and makes him worse. Celsus recommends cupping at the back of the neck when the patient has much watchfulness. Cullen thinks bleeding is right in recent cases of mania, and that it should be performed in the erect position; but Pinel reprobates it. He says that if deliquium takes place, it is apt to lead to fatuity; and he knew one case in which deliquium followed the loss of only four ounces of blood. He does not, however, forbid bleeding in all cases. An old practitioner recommended Dr. Traill never to open a vein in a lunatic, and the experience of Dr. Traill himself, rather favours the correctness of this precept. If there should be a flushed face, however, and other symptoms of excitement, local bleeding will sometimes be of service. In mania from suppression of the menses, bleeding in the feet is advisable. Dr. Haslam finds blisters to the legs of service in these cases, but not issues; but Dr. Traill approves of the latter, not only when the catamenia are suppressed, but also when insanity has come on after the drying up of a discharge. He never applied blisters to the head; but sometimes, and with benefit, to the back of the neck, or between the shoulders.

The practice of plunging insane persons under water, was begun by Van Helmont. Some have recommended that the patient should be held under water for a long time. This practice is defended by Boerhaave; and Cullen thinks it is sometimes beneficial. Dr. Haslam says it is liable to produce epilepsy; Pinel disapproves of it, and Dr. Traill thinks it barbarous and dangerous. Patients speak of it with indignation. Cox speaks of immersion in a chair, but prefers the

shower-bath, or water poured over the head. Some recommend a clay-cap, or a bladder of ice, to the shaved head; but all these plans are inferior to the douche. A quack in London cured several patients by applying ice to the head, while the body was immersed in warm water, or (as a patient described it) by "boiling the body while he froze the head." In using the douche, the diameter of the stream should be about the tenth of an inch, for if it be larger its application gives pain, being like ice falling on the head. It is sometimes required to fall by drops, and its application should never be continued longer than one or two minutes. At Hamburgh, where the baths are most complete, the douche sometimes instantly represses maniacal excitement. Tepid baths, from eighty-two degrees to ninety, are generally liked by the patients, and have a good effect, both in mania and monomania. Cullen doubts their utility, but I think in his time they were employed at too high a temperature, so as not to be tepid but hot baths. Dr. Haslam and others, when before the House of Commons, recommended the use of tepid.

Purgatives have been much employed in insanity, from the time of Hippocrates downward. The ancients used hellebore for this purpose, thinking it had a specific effect in unloading the vessels of the brain; but its only effect is in removing constipation, to which the insane are very subject; what this hellebore was is very uncertain. Wildenow says it was not the helleborus niger, but the helleborus orientalis. The best pill for the insane, is the compound colocynth, sometimes combined with a little extract of hyoscyamus. In cases of violent mania, the patient will often refuse to take a pill, from fear of being poisoned. Here you must either force down a liquid purgative, or give a powder in some article of diet. In public asylums, the common cathartic mixture, made with infusion of senna and Epsom salts, is very good; but in private practice it is better to have a variety, for the patient gets tired of any one that is exclusively employed, and the stomach and bowels are often irritable. Purgatives are thought to be very advantageous in mania, from the benefit which is sometimes observed to arise from spontaneous diarrhoea. But there is a kind of diarrhoea, attended by pain, which aggravates mania, and which evidently arises from irritation of the mucous membrane of the intestines. In this case you must give Dover's Powder.

Emetics are reprobated by Willis and Haslam, but are recommended by Cox and others. Pinel is guarded in the opinion which he gives of them, and they are not much used in France. Dr. Traill has not employed them much, as he thinks the cases which Cox brings forward, do not bear out his general observations. Emetics are very useful, however, in monomania, especially when there is much ropy mucous about the mouth. Dr. Traill has never used tartar emetic for this purpose, but ipecacuanha wine or ipecacuanha powder. The wine is most easily given. A solution of sulphate of zinc is very good, for it operates quickly, and leaves less debility than the others.

Opiates are much abused in insanity. In large doses they are seldom useful; but in great maniacal excitement they are often of great service. One large dose should be given, followed by small ones. Laudanum and soap-liniment make a very good preparation for rubbing in, or powdered opium in hog's lard. Opium applied in either of these modes soon finds its way into the system.

Camphor, used as a stimulant, often does harm, by increasing excitement; and used as a sedative Dr. Traill has no opinion of it, though he has found it do good in restoring the stomach to a proper state, after it has been disturbed by opium. In Java and Sumatra camphor is obtained from trees, by splitting them; it lies in the interstices of the wood, is very fragrant, and is said to be more sedative than common camphor; but only specimens of it reach this country.

In the latter stages of insanity the treatment must be of a moral kind. Music and conversation, together with skittles, billiards, playing at ball, and other amusements, must be put into requisition.

If the patients can afford it, the best plan is to let them out to ride, with a servant to each. Esquirol's private asylum was the best we have ever heard of. Every patient there had his own servant.

sian and German Campaigns of 1812 and 1813.

We now resume our notice of this truly interesting and practical work. Chap 3. treats of

Enteritis, which is characterized by a fixed pain in the abdomen, generally felt around the umbilicus, and which is increased by pressure and by moving. This pain is accompanied by an alteration of the features; by constipation, loss of appetite, nausea, vomiting, flatulence, anxiety, oppression, intense thirst. a sensation of internal heat, a certain difficulty of swallowing, want of sleep; by a pulse which is hard, unequal, irregular, often very frequent, very small and sometimes obliterated as if the pain and inflammation impeded the hearts' contractions; the tongue is, in the great majority of cases, red, diminished in size and pointed, or only red at its edges and apex. Sometimes dry and hardened, oftentimes loaded in the centre with a whitish or yellowish coat; the stomach rejects whatever food and drinks the patient swallows; extremities cold, mouth dry, abdomen generally painfully tense, in several cases swollen, and very hot to the touch; there is frequently fever, extreme paleness, sinking, delirium, cold sweat, &c. The inflammation may extend over the entire gastro-intestinal mucous membranes) the tenesmus and liquid, mucous, serous and bloody stools which supervene in enteritis prove that the inflammation extends into the large intestine. The accompanying symptoms just now enumerated, do not always exist combined and may have different degrees of severity.

This inflammation may be sometimes confounded with colic, from which it is to be distinguished by the fever as also the permanency of the pain. It is of the same nature as gastritis, and affects the intestines, as this latter affects the stomach.

Enteritis may be caused by acrid or irritating matters received into the intestines; by the use of bad food, or of a too great quantity of food difficult of digestion; by an external contusion on the abdomen; by iced drink or the impression of intense and sudden cold on the body while it is bathed in perspiration, and even by the impression of cold alone on the lower extremities or on the abdomen: by the unseasonable use of drastic purges; by the too sudden suppression of a diarrhoea, by strangulated hernia, by spasmodic diseases of the intestinal canal, &c. It may likewise sometimes depend

REVIEWS.

Histoire Des Maladies Observées A la Grande Armée Française, Pendant les Campagnes De Russie en 1812 et D'Allemagne en 1813. Par le Chevalier J. R. S. DE KERCKHOVE. Anvers, 1835. History of the Diseases observed in the Great Army of France in Rus-

on suppression of the hemorrhoidal flux, or of some of the exanthemata; in a word all the causes capable of giving rises to gastritis, may also produce enteritis. Young persons of a sanguineous and bilious temperament are most subject to it.

Our author here makes an observation of considerable importance in a practical point of view, namely, that it is not uncommon to take cases of enteritis for cases of typhus, in consequence of the cerebral phenomena, of the fever, the depression, paleness and miserably low state of the pulse, symptoms which are observed in inflammations of the intestinal canal, so that one is disposed to think that he has to combat a prostration of strength, whilst the case is in reality but an oppression of strength, or a false debility. Our author has the candour to acknowledge that this apparent asthenia has often caused him to commit serious mistakes, which he discovered only by an autopsy, and takes this opportunity of recording his obligations to M. Broussais, for having directed his attention to a pathological point of so much importance.

Enteritis is a very alarming disease. It seldom prolongs the duration of its acute stage beyond the seventh day. Its terminations are resolution, suppuration, induration, gangrene, and its transition to the chronic state. The first of these terminations is announced by the developement of the pulse; by the diminution or total disappearance of the febrile state, if it had previously existed; by the diminished tension and pain of the abdomen, and by the return of the stools. In the second termination the pain, though diminished, still continues, the patient experiences some anxiety, and vomiting at intervals, the pulse continues small, febrile accessions are observed, particularly towards evening, the symptoms of hectic fever soon become developed. This termination is almost always fatal, unless the pus is discharged by stool and the ulcer heals. If the pus is effused into the abdominal cavity, it constitutes what is called *purulent dropsy*. The termination by suppuration occurs more frequently in the large intestine than in the small. If the suppuration takes place in the colon, it not rarely gives rise to chronic and incurable diarrhœa.

The fatal termination by induration, which is extremely rare, is discovered by the continuance of a feeling of fixed pain in the belly, by the constipation, by chronic vomiting, by emaciation and slow fever.

The termination in gangrene which is here much more common than in gastritis, is known by the sudden cessation of pain after it has been very violent; by the general and total prostration of the vital powers; by the fall of the pulse, which is frequently imperceptible; by the meteorism; by the coldness of the extremities; by the cadaverous smell of the stools, which are frequent and involuntary; by the great alteration of the features, &c. This termination is not always fatal as in inflammation of the stomach. The gangrenous parts sometimes separate from the healthy parts, and are thrown off with the *feces*.

When the enteritis prolongs its duration, when it is in the chronic state, and febrile symptoms have ceased, and even if they should show themselves, it is but slightly, and after dinner; the redness of the edges of the tongue is no longer permanent, it sometimes disappears entirely, or is not observed till after the stomach has been stimulated; the heat, tension, swelling or tympanitic state of the abdomen no longer exist; the pulse is no longer either so hard or so small; it is occasionally in the state of health, principally in the morning, but it presents more or less frequency towards evening; the pain has become dull, oftentimes is felt only at intervals, increases some hours after eating, and in consequence of any stimulant being applied to the intestinal canal; but the thirst continues more or less, the flatulence annoys the patient very much; he is ordinarily sad and a prey to melancholy; the stools are difficult and dry, there is at times diarrhœa, &c. Towards evening the symptoms become more or less exasperated. The same phenomena are observed in chronic gastritis; but in the latter there is more frequently vomiting, or a disposition to vomit.

The enteritis which appeared among the French troops appeared to be rather of a bilious nature: for which reason it was called by our author *bilious enteritis* in the first edition of the present work. The autopsy showed that its seat was often limited to the small intestines; sometimes, however, the entire extent of the intestinal canal, even the mesenter^y, liver, and spleen participated in the inflammation. The two last viscera were almost invariably found affected in the dead bodies which were opened, during the summer, in the hospitals of Wittepsk and Smolensk.

The enteritis observed in the French army was ordinarily characterized by the

following symptoms: very painful tension and oftentimes swelling of the abdomen; depression; tongue covered with a yellowish mucous coat; dislike to food; mouth dry, bitter, or pasty; nausea, bilious vomiting; thirst, anxiety, oppression at the epigastrium; pulse small and unequal; loss of sleep; urine loaded and scalding; pyrexia oftentimes more or less intense; constipation, stools sometimes liquid and frequent; a sort of paleness or livid appearance of the lips; a wild appearance of the countenance, &c. According to the author it was principally occasioned by the too stimulant action on the intestinal mucous membrane of the bile which was effused into the intestinal canal in greater abundance than natural, which in some arose from irritation of the liver, and in others from relaxation of this organ. These two different pathological conditions arose from coarse food, from privations, from atmospheric causes and from fatigue, which, at the same time, rendered the bile of a much more acrid character. But besides this cause, there were others, such as the presence of indigestible matters in the intestinal canal; cold and icy drink taken while the body was bathed in sweat; sudden cold which took place when they stopped under the cool of the night, after having marched all day under the burning heat of the sun, &c. Suppression of the cutaneous transpiration chiefly occasioned inflammation of the intestinal mucous membrane, the latter being already irritated by the bad food and the over-abundance of very irritating bile. So that from this, one may see that there was in our soldiers a concurrence of several powerful causes combined to give rise to this inflammation.

Treatment.—The treatment of enteritis differs not from that of gastritis. The principal indication of cure is to combat the inflammatory state. Blood-letting, regulated according to the degree of inflammation, the intensity of the pain, the strength, temperament and age of the patient, are the first means to be employed: general bleeding must be employed when life is endangered by the violence of the inflammation, and when it is necessary to produce a speedy effect: local bleeding is preferable under ordinary circumstances as being less debilitating. These means must be accompanied by a strict attention to regimen; by the application of cataplasms or emollient fomentations over the abdomen; by mucilaginous mixtures or demulcent drinks, such as a solution of gum-arabic, barley water, marshmallow,

&c.; by the employment of mucilaginous and oily lavements, given however in small quantity. In the case of constipation, provided the enteritis owes its origin to the presence of acrid matters in the intestines, we then may administer with advantage, after the abstraction of a sufficient quantity of blood, laxative medicines, such as manna, &c., and above all purgative lavements, which may not only remove these matters, but likewise produce a good derivative effect, if the inflammation does not extend to the large intestines; but we should be cautious in employing the medicines now mentioned when the inflammation is intense, until we have combated it properly by bleeding.

With respect to blood-letting it may be remarked that the physician should not weaken the patient too far; that he should always keep in view the liability of enteritis to change into typhus; for if this change occurs and the strength be too much exhausted, nature has no longer sufficient resources to resist the disease. It is of importance that the bleeding should take place in the three or four first days of the disease: if employed at too late a period, they may be mischievous, and may bring on serious nervous complications. The cautious practitioner will make it a rule not to take any more blood after the fifth day except in cases of absolute necessity. When general bleeding is performed, our author prefers taking blood from the foot. If local bleeding be employed, the practitioner may, for instance, apply over the abdomen, in an adult of good constitution, from twenty to forty leeches and make the bites continue to bleed by means of a warm linseed poultice left on for two or three hours. The application of leeches to the anus is also deserving of commendation; it is principally indicated when the patient suffers from tenesmus, and when the symptoms should incline us to suspect that the large intestine was involved in the inflammation.

It is almost unnecessary to say that in the case where the enteritis results from a strangulated hernia, operation is oftentimes the chief means required. In cases wherein it arises from suppression of the hemorrhoidal flux, we should endeavour to recall this by the application of leeches to the fundament, and by emollient vapour baths, directed towards this part. In cases where it arises from the repercussion of gout, we must endeavour to direct it towards the extremities by means of the foot bath, sinapisms, &c. Where

it arises from suppression of the transpiration, from rheumatism, or some lurking cutaneous affection, our effort should be to bring it out to the surface of the body, to increase the action of the skin by hot baths, frictions, and sudorific medicines.

If after having sufficiently attacked the inflammation by the means now pointed out, we have still to combat pain, vomiting, diarrhœa or increased sensibility, which happens as in gastritis, we should then employ sinapisms and vesicatories along the back and on the thighs; warm-baths; opium internally; opiate frictions; opiate fomentations, or cataplasms over the abdomen; lavements of poppy-heads, mucilaginous lavements with laudanum, &c. But if there be fever, or a cerebral affection, we must not administer opium, as it might prove very mischievous.

When the enteritis has come to its chronic state, we must perseveringly continue the emollient and derivative treatment: some demulcent drinks; we must keep up a free state of the bowels by appropriate lavements; we should use derivatives; such as dry frictions along the back and extremities; an issue in the lumbar region, or blisters on the thighs, which should be kept open; warm-baths, in which some aromatic herbs may be infused; opiate frictions, or frictions with the extract of stramonium or belladonna over the abdomen, for the purpose of diminishing excessive sensibility; the use of mild food easy of digestion, &c.; all violent mental emotions and exertions of mind should be avoided; the patient should secure himself against cold, should wear flannel next the skin, should take every day moderate exercise; enjoy country if possible.

With respect to regimen it may be well to remark that we must not subject the patient for too long a time to severe regimen, as is so frequently done at the present day. The privation of the necessary food or too long continued abstinence are very injurious; they deprive nature of her resources, the strength fails, and the stomach becomes inflamed by the accumulation of the gastric juice. Do we not every day see patients who have been exhausted by strict diet regain strength rapidly, as soon as they commence to take proper food. I have frequently seen the bare employment of a mild diet re-establish the health of persons who were affected with acute epigastric pains, with fever and other symptoms of gastro-intestinal irritation, treated ineffectually on the principles of the physiological medicine.

These persons had not been allowed to take any thing for whole months, except barley-water, sugared-water and weak veal broth.

Our author having thus given what he considers the best plan of treatment for enteritis in general, next gives a detail of that which he adopted with most success in the French army placed under such extraordinary circumstances. Among the French soldiers, on whom the disease was most frequently produced by a superabundance of acrid and vitiated bile, by indigestible food, by the presence of saburral matters in the primæ viæ, or by the suppression of the transpiration, our author employed tartar emetic, which is generally contra-indicated in the treatment of enteritis and gastritis. This he gave not only with the view of relieving the intestinal canal of an acrimonious bile and of other irritating matters, which it might contain, but also for the purpose of increasing the action of the skin and of promoting transpiration. He assures us that he has uniformly experienced the best effects from the employment of this means, the utility of which in such cases is acknowledged by the experience of ages. If care was not taken to evacuate and destroy by the emetic the cause of the gastro-intestinal superexcitement, the complication with typhus, rapidly came on, in consequence of the irritation which was transmitted sympathetically to the encephalon. Where the inflammation was very intense, and the patient still retained his strength, he gave the emetic previous to bleeding; but exhausted and debilitated as the soldiers generally were, it was not deemed expedient to have recourse either to bleeding, or even to a long continuance of strict regimen.

We are free to acknowledge that we are so far Broussaists as to feel somewhat sceptical with respect to the safety or expediency of employing tartar emetic in inflammation of the intestinal mucous membrane; nor can the peculiarity of position in which the soldiers were placed, nor the unusual or extraordinary causes which gave rise to the enteritic affection in them, at all reconcile us to the treatment here recommended; and did we not know from other sources, that our author had as sovereign contempt for homœopathy as we ourselves have, we might be inclined to suspect that he was one of the dupes of that heresy.

As often as he suspected that the disease was caused by the copious effusion of acid bile into the intestinal canal, con-

sidering the increased secretion of this fluid as caused by relaxation or passive irritation of the liver, with the use of the emetic he combined frictions with volatile liniment, combined with mercurial ointment, over the region of this organ; emollient drinks, gentle laxative, and a large blister to the abdomen, when the inflammation was now passed the acute stage, constituted the remaining treatment. When the state of irritation gave place to a state of relaxation, which frequently came on between the sixth and twelfth day, he prescribed tonic mixture, such as infusion of camomile flowers, or of absinthium, to which he sometimes added ether, but more especially opium. In our next number we shall close on analysis of this truly valuable work.

On the Nature and Treatment of Diseases of the Heart, with some new Views on the Physiology of the Circulation. By JAMES WARDROP, M.D. to King George IV.. Lecturer on Surgery, &c. &c. 8vo., London, 1837. John Churchill.

Our author, like all scientific contemporaries, commences his work with an account of the structure of the organ of which he treats, and then he describes its function previous to detailing its diseases. Here the reader will find much novel information, as indeed there is in every page, as the following extracts prove.

"Before making any observations on the particular diseases of the heart, it may be well to review some of those striking peculiarities in the natural structure and functions of this important organ, to which I shall have occasion more especially to allude, as our pathological investigations require a constant reference to its healthy condition.

"Destined to propel the blood not only to the lungs, but throughout the whole system, the heart is endowed with a *muscular structure*, and this forms perhaps the most essential ingredient in its composition. The muscles of the heart are generally more firm and more elastic than other muscles; and the fibres of which they are composed are more compact, being separated only by a very delicate cellular tissue.

"The heart's muscles are excited to contract by the blood, in like manner as muscles of other organs are stimulated by the respective fluids which are naturally in contact with them, as in the instances

of the alimentary canal, and the urinary bladder.

"The muscles of the heart are also remarkable for having an unusual number of blood-vessels when compared with those of other muscles, an additional quantity of blood being required to enable them to perform their unceasing actions.

"There is, however, one essential difference in the function of the muscles of the heart from those of all other organs; they *have no repose*! their unceasing action being absolutely necessary for the continuation of life. "How is it," says the illustrious Haller, "that the heart, with its incessant motion during so many years as there are in a life-time, during so many days as there are in a year, and when in each hour it contracts not much less than five thousand times, never resting, but contraction perpetually succeeding repletion,—how is it that the heart is neither fatigued nor pained by so excessive an action, an action which no other muscle could endure even for a few hours?"

"Now it is this difference in the function of the muscles, to which I think may be attributed many of the peculiar feature in the diseases of the heart, and it is also this muscular part of its structure which is found to be most frequently affected.

"With regard to the muscles of the heart, it is easy to comprehend how, when they have been excited to ordinate action, the circumstance of their having no repose to enable them to recover the effects of fatigue must ultimately create changes in their structure, as well as in their function, which would not occur in muscles which can be placed in a state of perfect rest after violent exertion. And, as shall afterwards be pointed out, when the heart's muscles have been over-excited or fatigued a circumstance which is often taking place, they require a distinct system of treatment.

This unceasing action of the heart has, as might have been anticipated, an indirect influence in modifying the diseases of all the textures which enter into the composition of this organ; for, when either its external covering or its internal membrane becomes in the slightest degree inflamed, that inflammation cannot fail to be increased by the unremitting action of its muscles.

In the composition of the heart there is also a considerable quantity of the *yellow fibro-cartilaginous substance* similar to the fibrous coat of the arteries. This structure commences at the roots of the large vessels where they emerge from the

heart's cavities, and by its elasticity it assists these cavities alternately to expand and contract, and thus to accommodate themselves to the constant changes in the quantity of blood which is propelled into them.

" Besides the muscular and fibro-cartilaginous structures, the heart has a serous capsule, or *pericardium*, which covers it externally, and all the cavities are lined by a serous membrane or *endocardium*, the auricular portion presenting a structure similar to that lining the veins, and the ventricular portion having a lining membrane resembling that of the arteries.

" The *coronary arteries* of the heart are not only of larger dimensions than other arteries, in proportion to the bulk of the muscular structure which they supply, but they present a striking peculiarity in their trajet. These vessels, in place of being encircled by muscles, pass along the tendinous and deep grooves which separate the auricles from the ventricles, by which simple contrivance neither the arteries nor the veins can suffer any compression either from the auricular or ventricular contractions.

" The two coronary arteries supply not only the muscular structure of both auricles and ventricles, and the coats of those portions of the large arterial trunks which are within the pericardium, but some of their branches are also reflected on the pericardium itself. These arteries by anastomosing with branches of the internal mammaries, and with the bronchial vessels, establish a vascular connection amongst the different structures of the heart, a connection which is exemplified in many diseases.

" In general, throughout the system, it may be observed, that the blood in the veins flows in an opposite direction to that in the arteries, so that the two streams of blood are, as it were, opposed to each other. But, in the heart, the current of the blood in the large branches of the coronary veins, which vessels are placed alongside of the coronary arteries, runs in the same direction with the blood in the arteries.

" The heart has a smaller proportion of *nerves* than many other organs, and these being derived both from the great sympathetic and ganglionic system explains the influence which the mind exercises on the heart, as well as its sympathies with the respiratory and digestive apparatus,

" Independently of these diseases which
No. 25.

are confined to either the pulmonic or systemic heart, each of the heart's structures is liable, as in other organs, into the composition of which such tissues enter, either to be affected separately, or they may be all involved in one disease; and, whenever any part of the structure of the heart is changed, some of its functions become disturbed, and various alterations take place in the distribution of the blood. If, for example, from any change of structure, the blood cannot readily pass from the right auricle into the right ventricle, or from the right ventricle into the pulmonary artery, it will be naturally expected that either of these changes will produce some irregularity in the distribution of the *venous* blood. So, also, a variety of symptoms will arise from a disturbance in a circulation of the *arterial* blood, when either the left auricle or the left ventricle cannot propel the blood in its natural current, or with its usual velocity.

" On contemplating the structure and function of the central organ of the circulation for the purpose of elucidating the nature of its various diseases, it is essential that our researches be not limited to the function of the *heart* alone, but that enquiries be extended to those other organs which are intimately connected with the heart, and which materially contribute to the circulation of the blood."

Our author next describes the various causes of the circulation, and explains many phenomena which will interest all classes of readers.

" Though it may be strictly true that the blood flows in a circle, and that the heart, like a syringe, propels the sanguineous fluid throughout the whole system, there are other physical conditions, necessary for the due performance of that important function—conditions to which we must constantly refer in all our pathological researches.

" It is not only indispensable that a certain *quantity* of the blood be sent to every part of the body, but it is also requisite that the supply to different organs be variously *modified*. In some it is requisite that such supply be always equal and uniform, whilst, in others, it is necessary that the quantity of the blood can be either diminished or increased.

" Of the first of these conditions there is an example in the brain; to which, for the due performance of the intellectual functions, the supply of blood must be always uniform; and of the other we have an illustration in the stomach, to

which viscus, during the process of digestion, the quantity of blood is more or less increased.

"Another illustration of a temporary change in the quantity of blood in particular organs is afforded in the *erectile tissue*, this structure being employed in certain organs for the sole purpose of altering their form in order to enable the organs to which they belong to perform a particular function. Thus the erectile tissue of the nipple becomes injected with blood to enable the infant to withdraw the milk from the lacteal tubes.

"For thus regulating the distribution of the blood throughout the system, we shall find that there are employed no less than five other organs besides the heart; these are the arteries,—the capillaries,—the veins,—the muscles or active organs of motion,—and the respiratory apparatus.

"The arteries, whether by an elastic power alone, or by elasticity and muscularity combined, lend the heart an important aid in conveying the blood to the capillaries. I have already stated that it is not requisite that the blood be transmitted to all parts of the body with the same velocity, or that the supply to different organs be at all times uniform. These purposes, as well as to provide for the exigencies which certain organs may demand, when, from our habits or avocations the circulation becomes disturbed, are all fulfilled by particular modes in the distribution of the arteries.

"The length of different arterial trunks,—the different angles at which the branches leave the trunks,—the varieties in the course or trajet of arteries,—the different modes in which they ramify,—and the anastomoses of arteries, are all peculiarities which are contrived to modify the circulation of the blood in particular organs.

"A remarkable difference in the *length* of arteries as well as in the *angle* by which they come off from the trunk, is exemplified in the renal and spermatic vessels, whilst the carotids and vertebrales, and particularly the rete mirabile in quadrupeds,—the arteries of the uterus and of the spleen, and the distribution of the brachial and femoral arteries in the tardigrade animals are each examples of *tortuosities* in the distribution of arteries, obviously intended either to modify the momentum of the blood or to insure a regular supply to particular organs,—such modifications in the blood's circulation being required for the performance of the various functions of the œconomy.

"The *anastomoses* of arteries, as that formed by the coronary arteries of the heart, stomach, and lips, and by the arteries of the iris,—as well as the free inosculcation between the carotids and vertebrales by the basilar, are modifications in the distribution of arteries, which serve the essential purpose of preventing any interruption to the necessary supply of blood to the respective organs. For a similar purpose, some important organs are supplied with vessels from *several* trunks,—as the brain, with its two vertebral and two carotid arteries,—the stomach, with its different vessels, and the eye, with branches both from the internal and external carotids.

"The office either of *diminishing* or of *increasing* the quantity of blood in certain parts of the body at particular times, is a function of the circulation not depending altogether on the heart, but requiring the cooperation of the vascular system. When, for instance, food is taken into the stomach, its vessels become more replete with blood, which additional quantity is derived from the vessels of the spleen, that organ serving the purpose of a receptaculum.—When the intellectual powers are excited, an additional quantity of blood flows into the brain, and so with regard to the erectile tissues of the corpora cavernosa as well as the vessels of the uterus, and testes, whenever these organs are called on to perform their particular functions.

"In like manner we shall find that the heart itself requires a different quantity of blood in its varied conditions, and it becomes an interesting subject of enquiry to discover how that supply of the sanguineous fluid to the heart is always furnished with the requisite regularity; a function which I shall endeavour to show is performed by the muscles.

PRUNUS LAURO-CERASUS.—Dr. Bennett, of Charleston, in America, has published some cases of facial neuralgia, in which he has employed externally the distilled water of the prunus lauro-cerasus. The cases were of considerable standing and severity; the relief speedy and permanent. A lotion was made, consisting of four ounces of the laurel water, and one ounce of sulphuric ether, alone, or with from half a drachm to a drachm of the extract of belladonna. With this lotion the affected parts, previously covered with carded cotton, or cotton-wadding, were kept constantly

wet. In two cases, the belladonna was used. Dr. Bennett observes that he narrate more cases, but he believes that those he has already adduced, will be sufficient to prove the utility of the preparation.—*American Journal of the Medical Sciences.*

The London Medical AND Surgical Journal.

Saturday, September 23rd, 1837.

NORTH LONDON HOSPITAL.

Importance of the Evidence taken before the Committee in the Lithotripsy Case.

In none of our public hospitals could an investigation, implicating the veracity and honour of one of its medical officers towards a student, be more essential to its vital interests, and had not that investigation been instituted, would have more seriously tarnished the character of that school in which it forms a prominent character. We allude to the investigation which is now going forward at the NORTH LONDON, or as it has been lately surnamed (for unworthy reasons which we shall on a future occasion detail) the UNIVERSITY COLLEGE HOSPITAL.

This Hospital it will be recollected, was openly declared to have been instituted, not for the benefit or relief of the sick poor, but for the avowed purpose of instructing students of medicine, and in order to insure its success as an appendage to the liberal establishment of Gower Street, or rather for the indirect purpose of increasing the funds of this notable charity by students' fees, its projectors, the well known LIBERALS of the College, had the boldness publicly to announce their intention of procuring and advertising for a surgeon, who should possess such longerdmain qualifications, as would

attract students to the operating theatre, in like manner as the managers of Drury Lane and Covent Garden select for their boards such PERFORMERS as will draw the most crowded houses. Though this principle of selecting a surgeon to the North London Hospital was severely reprobated by several of the more respectable of those individuals interested with the North London Hospital School, even calling forth the well merited wrath of that journalist who had been specially devoted to defend the corrupt measures and fraudulent transactions of the "CLOSE BOARD OF GOWER STREET," still did the medical phalanx of that school continue to pursue a reckless policy, and appoint an individual as one of the surgeons of their ill-begotten Hospital, avowedly for no other purpose, than to perform operations, and to perform them in such a manner, as would give eclat, and increase the emoluments of their uncharitable and unchristian-like establishment. The consequence of adopting such a mode of recommending themselves as a seminary for the education of youth, has already been what might have been anticipated; and their Hospital has often been the arena of scenes most disreputable to the profession, and repugnant to the better feelings of human nature.

There are Hospitals which were instituted, and which are supported and regulated for no other purposes by the charitable than as asylums for the sick poor, wherein they may obtain all medical aid, given for no other purpose than the alleviation of their bodily infirmities. It was once a sentiment too common amongst our medical officers, that Hospitals were the places most appropriate for experiments, but since these unprincipled and licentious individuals have been closely watched by the literary Cerberus, and their mean practices become the subject of continual

and severe animadversion, there are comparatively few of those theatrical exhibitions of bloodshed which so long disgraced the Hospitals of this metropolis.

CHARING CROSS HOSPITAL.

DARING ATTEMPT TO OBTAIN ANOTHER RECOGNITION.

Base, corrupt, and contemptible, as the conduct of the council of the College of Surgeons has been on far too many occasions, and it has been our painful duty to animadvert on them in this journal, it is but justice to state, that they have refused to grant a RECOGNITION to the Charing Cross Hospital, within the last few days.

Our readers will scarcely credit that the DICTATOR GENERAL conjointly, with his MEDICAL STAFF, should have had the daring effrontery, after the public exposure which had been made of the fraud which they committed on the Council of the College of Surgeons, again to come forward with a petition, praying that their fraudulent institution should be recognized as a fit place for the education of youth.

Two years have scarcely elapsed since, under the immediate superintendence, and with the sanction and support of the DICTATOR-GENERAL, the requisite number of paupers from the adjoining parishes were induced to pay a visit of a few days to the Charing Cross Hospital, in order that the number of *beds* required by the College of Surgeons to enable them to grant a recognition, should be occupied, when the day for the deputation of the Council to visit the hospital was decided upon. The *ruse* was so successful that when the worthy Barons Cooper and Brodie made their official

visit, they were so completely satisfied, that the hospital not only contained upwards of one hundred beds, but that there were absolutely one hundred and twelve in-patients then under the treatment of the medical officers. It was not, however, long until the fraud became the subject of general conversation and severe animadversion, but the Council of the College of Surgeons, from several considerations, had it not in their power to withdraw their recognition, and expose the perpetrators of the base fraud which had been committed upon them, until dissatisfaction and mutiny appeared amongst the troops of the Dictator. It then appeared that Mr. Howship, who was one of the surgeons of the hospital, and who had purchased the office for *five hundred pounds sterling*, was more than anxious to procure the RECOGNITION, without which he could not indulge the most distant of hope of reimbursement; and he was enabled to anticipate this object with the greater certainty, as being himself one of the Council.

The whole matter having come before the Council of the College in a tangible shape, nothing was left for their decision but to consider the propriety of withdrawing the *recognition* surreptitiously obtained, and the manner they should deal with that member of their own Council who was an accessory "before, to, and after" the commission of the act.

It was resolved upon with, we believe, only one dissentient voice, that the *recognition* granted to the Charing Cross Hospital should be withdrawn; and after a protracted and warm debate, it was unanimously agreed upon, that as several other members of the council were implicated in the disposal of official situations, both in hospitals and medical schools, either by direct sale, or by some

species of barter, it would be prudent and judicious to take no steps towards the removal of any individual appertaining to the council.

With the details of these disgraceful proceedings and infamous conduct of the medical officers of the Charing Cross Hospital towards the College of Surgeons, and with the minutes of the proceedings recorded in their own journals, it is not paying the Council of the College any very high compliment to inform their COMMONALTY, that they rejected the *recognition* with those feelings of contempt and indignation which the whole proceedings so justly merited.

Many expressed their surprise, and doubted our veracity as journalists, when we, some time ago, stated that this application to renew the *recognition* of the Charing Cross Hospital was about to be made. But those who were aware of the tottering state of the Medical School at King's College, Strand, and who knew the purpose for which the alliance between their anatomical demonstrator and the Charing Cross Hospital was formed, were quite prepared that one of the first intrigues in which Mr. Partridge would bestow his ingenuity, and display his peculiar talents, would be to effect the *recognition*, as there could be no doubt that had such recognition been obtained, the same talented individuals would have contrived means to further the pecuniary speculations of both these notorious institutions.

The absence of Sir Astley Cooper and Sir Benjamin Brodie from the metropolis when the subject of this new recognition was brought before the Council—the very two individuals who were appointed by that body on the former occasion to report to them the state of the Charing Cross Hospital, as regarded the propriety of granting a *recognition*, must not be

considered as a mere coincidence, but must be viewed as one of those unaccountable and mysterious combinations of circumstances, which nothing but the profound physiological researches of a Todd, the microscopical observations of a Partridge, or the application of the reflex motory movement doctrines of the great modern Sydenham himself, could by any possibility elucidate or explain.

ANIMAL MAGNETISM, AT THE NORTH LONDON HOSPITAL.

(From the Times, September 20, 1837.)

We publish the following, because we have been informed that some exhibitions of the revolting imposture which is called "Animal Magnetism," have recently taken place at the North London Hospital. If these displays have been made with any other view than to put the pupils on their guard against the extent and impudence of which quackery is capable, it is very essential that it should be generally known that the North London Hospital is only a seminary for mountebankery. The knowledge of this fact is especially due to parents who have sent their sons there to learn the science of medicine, not to be taught to practice the arts of Charlatans!!!

APPOINTMENT OF A PHYSICIAN TO GUY'S HOSPITAL.

DOCTOR BABINGTON has been appointed to the office of Assistant Physician to this Hospital, an appointment which has given general satisfaction, not only from his professional acquirements, but as a tribute of respect and gratitude to the long and meritorious services of his late esteemed parent, who had for many years

performed the important duties of Apothecary to the Hospital, and who afterwards, from his zeal, ability, and good conduct, was appointed one of the Physician of the Charity.

The appointment of Dr. Hodgkin, one of the Society of Friends, was never seriously contemplated; the ability he showed as curator of the museum, and his nicety in putting up preparations, though fully estimated by the governors, were not considered sufficient recommendations in themselves to qualify him for the office of physician; and however assiduous in his Harrissonian devotions he may have been, and extravagant in his *complimentary* systems to the *friends* of Guy's, they have had no effect in consummating his wishes, and realizing his expectations.

DEATH OF MR. SHERWOOD.

Mr. Sherwood's death, from his long and continued connexion with the medical press, has been a just cause of deep regret amongst a large class of the medical faculty. Mr. Sherwood was not only one of the principal publishers in the metropolis, but contributed more than any other individual to give an impetus to British Medical Literature. To his zeal, industry, and intelligence, we entirely owe the publication of the *Cyclopædia of Medicine*, the *Cyclopædia of Anatomy*, and the *Cyclopædia of Surgery*, in all which works are to be found articles from the pen of many of the most eminent individuals of the medical profession in the united kingdom. Besides these truly national works, Mr. Sherwood took an active part in the publication of the *British and Foreign Medical Quarterly Review*, as well as the *Annals of Medicine*. The first of these periodicals must be considered as one of great labour, and well calculated to promote the diffusion of foreign literature in this country; and the "*Annals*" must as yet be considered an infantile hebdomadary; it is, however, to be hoped that its conductors will step forward more and more boldly in the Cause of Medical Reform, and that they will co-operate with us in exposing and

correcting the numerous abuses and fearful state of corruption which still defaces the portals of our Medical institutions—we say co-operate with us, because it is a lamentable fact that the other Medical hebdomadaries are not likely to promote the good cause; the *Medical Gazette* having openly come forward as the avowed advocate of abuse and monopoly, whilst the *Lancet*, their avowed enemy during its early career, has, on many late occasions, paid no attention to some of the most flagrant abuses, and attempted to vindicate the conduct, and lent itself as the advocate of many notorious jobs, more particularly of the transactions of the University College and North London Hospital. Besides the publications alluded to, Mr. Sherwood is entitled to the credit of having first introduced a *British Medical Almanack*; a work though small, on which he bestowed great labour and attention, and incurred very considerable expense.

THE WORKING OF THE ANATOMY BILL.

In consequence of the repeated remon-
stances which have been made by various teachers of anatomy in London, Scotland, and Ireland, of the unequal distribution of subjects, and other mal-practices in the administration of the Anatomy Act, the Officers of the Crown have not only dispensed with the services of certain individuals, but regulations have been made at the Home Office which will go far in securing a just distribution of subjects, and be a check to all improper charges in the shape of a *bonus*, and at once secure a prompt attention to all grievances and complaints, whether of the *teacher* or the *student*.

PROVINCIAL AND METROPOLITAN HOSPITALS.

To the Editor of the Medical and Surgical Journal.

Sir—Having served an apprenticeship at a county hospital, and accustomed to read only the *Lancet* and *Medical Gazette*, they gave me an impression that no operations performed by the London purers were ever unsuccessful, until I took to reading your Journal regularly, by

which it appears that there are not only a number of operations performed very unsuccessfully, and for the purpose of making a theatrical display to the students; but many of them are completely unsuccessful, and not a few prove fatal. The lithotripsy case at the North London Hospital, though highly interesting and instructive, proving the danger of that operation in inexperienced hands, was to me more than equalled in importance by the fatal Taliacotian operation, performed by the surgeon. There are men, I do think, rash and unthinking enough to undertake operations which they cannot perform, and which endanger life. But few young practitioners are aware that one of the minor operations, such as the Taliacotian, should, when performed under unfavourable circumstances, or the patient treated injudiciously after the operation, prove fatal. It will, therefore, be highly instructive and satisfactory to your numerous readers, if you could find out and publish in your valuable Journal an account of the Taliacotian operation in the case alluded to, which proved so rapidly fatal.

In our provincial hospital, operations might have been sometimes performed unnecessarily, but scarcely ever a *fatal case* occurred during my five years apprenticeship. It was a fixed rule with both Mr. S. and Mr. H. never to operate in any case where delay was admissible, without preparing the patient by a proper course of purgatives, alteration in diet, &c.; and after an operation had been performed, they always appeared to pay the strictest attention to the after-treatment, disregarding dressings and bandages in comparison to the patient's general health and constitution. In all cases where the patient's health remained in a bad state, notwithstanding their efforts to improve it, nothing would have induced them to perform an operation: and, as Mr. H. often used to tell his apprentices, if they could not save life, it was their duty, as Christians, not to take it away!!

Your constant reader,

G—r, September.

J. W.

[The death of the patient alluded to, could be very satisfactorily accounted for, by the very bad state of his general health when the operation was undertaken. His state of debility was such, that he was unable to stand the shock of the operation.—Ed.]

CLINICAL REPORTS.

EDINBURGH INFIRMARY.

CANCER OF THE UTERUS.

M. H., a widow, thirty-nine years of age, and who has borne children, was admitted into hospital, complaining of pain in the hypogastric region, much increased on pressure; with constant aching pain in the back. She has also very severe bearing down pains, and pain in passing urine, which is scanty, fetid, and throws down a white mucous deposit. There is a sense of weight, accompanied by pains in the forehead. Pulse a hundred; tongue natural. The bowels have been more open than they ought to be for the last two days.

About ten months ago, on passing through a small stream while the catamenia were present, their flow was arrested; and, a fortnight afterwards, she was attacked with severe pain in the bowels, resembling choleric; for which various purgatives and other medicines were taken. She got better in about a month, but shortly afterwards, on making great exertions, a copious discharge took place from the vagina, resembling the menses, but lasting for three months, though in diminished quantity. When this discharge ceased, violent flooding took place, and recurred after a month's interval; since which there has been a constant, fetid, yellow discharge, which has lasted to the present time, a period of more than four months. It is two months since the pain in the back came on.

This patient remained in the hospital till her death; which did not take place for nearly three months. The treatment, however, may be summoned up in a very short space. It consisted chiefly of opiates of various kinds, and in different forms; sometimes by the mouth, and at other times by injection. She uniformly complained, however, of being hurt by the introduction of the enema-pipe; probably from the rectum being engaged in the cancerous degeneration. Leeches were occasionally applied to the hypogastrium, especially the right side; where a tumour gradually forms hard and irregular, extending far into the right iliac region, purgatives were frequently necessary; and consisted principally of colocyath and hyosciamus pills, or castor-oil, with a few drops of some anodyne tincture. A solution of acetate of lead, and afterwards a decoction of poppy heads, was ordered.

to be thrown up the vagina; but these injections she refused to allow, on the score of shame; of which, according to her own account, she had an abundant stock. The same feeling prevented an examination being obtained, till a few days before her death; when the upper part of the vagina was felt to be closed up by irregular, hard projections, no doubt consisting of depositions of scirrhus matter, into which the uterus had degenerated; and an extension of which, there is little doubt formed the tumour in the hypogastrium. Nothing like the neck or mouth of the womb could be discovered.

Considerable mitigation of pain was obtained by the opiates; but the debility, emaciation, and that peculiar leaden hue, so characteristic of these cases, progressively increased. For the last week, quiet nights were procured by the administration every evening of a pill, containing a grain of the muriate of morphia; equal in strength to about four grains of opium; besides which she took daily three or four pills, containing a grain and a half of opium in each. In the latter stages of the disease, she was allowed wine, beef steaks, and eggs. Her intellects remained clear to the last; for she knew me late on the evening before she died; but on going to her bed next morning, I found her dead. She had been left only a few minutes before by her sister. The latter, to whom a general order of admission had been given, to see her sister whenever she pleased, at first willingly consented to have the body examined; pretending to be very grateful for the kindness which had been shown to both; but when she found there was no money forthcoming, she recalled the permission. This was the reward for all the expense and trouble of maintaining and treating this patient, whom it was disgusting to approach, on account of the horribly fetid discharge. It is a specimen of the gratitude but too often met with in such cases. During the progress of the case, the following remarks were made.

Clinical remarks by the attending Physician.—This is a melancholy case. The symptoms are pain in the hypogastrium and the loins, menorrhagia, bearing down pains, a constant diarrhœa, hectic. My belief is, that it is utterly hopeless. We can only attack the symptoms as they arise. Emollient enemata ought not to be neglected here; as the feces are liable to lodge in the rectum, and to increase the uterine irritation. Purging, however, would be most injurious; for

by irritating the bowels, it would increase the sufferings of the patient. Opiates administered by the mouth, do not appear to have so powerful an effect, as when administered through the rectum; for in the latter case they act locally, as well as generally. We have now substituted a solution of morphia for laudanum, as it causes less nausea. The pain often ceases altogether in the last stage, which excites great surprise when the ravages of the disease are revealed by dissection; but sometimes the pain is agonizing, and attended by delirium. Such cases have been remarkably prevalent of late. Death is inevitable.

INDIAN MEDICINE.

MADRAS EYE INFIRMARY.

Communicated by W. Rose, Esq., Assistant Surgeon to the Madras Army.

AMAUROSIS FROM WORMS.

Lutching, a Malabar woman, aged twenty-five, of a thin spare habit of body, was admitted into the Madras Eye Infirmary, on the 10th of September, 1835, under the care of Dr. Mortimer (in temporary charge of the Hospital during the absence of the surgeon, T. Moore Lane, Esq., on sick leave at the Neilgherries.) She complained of total loss of sight in both eyes, attended with pain of the temples, occasional shooting along the forehead, and also of the occiput. On examination the eyes appear nearly in their natural state; the ball full and firm; cornea lustrous and clear; humors transparent; but the iris is immoveable in both, and that of the left eye rather of an angular shape.

The whole surface of the body is covered with a psorose eruption; skin cool; pulse eighty, and rather feeble; tongue white, large, and flat, and present-

* Mr. Moore Lane is one of the most dexterous and successful operators on diseases of the eye of this age. Like Mr. Lawder, he is an ornament not only to Indian but to British Surgery. We are deeply indebted to Mr. Rose for these valuable reports. We feel great gratification that an old pupil of ours should evince so much practical knowledge, though we long since augured this, from his zeal, industry, and talent in the pursuit of his profession.—Ed.

ing, in rather a marked degree, the speckled appearance; menstrual discharge regular; bowels open every day; abdomen natural; no pain even on considerable pressure; appetite pretty good.

States that she is a married woman and has four children; has been blind for the last two months; cannot attribute the disease to any particular cause; never received any injury on the head, nor had she had ever any affection of her eyes before the present. About three months ago she found the sight of the right eye weak; it became gradually worse, and at the end of a fortnight the left became similarly affected; the sight gradually diminished in both, but she became completely blind of the left eye a few days before sight failed in the right.

The psorous affection has been of about three months' duration.

She applied to a native practitioner, who gave her some medicine; but she fancied she became worse under his treatment.

Descendat in balneum tepidum statim et capiat hora somni pilulæ hydrargyri, grana decem.

R.—Solutionis sulphatis magnesiæ.

Aquæ menthæ sativæ, aa ʒss.

Fiat haustus cras primo mane sumendus.

Low diet.

11th.—Bowels opened two or three times; stools clay-coloured and slimy; pain of temples and occiput as before; the other functions same as on admission.

Applicentur hirudines duodecim temporibus, et emplastrum lyttæ nuchæ.

Rep.—Pilulæ hora somni, et haustus catharticus cras primo mane.

12th.—Pain of the temple and occiput rather less; leeches bled freely; bowels opened four times; stools much of same character as before; vision not at all improved; psorous eruption continues same as before.

Rep.—Balneum statim et postea perficitur corpus peroptime unguento sulphuris composito.

Rep.—Pilulæ hora somni et haustus cras mane.

14th.—Bowels opened freely; stools much of the same character as before; psorous eruption dying away; pain of the temples and forehead rather more severe this morning; vision continues unimproved; the other functions continue as before.

Repetentur hirudines temporibus.

R.—Pilulæ hydrargyri, gr. iij.

Extracti hyoscyami, gr. x.

Fiat pilulæ tres, h.s.s.

R.—Olei ricini, ʒss.

Aq. menthæ piperitidis, ʒj.

Sit haustus cras mane sumendus.

16th.—Pain of head much relieved; psorous eruption nearly gone; bowels opened three times yesterday; alvine dejections more natural; vision still unimproved; tongue continues in the same state as on admission, the speckled appearance if anything more developed, and the dental impressions strongly marked on the sides of the organ; in other respects as before.

Rep. balneum, et postea frictio cum unguento sulphuris composito.

Cont. pilulæ hora somni et capiat haustum sequentium cras mane.

R.—Olei ricini,

— terebinthinæ, aa ʒss. M.

17th.—Pain of temples quite gone; that of the occiput still troublesome; bowels opened three times since last report; stools slimy and whitish; tongue as in yesterday's report; other functions continue as before.

Rep. emplastrum epispasticum nuchæ.

Pilulæ et haustus ut antea.

18th.—Head quite free from pain; bowels opened three times; dejections nearly of the same character as yesterday, but with the last she passed four lumbrici, each from ten to twelve inches long; vision unimproved; other functions as before.

Repetantur pilulæ et haustus.

19th.—Passed five more lumbrici since yesterday morning, of about the same length as the former; dejections of the same character as before; vision still unimproved; head continues free from pain; other functions as in last report.

Cont. omnia.

20th.—Nine lumbrici have been passed since yesterday morning, of the same size as the others; alvine dejections somewhat improved in appearance; tongue still presenting the same characters as before; vision unimproved; in others respects as before.

Rep. omnia.

21st.—Passed four worms since last visit; stools more natural; vision in right eye somewhat improved; when the hand is drawn slowly before the eyes, says she can perceive some dark object; left eye continues as before; head still free from pain; psora quite gone.

Perstat.

22d.—Two worms expelled this morning, rather longer than the former and quite black; character of dejections more

natural; vision in the right eye greatly improved, can distinguish objects also with the left this morning; in other respects as before.

Pergat.

23rd.—Three worms expelled since last report, of the same length and colour as the last, making on the whole twenty-seven; sight of both eyes much improved; alvine motions of a better colour and consistence; tongue cleaning; the remaining functions regular.

Perstat.

26th. No more worms; vision much improved; can walk about the compound unaccompanied; head free from pain; tongue nearly quite clean; other functions natural.

Rep. pilulæ hora somni, repatur haustus.

30th.—Vision quite restored; no more worms; says she feels quite well, and wishes to be discharged; all the functions natural.

Cont. pilulæ.

1st Sept.—Discharged—cured.

MADRAS GENERAL HOSPITAL.

DYSENTERY FROM WORMS.

Amelia Howard, aged nine, of European parentage, and of a lencophlegmatic temperament, was admitted into the Madras General Hospital on the 22d July, 1835. Complains of occasional griping pains of the abdomen, with relaxation; bowels moved several times in the day; slight pain, on pressure, along the course of the colon, but not confined to any particular part; tongue foul in the centre and at the root, but the tip and edges are clean and moist, and the entire organ presents a peculiar kind of speckled appearance; pulse 120, small and compressible; skin cool and moist.

Before admission this morning took a table-spoonful of castor-oil, which acted four or five times on the bowels; stools yellow, liquid feculent, and containing several small flakes of mucus, very offensive, but unaccompanied by tenesmus, or any appearance of blood; no particular pain on pressure about the right hypochondrium or caput coli.

Her mother states, that the girl has been ill for the last twelve or thirteen days; has been frequently purged, and the stools contained "matter and blood;" took castor-oil occasionally; has observed

no regularity in her diet; her bowels, previously to her illness, have been confined, but in other respects has always been very healthy.

Foveatur abdomen bend—Spoon diet.

Vesperæ.—Had three stools during the day, the two first feculent, yellow, and of a good consistence, the last scanty and contained a small quantity of blood and mucus; no tenesmus; urine copious and clear; all the other functions as in the morning report.

R.—Hydrarg. chlorid.

Pulveris ipecacuanhæ, āā gr. iij.

Fiant pilulæ duæ, hora somni sumendæ.

Habeat olei ricini ꝑss. eras mane.

Continuantur Fomenta.

23rd, six, A.M.—Slept pretty well last night; bowels opened twice; stools feculent, rather dark-coloured, containing mucus and blood; urine copious and clear; tongue moist and rather clean, speckled appearance more marked; pulse 100, and small; skin rather warm; complains of slight tenderness on free pressure over the abdomen; appetite pretty good.

R.—Pulveris ipecacuanhæ.

— acaciæ, āā gr. ij.

Fiat pulvis secunda quaque hora sumendus haustus primo mane ut antea.

24th, six, A.M.—Had a tolerably good night; bowels opened four times since last report; stools feculent and dark-coloured, except the last, which was rather copious, and consisted entirely of mucus-sanguinous matter, accompanied with a distressing tenesmus; all the other functions as in last report.

R.—Pulveris ipecacuanhæ,

— acaciæ, āā gr. iij.

Sit pulvis secunda quaque hora capiendus.

R.—Pil. hydrargyri,

Pulv. ipecacuanhæ, āā gr. iij.

Fiant pilulæ duæ, hora somni sum.

Repetatur oleum, eras mane.

Continuantur Fomenta.

25th.—Passed a sleepless night; bowels opened three or four times; dejections still rather dark-coloured and feculent, and containing a considerable quantity of blood and mucus; tongue as before; pulse 100 and small; skin cool and soft; tenderness of abdomen still continues; yesterday every dose of the ipecacuan was rejected by vomiting.

R.—Pulveris ipecacuanhæ.

— acaciæ, āā gr. ij.

Fiat pulvis, secunda quaque hora sumendus.

Continuantur fomenta pilulæ duæ
hora somni et haustus cras mane.

25th, six, A.M.—Had rather a restless night; bowels opened three times since last report; stools yellowish, feculent, and containing a considerable quantity of mæco-sanguineous matter; tenesmus; pulse ninety and small; skin cool and soft; urinary excretion natural; appetite rather immoderate; abdomen somewhat tense and still, painful, but not particularly so; lips rather parched; speckled state of the tongue particularly marked this morning.

I directed the attention of Dr. Mortimer, Chief Surgeon to the Hospital, to this peculiar state of the tongue, and he remarked, that during the course of his long practice in India, he had invariably observed this state of tongue, both in natives and Europeans, as symptomatic of worms in the intestinal canal; and that in the present case, considered in connexion with the state of the appetite, abdomen, and lips, there was a strong presumption in favour of such a diagnosis. He recommended, then, that the patient should continue her medicines as before, have her pills at night, and the following draught to-morrow morning.

R.—Olei. ricini,

— terebinthine æā ʒss.

Fiat haustus.

Continuantur Fomenta.

27th, six, A.M.—Spent rather a better night; slept pretty well; bowels opened three times this morning; dejections rather feculent, lighter coloured than usual, containing mucus and blood, and with the last she passed a lumbricus teres, nine inches long; tongue and abdomen as before; skin cool and moist; the other functions as in yesterday's report.

Continuantur omnia.

38th, six, A.M.—Spent a quiet night; two alvine evacuations since last report, of nearly the same character as before; as in the first she passed two more lumbrici of the same length as the former one; tongue becoming cleaner; abdomen less tumid and painful; appetite more natural; pulse ninety and small; skin cool and soft; the other functions as before.

Continuantur omnia.

29th, six, A.M.—Passed a good night; slept well; bowels opened four times yesterday; motions yellow and feculent, but of a curdy appearance without mucus or blood; no more worms passed; tongue cleaner; the other functions as before.

Rep. pulveres et pilulæ hora somni.

30th, six, A.M.—Complained of pain in both ears last night; they were fomented, which relieved her; bowels opened three times; dejections more natural; tongue still a little speckled; pulse pretty regular; skin cool and soft; urine natural; had some castor oil this morning.

Continuantur pulveres pilulæ hora somni et oleum ricini cras mane.

31st, six, A.M.—Says she feels quite well; bowels not opened since yesterday morning; tongue clean, speckled appearance quite gone; pulse natural; tumid state of abdomen subsided; no pain on free pressure; all other functions natural.

Perstat.

August 1st.—Feels quite well; bowels opened two or three times yesterday; stools natural; no worms passed; all the remaining functions regular.

Discharged.

[These cases are extremely instructive, in relation to that of apparent tetanus in our last number.—Ed.]

EXPERIMENTS

On the Effects of the Hydrated Peroxyde of Iron as an Antidote to Arsenious Acid.

By Dr. VON SPECZ, Professor of Chemistry in the Theresian Academy of Vienna.

IN the year 1834, as our readers are aware, Dr. R. W. Bunsen and Dr. A. A. Berthold published a small work at Göttingen, on the use of hydrated per-oxyde of iron as an antidote to arsenic, in which they claimed for this remedy all the properties of a true specific. With the view of testing the accuracy of their results, Dr. Von Specz prepared a large quantity of the hydrated peroxyde of iron, and instituted a series of experiments with it, on animals.

Experiment 1. On the 5th of October 1834, at ten o'clock in the forenoon, twelve grains of white arsenic, mixed with a portion of boiled meat, was administered to a cat six months old. At twelve, retching and vomiting commenced. An attempt was made to administer the antidote mixed with water, by means of a tin funnel, but the animal was so extremely restive, that no more than a drachm of the hydrated peroxyde could be given. Death occurred about one o'clock.

Experiment 2. On the 15th of June, 1835, at ten o'clock in the forenoon, a scruple of the white oxyde of arsenic was given in some sausage to a dog six months

old. Half an hour afterwards, Dr. Von Specz attempted to introduce the antidote, by means of a syringe furnished with an elastic tube. The dog, however, bit the tube, and was otherwise so unmanageable, that scarcely any could be administered. He died at half-past twelve.

Dr. Von Specz finding that the hydrated peroxyde of iron could not be given in a sufficient dose in this way, made the following change in the mode of exhibition.

Experiment 3. On the 28th of October, 1835, at ten o'clock in the forenoon, a drachm of finely powdered arsenic was administered to a mastiff six months old, which had been sparingly fed the day before. About five minutes afterwards, an ounce of the dry hydrated peroxyde of iron, finely powdered, and mixed with a sufficient quantity of fried liver pudding, was laid before him. He ate the whole, and afterwards drank about three ounces of milk. About eleven o'clock, he had some fluid evacuations from the bowels, but still appeared lively. About three o'clock P.M. he looked dejected, went to his bed, and lay there quietly; during the night he had five fluid evacuations. On the 29th, he looked dejected, did not stir from his bed, and neither ate nor drank. On the 30th he ate a little meat, drank about six ounces of milk, and returned to his bed. On the morning of the 1st of November, he was quite lively, and ate every thing that was offered to him.

Experiment 4. On the 10th of December, 1835, at ten o'clock in the forenoon, a drachm of finely powdered arsenic was given in some pudding to a bitch twelve months old. Five minutes afterwards, an ounce of the antidote was given, mixed with liver pudding, the whole of which was devoured by the animal. At eleven o'clock she went to her bed, appeared shy and timid, and refused to eat. She remained quietly in her bed the whole night, without vomiting or purging. On the morning of the 11th she had three fluid evacuations from the bowels, and did not appear to be ill; on the 12th she was running about as usual.

The foregoing mode of exhibiting the antidote to animals may be employed until vomiting commences; after this occurrence, it must be administered by means of a syringe.

As one sixth of the quantity of arsenic administered in Experiments 3 and 4, is more than sufficient to kill a dog, Dr. Von Specz looks upon the hydrated peroxyde of iron as a true specific, and thinks that its failure in any given case is to be attri-

buted to its being employed too late, or given in too small a quantity. In order to ensure the giving of a sufficient dose, ten times the quantity of hydrated peroxyde of iron must be administered; but a much larger quantity may be safely given, as this remedy does not exercise any deleterious effect on the animal economy. In order to obtain the remedy in a state of purity, and free from any admixture of copper, he recommends the precipitation of the iron by ammonia, and states that this preparation when properly made, and preserved in bottles with good glass stoppers, will retain its virtues for a very considerable time. The following is the mode of exhibition which he recommends in cases of poisoning by arsenic.—*R. Olei Amygdal. dulcis, Pulv. Gummi Arabici, Pulv. Sacchari Albi aa ʒij. tere simul et affunde, sensim terendo, Aquæ destillatæ ʒxv.; Hydratis Ferri ʒijj.;* of this mixture, previously well shaken, a dessert-spoonful is to be given every three minutes.

Dr. Von Specz resumed his investigations the following year, but instead of the pure hydrated peroxyde, he employed substances in which it is known to exist in considerable quantity, and which require no previous preparation, namely, rust of iron, and hæmatite (red iron ore.)

Experiment 1. On the 16th of January, 1836, at ten o'clock in the forenoon, a drachm of finely pulverized arsenic, mixed with about an ounce of fried liver pudding, was given to a dog twelve months old. Immediately afterwards, a mixture of two ounces of hæmatite with seven ounces of liver pudding was offered to him, the whole of which was devoured, and then drank a small quantity of milk. Forty minutes afterwards, he was attacked with violent retching; the anterior extremities were extended spasmodically forwards, and the posterior drawn backwards, as is usual in cases of poisoning from arsenic; he also had severe vomiting, and convulsive spasms of the abdominal muscles. At eleven o'clock he went to his bed and was peevish; the retching continued during the afternoon, and he had five dark-coloured evacuations from the bowels. On the 17th of January, he remained the whole day in his bed, refused to eat or drink, and had six dark-coloured evacuations. On the 18th he appeared quite lively, sprang to meet the servant, and ate and drank with much desire.

Experiment 2. On the 19th of March, 1836, at eleven o'clock in the forenoon, a drachm of finely powdered arsenic, mixed with three quarters of an ounce of liver

pudding, was given to a dog four months old, and immediately afterwards an ounce and a half of rust of iron mixed with six ounces of liver pudding. The animal ate only three fourths of the antidote, and then drank a small quantity of milk. At half-past eleven he vomited, but still appeared lively; at one o'clock he had a green evacuation from the bowels. During the afternoon he had five alvine evacuations and frequent retching, but no vomiting. In the evening he went to his bed, and remained there quietly during the night; on the morning of the 20th, he had several dark brown fluid evacuations, but was in other respects lively, had a good appetite, ate bread, and did not exhibit the slightest trace of illness.

Experiment 3. On the 19th of March, 1836, at two o'clock in the afternoon, a drachm of finely powdered arsenic, which had been previously dissolved in two ounces of hot water, was poured down the throat of a dog four months old, while the solution was still warm, by means of a tin funnel, and about ten minutes afterwards, an ounce and a half of rust of iron, mixed with a quantity of milk, was administered in the same way. Five minutes afterwards, the dog was attacked with convulsions and retching, and dropt down as if dead: after fifteen minutes, he got up, crawled into a corner, and vomited violently. During the night he had several dark-coloured alvine evacuations. On the 20th he was sullen, and refused to eat; on the 21st he was fresh and lively, and greedily ate some bread offered to him.

Experiment 4. On the 24th of March, 1836, at nine o'clock in the forenoon, a drachm of arsenic, mixed with an ounce of liver pudding, was given to a dog four months old, and then an ounce and a half of hæmatite, mixed with five ounces of liver pudding: the animal devoured the whole. Forty minutes afterwards, he was attacked with retching and convulsions followed by severe vomiting; as soon as the retching ceased, he ate up again what had been ejected from the stomach. At twelve o'clock he began to vomit again, became dejected, and went to his bed; he whined, retched continually, and his jaws were covered with a whitish foam. During the afternoon he had several alvine evacuations of a reddish colour, trembled, and was affected with constant retching and convulsive twitches. In the evening he was more tranquil. On the 25th he was quite lively, sprang to meet us, and ate with a good appetite.

Experiment 5. On the 24th of March, 1836, at eleven o'clock in the forenoon, a drachm of finely pulverized arsenic, mixed with an ounce of liver pudding, was given to a dog three months old, and immediately afterwards an ounce and a half of lapis hæmatites mixed with five ounces of liver pudding; the animal consumed only two thirds of the antidote. Twenty minutes afterwards he began to vomit, and at the same time had an evacuation from the bowels: he was then attacked with retching, vomiting, and convulsions, which lasted until one o'clock; during this time he vomited six times. At two o'clock he became dejected, shivered, and sought his bed; the retching was extremely severe, and his jaws were covered with foam. These symptoms disappeared about eight o'clock in the evening. On the 25th, he remained in his bed; about ten o'clock in the forenoon, he vomited twice a white frothy fluid; at eleven, he had some fluid evacuations from the bowels. On the 26th, he had several greenish-brown evacuations, but appeared lively and ate with appetite.

From these experiments Dr. Von Specz is led to conclude, that rust of iron and hæmatite, although they do not prevent all the bad effects of arsenic on the system, may, in defect of the hydrated peroxyde of iron, be employed as antidotes to that poison. To the hydrated peroxyde, which is capable of neutralizing all the deleterious properties of the poison, he assigns the first rank as an antidote to arsenious acid, next to this stands rust of iron, and then *sed longo intervallo*, hæmatite, which in consequence of its slow operation, may be used without any beneficial result where the poison is exercising a very powerful action on the system. Experiments 1, 4, and 5, of the second series, show distinctly the predominant influence of arsenic on the system, although hæmatite was administered immediately after the poison, and before its specific effects could be produced. The animal's, it is true did not die, but the counteracting powers of the antidote were not manifested until nearly three hours after its exhibition. These objections do not apply with any thing like the same force to rust of iron, which Dr. Von Specz thinks may be advantageously employed as an antidote in defect of the hydrated peroxyde. Its great efficacy as an antidote is shown in Experiments 2 and 3 of the second series. The remarkable effects of the arsenic in Experiment 3 are to be attributed to the mode of administration, for

Dr. Von Speck has repeatedly found that the poison operates much more rapidly when introduced into the stomach in a state of solution. A drachm of arsenic in powder does not produce its deadly effects on the system in less than six or eight hours, while the same quantity dissolved in warm water destroys life in a much shorter time. Rust of iron has also the additional advantage, that it can always be procured with facility.—*British and Foreign Medical Quarterly Review*.

CASE OF POISONING BY LIQUOR POTASSE.

By DARTO-MASSART, Pharmacien at Mons.

Mr. D., aged thirty-five, drank, instead of wine, a quantity of water of potash. Soon perceiving the error, he complained of severe pains in the epigastric region and nausea, and, in the course of a quarter of an hour, of general coldness; face pale, presenting the appearance of intense suffering. A solution of tartaric acid was administered, (four drachms to the pint of water,) and given at short intervals. Sinapisms were applied to the feet, and emollient fomentations to the abdomen, with frequent enemas. In a short time the symptoms abated, and he began to grow warm; a slight perspiration continued for two hours, followed by a black stool. Two days after, the tongue and back part of the mouth threw off a very thick and tough membrane. The patient took small quantities of broth, and shortly recovered his health.—*Id.*

ON THE TREATMENT OF VARUS AND PES EQUINUS, BY THE DIVISION OF THE TENDO ACHILLES.

By Dr. BOUVIER.

Dr. Bouvier presented to the Academy of Medicine (1) the extensor tendons of the foot of a dog, which had been divided, thirty days before it was killed; (2) a man aged forty-six, whom he had cured of pes equinus, by a division of his tendo achillis. The divided extremities in the case of the dog were united by solid substance, which was an inch in length, consisting of a new fibrous tissue, having externally the form and appearance of the tendon itself, adhering loosely to a cellular sheath in

which it was enclosed, so as to fulfil perfectly, as far as solidity and mobility were concerned, the functions of a tendon. It illustrated comparatively the case of the man. The deformity of his foot had existed from infancy. The section of the tendo achillis was performed in the month of February. At the present time (October) it is difficult to ascertain the point at which the tendon was divided, although, immediately after the operation, the extremities were placed more than an inch apart, and this distance has since increased. The foot forms a right angle with the leg, the heel resting on the ground both whilst standing and walking, and the muscles of the calf act upon the calcaneum, so as to extend the foot as before the operation. The treatment lasted only fourteen days.

In a subsequent paper, Dr. Bouvier records other cases successfully treated both by himself and others. His mode of operation is as follows. The patient lies upon his belly. A slight incision is made with a lancet, parallel to the axis of the limb, a few lines in length, and at that part where the tendon is the smallest and the least prominent. Through this incision is introduced, beneath the skin, a small straight knife, with a blunt point. The tendon is then divided from without inwards, without wounding the integuments. The limb is then placed in such a way as to keep the ends of the tendon separated, the foot being flexed on the leg. The subsequent treatment is very simple. It consists in gradually increasing the flexion of the foot, until it forms an acute angle with the leg: this is accomplished in an indefinite time, according to the condition of the articular surfaces of the tarsus. If, conjointly with the elevation of the heel, the foot is turned inwards, the apparatus must be so constructed as to correct this deviation. The reunion of the tendon takes place rapidly. The cicatrix is of considerable solidity, by the fifteenth or twentieth day. Two of the six patients operated on were affected with varus; one being a young man, twenty-three years of age; the other, a female aged fifty-four. The form of the foot in each case was greatly improved. The other four as well as a patient operated on by M. Roux were completely cured. They all were affected with pes equinus.—*British and Foreign Medical Quarterly Review*.

FRACTURE OF THE SKULL

And Rupture of the Longitudinal Sinus during Natural Labour.

By Dr. MICHAEDIS, of Kiel.

A woman, aged thirty-six, was taken in labour with her first child on the 27th February, 1836. After slight pains for thirty-six hours, the waters came away at four P.M., of the 29th. At this time the midwife found the os uteri open, but full and hard. At eight o'clock on the following morning, Dr. M. was called, and found the patient, as is common in Germany, on the labour-chair, with sufficient but not severe labour pains, the vagina extremely tender, dry, and hot, and the perineum tense, and the child's head completely in the pelvis. The woman was put into bed, and warm cataplasms applied to the genitals; and in two hours things were completely changed, the parts being now only moderately swelled, lubricated, and not painful, while the head advanced under good pains, only apparently strongly jammed against the immovable coccyx. At eleven o'clock the child was born. Examination immediately after the child was born detected no deformity of the pelvis, the diameter of the outlet being certainly not less than three inches and three quarters. The child breathed both during birth and immediately after, but then died.

The head was much disfigured, and, on examining it carefully, the following appearances were found: 1. The frontal bones were normal as to structure and uninjured, but so flattened that the frontal and parietal portions lay nearly in the same plane. 2. The fontanelle and anterior two-thirds of the sagittal suture projected high up, and the sagittal borders of the parietal bones were thrown open and partook of the displacement. 3. The left parietal bone was not otherwise affected, and, with the exception of a few points which were very thin, it was well-formed. 4. In the posterior third part of the sagittal suture, where the parietal bones were firm and well formed, and the suture only two lines in width, were seen small livid portions of the longitudinal sinus forced between the bones. 5. The occipital bone was flattened and forced deep under the parietal bones, but not otherwise injured. 6. The right parietal bone, which during the birth had been directed towards the promontory of the sacrum,

was found covered anteriorly and above with effused blood, and, on removal of the periosteum, was found fractured in five places. These fractures or fissures were as follows: *a.* a small fissure near the *tuber ossis frontis*, four lines long; *b.* a much larger one running from the fontanelle through the centre of the parietal bone, very nearly two inches in length; *c. d.* two small fissures half an inch in length, near the sagittal suture. There were also four small openings, from incomplete ossification, in the same bone, which was throughout very thin.

On opening the skull, there was found no extravasation beneath the fissures, but posteriorly, under the sagittal suture, the longitudinal sinus was found ruptured, and there was an extensive coagulum on the cerebrum on both sides, under the dura mater, and on the tentorium cerebelli.

The peculiarity of this case is, the occurrence of so extensive injury during natural labour, and with a well-formed pelvis; and is explained by the natural weakness of the bone, and the unfavourable position of the head during birth.—*Ibid.*

ACCOUNT OF A NEW INSTRUMENT FOR PLUGGING THE POSTERIOR NARES.

By M. MARTIN SAINT ANGE.

This instrument (which its inventor M. Saint Ange, names *Rhinobyon*,) consists of a straight canula of silver, five inches long, and of the diameter of a crow-quill. To one extremity is attached, by means of a circular groove, a small delicate bladder; the other, slightly belled, is furnished with a stop-cock; between this and the centre of the canula runs a slide (*coursour*) with a projecting tongue.

In a case of epistaxis, the bladder extremity of the instrument is passed through the affected nostril to the posterior nares; air is blown in through the bell mouth; the cock is closed; the moveable tongue prevents the descent of the instrument into the pharynx by its pressure against the ala or septum of the nose, and is securely fixed by a screw. Air has been found preferable to cold water. A portion of intestine about three inches in length, or other similar membrane, might be made to fulfil the double indication of plugging the nares posteriorly, and of exerting pressure on the nasal walls.—*Ibid.*

LITERARY INTELLIGENCE.

Preparing for the press, the Law of God, and the Law of Man, considered with reference to the Punishment of Death. By William Hempson Denham.

TO CORRESPONDENTS.

Inquirer.—The editorial functions have been chiefly performed by Dr. Roderick, since the death of the illustrious Cummin.

House Surgeon.—We would recommend him to put the patient through a course of the "Mistura Gregorii" cum aliis, as recommended in the Medico-Chirurgical formulary.

An Army Surgeon.—We do not know whether the amputation performed on his medical friend was the cause of death. It is quite certain it was not the means of prolonging life. In malignant diseases, operations, however rapidly performed, are, we lament to say, too frequently unsuccessful, and they usually hasten the patient's death.

Argus.—Most assuredly,—a chartered body has the power, not only of *reprimanding* but of *dismissing* him.

Vaccinator.—There are only three *Directors* that we know of, besides those of the East India Company—the Director-General of the Army Medical Board—the Director-General of the Vaccine Institution—and the Director-General of Charing-Cross.

Humanitas.—The "beautiful house" is not occupied by Dr. Golding. The enormous rent may be for the purpose of frightening away tenants.

A. M.'s case is complicated, and is one *de omnibus rebus*. The brain and spinal chord, the respiratory and circulating organs, as well as the chylopoietic viscera, are all in a more or less disturbed state, and each requiring the strictest attention.

Cantab.—Moscatti is still in town, and the information may be had on the subject by a personal application.

Bos.—There is only one other instance of *rumination* in the human subject.

Animal Chemist.—The indistinct appearance of the armorial bearings, must have arisen from the deposit of the lithic acid. The phosphate of lime, ammoniacal magnesian phosphate, the urate of soda, might either of them produce a similar effect under certain circumstances.

Scalpel.—We are not acquainted with the precise terms; satisfactory informa-

tion may be had by applying to Sir Charles Scudamore.

Coroner.—We cannot receive his communications even on the same terms as those of Van Butchell or Mr. Copeland.

Theatrical Exhibitions.—In consequence of the commencement of the next session being near at hand, the hospital functionaries will henceforth postpone the performance of every operation, which can possibly admit of delay, until the "lads" arrive from the country. We have ordered our reporters at the different hospitals to watch this contemptible, and no less immoral, measure of certain surgeons.

A Voter in Finsbury.—The North London Lion liberally subscribed five pounds to defray the expenses of the *first* election.

A Constant Reader.—Contributions are readily received from subscribers.

J's communication has been received.

A Young Practitioner.—If the worthy Baronet's opinion be required, it would be satisfactory to get him to *sketch a diagram* of the case. No additional fee is required for the drawing.

Lithotriety.—The hole made in the fundus of the bladder by the lithotrite, was not so large as to admit the operator's thumb.

T., of Newcastle, will find the business he alluded to detailed in the *Lancet* of 1829-30, vol. ii., pp. 140 and 698. Dr. Knott's conduct on that occasion was no less useful to the student than honourable to himself, and met with the highest approbation of the managers.

Catheterism.—If the urethra be lacerated by the percussor, the introduction of a catheter soon afterwards cannot be so easily accomplished as if no mischief had been done by the percussor. The preparation was carried off instantly after the clinical lecture, by the ingenious operator in a hackney coach, to his *private* residence. We are doubtful if an accurate inspection would be permitted.

The Magnetic exhibits daily at three o'clock.

Scrutator.—Will he favour us with his name and address—incontrovertible proof must be given that the *Professor* alluded to, has a pecuniary interest in recommending pupils of the University College to *another* College.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

London Medical and Surgical Journal.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETZ,

Reported by MM. Cazenave and Schedel.

ECZEMA.

2d.—Eczema appears, in most cases, in a more acute form, which presents two very distinct degrees.

*First degree, (eczema rubrum).—*Here the eruption is generally preceded, and always accompanied, by heat and well-marked tension; the skin is inflamed, it presents a bright red tint: if it be closely examined, it is observed to be roughened, as it were, with small projecting points, with a silvery appearance. At a later period real vesicles are distinguished, which, after having acquired their full developement, soon appear under the form and of the size of a small pin's head, transparent, and surrounded with a well-marked inflammatory areola.

From the sixth to the eighth day, sometimes sooner, the redness diminishes, the re-absorbed fluid has disappeared, the vesicles have faded, and the disease terminates by a slight exfoliation, produced by the remains of the vesicles. The eruption, examined at this time, still presents well-marked characters. There is observed a surface of a reddish tint (a tint which still continues some days after the cure), traversed with small rounded points, surrounded with a whitish border, irregularly cut, which indicates the line of demarcation between the elevations of the epidermis which formed the vesicle, and the areola which surrounded its base.

Ecze^ma ru^brum does not always terminate so simply; the inflammation, instead of diminishing continues, or even

increases in some cases; the vessels having become confluent, break, and allow the contained fluid to escape, which, from having been transparent, usually takes on a milky appearance. This fluid flows over a surface already inflamed, irritates it more, occasions superficial excoriations, whence there oozes a greater or less quantity of serosity. However this serosity diminishes; it thickens, becomes concrete, and forms thin soft plates, oftentimes very broad, which being frequently renewed, leave behind them, when they fall, surfaces more or less inflamed. The serous exhalation ceases by degrees; the scales, now drier, become also more adherent, and fall less frequently. The skin slowly resumes its natural state around the diseased surface, and the cure proceeding the circumference to the centre, the disease terminates in two or three weeks. These symptoms often, instead of improving, continue a much longer time, become at intervals more severe, and the disease, having become chronic, constitutes a very remarkable state, which we shall describe presently.

Second degree.—Whether vesicles of *eczema rubrum* have been observed in the first instance, as generally happens, or the course of inflammation has been so rapid that its products have not presented themselves to us until the disease is in a more advanced degree, it often happens that the eczema assumes a state, bordering at one and the same time, both on vascular and pustular affections (*eczema impetiginodes*.)

In the *eczema impetiginodes* the inflammation is very intense; the skin on the surfaces, which are the seat of the eruption, is, as it were, swollen; the fluid contained in the vesicles has lost its transparency, and has become sero-purulent. These pustular vesicles, crowded together, confluent, and often united, open at an early period; the liquid soon thickens,

becomes concrete, and gives rise, not to plates (*lamelles*) as in *eczema rubrum*, but to yellowish soft scales, formed of laminæ placed over one another, sometimes of considerable size. These scales fall and expose surfaces, from which a reddish serum issues; new ones form, which follow the same course, and thus, until the inflammation at length becoming less, the pustular vesicles are less frequently developed, and in smaller numbers, by little and little the scales again become thinner; on falling they leave behind surfaces less red, and at length the skin thus resumes its natural state. This eruption may last for two or three weeks; it may be confined to a single surface; sometimes it is general, and is, in this case, very severe; it is then accompanied with general symptoms; the pulse is frequent, there is thirst, loss of appetite, &c.

It most generally happens that different degrees of inflammation may be observed in the same individual, especially when the eruption is general, or at least sufficiently extensive. Thus we see the vesicles arise; being at first transparent they are seen to pass into the state of pustular vesicles, and we have observed vesicles of which one half being milky had not yet passed into the purulent state; whilst a yellowish tint, and a greater thickening, indicated this change in the other.

In the cases of *eczema impetiginodes* confined to a single surface, there are frequently observed around the seat of the vesiculo-pustular eruption some vesicles of *eczema rubrum*.

Lastly, *eczema impetiginodes*, instead of terminating in twenty or thirty days, may also pass into the chronic state; but then it does not differ from the chronic *eczema* which succeeds the *eczema rubrum*, and even at this period it is only true vesicles which are developed, the pustular vesicles having become much fewer in number.

The *eczema impetiginodes* is not then an *eczema rubrum*, complicated with pustules of impetigo, but an eruption of which the vesicles, at first transparent, pass not into the state of real pustules, but of pustular vesicles. The disease would otherwise be a real *impetigo*, for at a certain period almost all the vesicles are become pustular, and yet we shall see, when speaking of the diagnosis, that well-marked differences exist between these two eruptions.

The inflammation is sometimes so intense, that the *eczema* (this happens often

enough) may become complicated with some pustules of real impetigo, and with still larger pustules of *ecthyma*. But these elevations of the endermis contain pus almost from the very moment of their formation; their base is in general larger, the liquid they contain is yellower and thicker.

Acute *eczema* is scarcely ever accompanied with constitutional symptoms of any severity; sometimes occupying a certain extent, it seems calculated to constitute a very serious disease, and still it follows a regular course, and quickly terminates without having occasioned any other symptoms than a slight elevation of the pulse.

Chronic eczema.—Whatever may have been the primary symptoms with which it appeared, *eczema* often passes into the chronic state. The skin, necessarily irritated by the presence of the ichorous fluid, and by successive eruptions, far from gradually recovering its natural state becomes very severely inflamed; it is excoriated, cracks are formed, particularly in the vicinity of the joints; lastly, there is a constant and very profuse exhalation of serum; it becomes necessary frequently to change the linen, which soon becomes soiled with this fluid, and on removing it the greatest attention is required, so as not to tear it off and so produce small lacerations, which are sometimes followed by a considerable discharge of blood; they expose red surfaces, of a swollen and softened appearance, on which the impression of them often continues. The eruption may remain during several months without the exhalation of serum diminishing much.

On other occasions, after a certain space of time, the fluid is exhaled in smaller quantity: it thickens and forms plates, and small, thin, soft scales, of a yellowish colour, not adherent, often of considerable extent, leaving beneath them, at the time of their fall, an inflamed surface, a little moistened. These plates are formed more slowly, they are drier, and the disease appears to be on the point of being cured, when, without any known cause, the inflammation assumes a new degree of severity. The surfaces again become very red, they are again covered with vesicles, which soon burst, and the disease pursues the same course. This disease may thus last for years with similar exacerbations more or less severe.

Lastly, in some cases, the least exhalation does not take place, nor even the least oozing; the scales become drier,

less yellow, and more adherent; the skin is cleft and thickened. The scales, which are easily detached, present beneath them a surface which usually is but little inflamed. Sometimes, however, and chiefly in cases of general chronic eczema, the entire skin has remained, even after a space of several months, of a bright red colour, and it is covered here and there with dry and thin scales; it is also cleft, and there is not observed on it any perceptible exhalation of serum. In this case the eczema resembles certain scaly affections, properly so called (*psoriasis*), so much the more as these scales are no longer produced by the concretion of an exhaled and thickened fluid, but seem to be (as in scaly diseases) plates of altered epidermis. The appearance of the vesicles might throw a light on the true nature of the eruption. M. Biett, has shown, in his lectures, several examples of this *eczema* which became real scaly diseases. The vesicular character became more and more marked, according as they progressed towards a cure.

In some cases, more particularly when the eczema is situated on the legs, there remain but one or two small surfaces, around which the skin, as if attenuated, is smooth, tense, and shining; its surface is covered with whitish scales, extremely thin, and as it were epidermic; no vesicle is observed on these shining surfaces, and the diagnosis might become very difficult if a new eruption, or the exact knowledge of the preceding, and sometimes even the presence of small vesicles dispersed over the circumference, did not sufficiently explain the nature of the disease.

The chronic eczema, at first confined to a small space, may extend over larger surfaces, and in some rare cases, we may see this affection, which occupied at first only the breadth of a five franc piece, gradually extend so as to cover whole limbs.

In all these states the chronic eczema is constantly accompanied with the most severe itching, sometimes harder to be borne than the most intense pain. In vain does the patient arm himself with all his reason and all his courage; he cannot resist the imperative necessity of scratching himself; thus the itching increases, and often returns with severe exacerbations.

This itching is particularly intolerable, and throws the patient into truly pitiable anguish, when the eczema is seated on certain parts; thus when it has its seat on the inner and upper part of the thighs,

being often kept up in females by a chronic discharge, it extends to the anus and vulva, and there occasions an itching, which sometimes reaches the vagina, and which cruelly tortures the patient.

After a longer or shorter space of time the itching is mitigated, the serous exhalation gradually lessens; it soon ceases; the scales become drier; the skin is less inflamed. The surface, which is the seat of the eruption, diminishes; the circumference is first cured; the plates become thinner and smaller; they soon cease to be formed; the skin remains a little redder than in the natural state, but this colour soon disappears. Ultimately the disease is often reduced to a very small, red dry surface, covered with extremely thin plates. The surrounding skin is smooth, tense, and unbroken; it resumes its natural state but slowly; the redness, as we have shown, always continues for a certain time after the disappearance of the eruption.

The duration of chronic eczema is almost indefinite; it may continue for months and even for years.

Seat. There is no point of the surface of the skin which may not become the seat of eczema; but there are some parts which it attacks in preference; as those parts covered with hair, where the follicles are more numerous: the pubis, groins, scrotum, axillæ, &c. &c. It may be confined to a single part, to the breast, scrotum, hairy scalp, the ears, and constitutes some local varieties of considerable importance.

Most frequently it attacks several parts at one and the same time: again we have seen it occupy the entire skin at once, both in the acute and chronic form.

Causes.—Eczema is not contagious, but in some very uncommon circumstances it may be transmitted from individual to another, by the contact of two mucous surfaces. Thus, M. Biett has stated in his clinical lectures, several instances of eczema which were transmitted during the act of coition. It often attacks adults; women appear to be more frequently affected with it than men; it often appears in spring and summer. The return of the seasons is in general the period when chronic eczema becomes exacerbated; the same may be said of sudden changes of temperature. It is often developed under the influence of an unknown cause, but it is sometimes the result of a direct appreciable agent; thus it may be occasioned by the action of a strong fire, by the rays of the sun (*Ec.*

solare, Willan); it is frequently observed after the application of a blister, and the eruption may attack the entire arm or the entire thigh.

It is often produced by dry frictions, and especially those made with pommades of a less irritating quality; it is in this way the eczema is produced which goes by the name of *mercurial*. It differs not in the least from the other varieties, either in its symptoms or in its course. In persons who work in refined sugar manufactories attacks of eczema are often developed after burns; lastly, it is frequently produced by excesses, more especially by the abuse of alcoholic potations.

Whatever may be said of the influence of the direct causes on the development of acute eczema, it appears evident to us that it is to a particular predisposition of the system that we must attribute its transition to the chronic state, and its greater or less duration in this state.

Certain local species of this affection are produced and often kept up by causes referrible to the seat which they occupy. Thus profuse chronic leucorrhœa often keeps up an eczema for an indefinite length of time.

The handling of metals, touching powdered substances, as sugar, &c., are a frequent cause of eczema on the hands, &c.

It is one of these varieties which has received the name of the bakers' disease. But this affection is produced sometimes be papule, sometimes by vesicles. This is an additional proof of the little dependence to be placed on a classification founded on causes.

Diagnosis.—Eczema, in each of its stages, might be confounded with eruptions of an entirely different character, and its diagnosis is of the highest importance.

Eczema simplex has been frequently taken for the itch, to which, at first sight, it seems to bear a close resemblance: like it, it is developed without inflammation; like it, it generally attacks particular parts, the wrists and the sides of the fingers; like it, it produces intense itching; but the vesicles of eczema are flattened, whilst they are pointed in the itch: those in eczema are always crowded together; they are in general isolated, and entirely distinct in the itch, wherein we often see but one, or two, or three over a considerable extent of surface, between two fingers, for instance, a thing which is never met in eczema. The itching of this latter affection is a kind of smarting very dif-

ferent from the exacerbations of itch: in the former case it is a real pain, while in the latter it is rather an agreeable than a painful sensation; lastly, the itch is essentially contagious, and eczema is not generally so.

Eczema rubrum presents characters by which one might confound it with the miliary eruption; but in the latter the vesicles are never confluent as in the eczema rubrum, where in a very small space a numberless crowd of them may be seen. These are larger in the miliary eruption than in eczema; besides the constitutional symptoms which always accompany the symptomatic miliary eruption, and which are those of an affection more or less severe, are sufficient to distinguish this affection from that now in question. That variety of the miliary eruption which is observed in certain individuals who have taken violent exercise in very hot summer weather, presents considerable resemblance to eczema; but the vesicles are more scattered, there is perspiration more or less profuse, and the disease disappears very rapidly.

Eczema impetiginodes differs from impetigo by very marked characters: the vesicular affection always occupies large surfaces; impetigo on the contrary is most frequently confined to a small surface. The pustules of impetigo never contain a transparent serum at their onset; they present a broader base, and the contained fluid is thicker. The pustular vesicles of the *eczema impetiginodes* are always vesicular at their onset and never contain real pus, but a yellowish serum, a sero-purulent liquid. Again what establishes an additional distinction between these vesicles and the pustules of impetigo, is the difference of the products. In impetigo the pustules constantly give rise to real crusts which are always thick, more or less yellow, rough, and uneven, while the pustular vesicles of eczema never form any thing but thin scales, rather broad than prominent; and further, in this latter affection, we always find around the eruption vesicles of *eczema rubrum*, which are never met in impetigo.

Lastly, the traces which these two affections leave behind, also present very marked characters. Those of impetigo present a brighter redness, and sometimes too this eruption is followed by slight cicatrices, which never takes place in the *eczema impetiginodes*, after which there are only found slight traces of a much less bright red.

It would be easier to confound *eczema*

impetiginodes with the itch, when the vesicles of the latter are accompanied with pustules; but leaving out the pustules, which in nearly all the cases are but a complication, attention should be directed only to the pustules which are always more numerous, and we should apply to them in forming our diagnosis the characters above noticed, to distinguish the itch from *eczema simplex*.

Chronic eczema often presents much greater difficulties in the diagnosis. Among the eruptions with which it might sometimes be confounded, we shall remark lichen which may present two states in which it is very liable to be taken for eczema.

Lichen agrius is also accompanied by an exhalation of serum, followed by the formation of scales; but these scales, smaller in size, thicker and yellower than those of eczema, approximate a little to the nature of crusts; on falling they expose not a red, smooth surface, generally shining and slightly excoriated as in eczema, but a surface as it were fretted with small prominent points (*papulae*) generally visible to the eye, and invariably perceptible to the finger, when it is carried over the eruption.

At other times, as in the chronic eczema, lichen may present thin dry scales, without any perceptible quantity of serum, without local inflammation, but then the skin is much thicker and rougher than in eczema, so much so that we often have some difficulty in raising it between the fingers. Again, in lichen we always find here and there close to the eruption some *papulae* readily recognized by their hardness, by their chronic course, in the same way as eczema almost always presents around the patches *vesicles* easily distinguished from the elements of lichen.

It is chiefly when these varieties, either of lichen, or of eczema, occupy the hands, that very great attention is sometimes necessary to distinguish them.

Certain varieties of chronic eczema resemble *psoriasis* very closely; but in eczema in order to distinguish it we shall have the presence of vesicles around the eruption, or else their consecutive development; besides, the scales are always thinner, less dry, and less friable, though softer. They are almost always accompanied by an oozing, which does not exist in *psoriasis*. After their fall the skin does not present, as in *psoriasis*, a smooth, red, elevated surface, but a surface which is marked with clefts and fissures.

However, in certain cases of chronic

eczema, very rare no doubt, the eruption may be general, and the skin may present a red tint, at the same time that it is covered with whitish scales of greater or less extent; here the diagnosis is so much the more difficult, when we have not followed up the very first phases of the disease, and when no exhalation exists. We shall distinguish this state from *psoriasis* by the circumstance of the skin presenting no elevation or hypertrophy, as in this latter disease; and because the fissures observed are proportioned to the muscular movements, and do not cover the surface of the skin in every direction, as in *psoriasis inveterata*. But, we repeat it, much attention is required in these cases, and it will sometimes be necessary to wait till a new exacerbation comes to remove all our doubts.

We shall consider the prognosis and treatment at our next meeting.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

Of Suppurative and Ulcerative Inflammation; Granulation, Skinning, Hectic Fever, and Dissolution.

When an inflammation exceeds the adhesive state, and has got beyond the power of resolution, and when the adhesive has set bounds to the suppurative inflammation, the suppurative begins; or in internal surfaces, where the adhesive cannot take place, the suppurative begins. The irritation which is the immediate cause of suppuration is the same, from whatever cause it may have been produced: it is a similar process, going through the same stages, whether it takes its rise from external violence, or from the constitution, or from disposition for disease in a part, if all other circumstances are equal. It is very difficult to give a true and clear idea of the whole chain of causes which lead to suppuration. Irritation simply is not always sufficient; it often only brings on the adhesive inflammation. Violence done to a part is one of the great causes of suppuration, but this alone is not sufficient; it must be with a prevention of union by the first intention, or by adhesive inflammation; it must be attended with death in the part, as in bruises. The application of air to internal surfaces has generally been assigned as a cause of inflam-

mation, when it happened in consequence of destruction of a part; but air has certainly no such effect, for a stimulus would arise from a wound were it even contained in a vacuum; nor does it get to the parts forming circumscribed abscesses, which yet suppurate, in consequence of inflammation, as readily as exposed surfaces. In many cases of emphysema, where the air is diffused over the whole body, we have no such effect, excepting there is produced an exposure of some internal surface for the air to make its escape by, and then the wound inflames. In birds we find the cells in their bones communicating with the lungs, so that they have at all times more or less air in them, although they never inflame; but if these are exposed by a wound, the stimulus of imperfection is given, and inflammation begins, and suppuration may succeed. The same observation is applicable to a wound made in the abdomen of a fowl, for there the wound inflames and unites the intestines, to make the cavity perfect again; but if the union is not allowed to take place, more or less of the abdomen will inflame and suppurate. How should we account also for suppuration taking place in the nose during catarrh, since it is not more exposed to air then than at other times? Air, therefore, is not the cause of suppuration.

We are at a loss to say, with regard to spontaneous inflammation, whether it is a disease in which the constitution will be injured, or whether it is a salutary process in which nature is endeavouring to relieve herself; and it is evident that the same action may arise from different causes.

Suppuration does not depend on the violence of the inflammation; for that circumstance, simply considered, rather tends to produce mortification; and we see that in gout, which does not suppurate, there often is more violent inflammation than in many other cases that do; and in true scrofula we have suppuration without any visible inflammation; so that this does not seem essential to suppuration. Although we find that inflammation and suppuration from injury are very violent, yet that which occurs spontaneously generally exceeds it in violence. In inflammation of the breasts in women, and of the testicles in men, the quicker the inflammation proceeds the better; for where it is slow it gives the idea of specific inflammation, as this generally proceeds slower than simple inflammation.

Suppuration takes place more readily from the surface of canals than in either

the cellular or investing membranes; the same degree of inflammation which will produce suppurative in the first-mentioned parts will only produce adhesive in the latter. If a bougie be introduced into the urethra, it may produce suppuration; but if introduced into tunica vaginalis or abdomen, it will only give a disposition for adhesions.

Symptoms of suppurative inflammation.—The sensations arising from a disease generally convey some idea of its nature. Some diseases give what is called a heavy, a dull, or a gnawing pain, &c.; but the suppurative inflammation gives as much as possible the idea of a simple pain, without having relation to any other mode of sensation: this pain is increased at the time of the dilatation of the arteries with the sensation called throbbing. The part now becomes more swelled by the greater dilatation of the vessels and a greater quantity of extravasated fluid being poured out, and a scarlet colour increases from the admission of red globules into vessels not naturally conveying them and the formation of new vessels, and an oedematous appearance, like that in erysipelas takes place. One, two, or three parts of the inflammation lose the power of resolution, and take on exactly the same disposition with that of exposed surfaces, or a surface in contact with an extraneous body. If it is in the cellular membrane that this disposition takes place, or in the investing membrane of circumscribed cavities, the vessels now begin to alter their disposition and mode of action, and continue changing till they bring themselves to that state which fits them to form matter. But as this change does not take place all at once, some parts may for some time continue to discharge coagulable lymph, as in the adhesive state, whilst those parts which have taken on the suppurative action pour out matter; and hence, if tumour be now opened, it will be found to contain both matter and coagulable lymph: in which state it has always been imagined that the matter had not arrived at a state of ripeness by those who supposed its purulence to depend on its confinement and stay. It would appear, from matter forming from the investing membranes of internal cavities and mucous surfaces, that matter may be formed without any breach of surface.

There is a certain period in inflammation when suppuration begins, and which is discovered by new symptoms, as shivering, &c.; and though the change is pretty

quick, time must be allowed for the vessels to be fitted for the suppurative state. The effect of inflammation seems to be the producing the suppurative disposition, or that state of parts which disposes them to secrete pus: in doing this, inflammation seems to be carried to such a length as to destroy that state of parts on which itself depends; the consequence of which is that they lose the inflammatory and come into that disposition which fits them for throwing out matter. That the suppurative is very different from the adhesive inflammation is plain from this, that if a wound in a suppurative state, yielding good matter, has by irritation of any kind the adhesive inflammation produced in it to any degree, the discharge lessens, and the wound puts on appearances very different from what it had before. It seems a fixed and useful law in the animal economy, that when inflammation has gone to the length of destroying the natural functions of parts, so as to prevent their returning by a retrograde motion to that state from which they set out, suppuration should come on to give them a disposition for a second mode of cure.

Treatment of Suppuration.—Suppuration may sometimes be removed by producing actions in other parts; thus, I have seen a bubo cured by a vomit, and similar effects are producible on scrofulous tumours. When suppuration cannot be stopped or resolved, in most cases it is to be hurried on towards the skin, which generally is the first step taken by surgeons. How far suppuration can be increased by medicines or applications I do not know, but attempts are generally made; hence we have I think, in the pharmacopoeia, (though I do not read many books,) suppurating cataplasms, maturing, &c., but I doubt if they have considerable effect in this way, for the same applications applied to a sore would hardly increase the discharge of that sore. However, in cases where the parts are indolent, and hardly admit of suppuration, by stimulating the skin more salutary inflammation may be produced, and of course quicker suppuration; but with true suppuration, preceded by inflammation, it is I believe hardly necessary to do anything with respect to the suppuration itself. Nevertheless it has perhaps been found by experience that these applications tend to bring matter faster to the skin, even in the rapid suppurations; only, however, in those cases where the inner surface of the abscess is within the influence of the skin. This effect, too,

may arise from another mode of action being produced than that of quicker suppuration, which is the hastening of an ulceration. Poultices of bread and milk are commonly used to inflamed parts when suppuration is known to have taken place: this application can have no effect, except that of lessening the inflammation, or rather making the skin easy.

Of suppuration without inflammation.—I have hinted that thickening of parts took place sometimes without inflammation, and also that the suppurative inflammation might take place without being preceded by the adhesive. Many indolent tumours, slow swellings of the joints, swellings in the lymphatic glands, tubercles in the lungs, and swellings in many parts of the body, are of the first kind, namely, thickening without visible inflammation; and the contents of some kind of encysted tumours, the matter of many scrofulous suppurations, as in the lymphatic glands, and in the joints of the foot and hand, for instance, and in the hip-joint, called hip cases, of the loins, called lumbar abscesses, the suppuration of tubercles in the lungs and in many other parts of the body, all exhibit the formation of matter without any previous visible inflammation. They come on insensibly, the first symptom being a swelling in consequence of the thickening, (which is not the case in inflammation, for there sensation is the first symptom,) and this swelling is increased by the formation of matter.

The nature of the matter is another distinguishing mark between suppuration in consequence of inflammation and that without it, the latter being generally composed of a curdly substance mixed with matter. The curdly matter is, we may suppose, the coagulable lymph deprived of serum, the thinner part is true pus, having the globules and specific properties of pus, and is often as thick as the common pus formed in consequence of inflammation.

All parts which form pus of any kind, whether in consequence of inflammation or otherwise, must go through similar processes to produce the ultimate effect or cure. The first step, in either case, is the evacuation of this matter, for till that is effected nature cannot take means towards a cure; the second step is granulation; the third, cicatrization.

There are three modes of doing the first; one is the absorption of matter, which is very common in the scrofulous kind, but not in those suppurations which

are the consequences of inflammation, and which produces no alteration of the part except the gradually creeping into a sound state; the other modes of discharging this matter are, either opening the abscess, to allow it to pass out, or allowing ulceration to take place on the inside to produce its escape; which process in the present case, having peculiarities different from those arising from inflammation, it is necessary to explain still further.

Ulceration in consequence of suppuration arising from inflammation, is very rapid, especially if the suppuration is very rapid; but ulceration in consequence of suppuration not the effect of inflammation, is extremely slow: it may remain months, or even years, before the parts give way.

When an abscess, in consequence of inflammation, is opened, it immediately proceeds towards a cure, and perhaps may have gone some steps towards a cure before the opening. As inflammation lessens, suppuration becomes still more perfect, granulations begin to form, &c. But when an abscess, not preceded by the common inflammation, is opened, a very different process is first to take place; the consequence is, that inflammation now takes place over the whole cavity of the abscess, which afterwards produces perfect matter, like that produced when inflammation is the original disease. However, it sometimes happens that they inflame before they are opened, in consequence of the matter distending the cavity acting like an extraneous body, not in consequence of the cause of suppuration. I have seen white swellings of the knee inflame before they were opened, when ulceration took place, and the pus was brought soon to the skin, though before it had been for months without producing the least tendency to ulceration, and of course none to inflammation; but the confinement of matter became the cause of inflammation. The inflammation and new suppuration taking place in consequence of an opening into these abscesses, is exactly similar to those inflammations and suppurations which take place in consequence of an opening made into internal cavities; and it is extraordinary that often upon opening these swellings, inflammation, fever, nay, death, shall follow, but if suffered to break of themselves no such effect is produced.

Of Pus.

The immediate effect of the modes of action above described is the formation of

matter, commonly termed pus. This matter is very different from what was discharged during the adhesive stage of inflammation, and also very different from the common secretion of internal canals; yet when these surfaces form pus it is probable they are formed by the same vessels: if so, their mode of action must be greatly altered.

In suppuration of the cellular membrane, or of circumscribed cavities, their vessels are but little changed at the commencement of the suppurative disposition, so that they still retain much of they acquired by the first stage. The discharge is, at the beginning, little more than coagulable lymph mixed with some serum; this is scarce different from the discharge in the adhesive stage of the inflammation; but as the inflammatory disposition subsides, a new disposition is every instant altering these vessels to the suppurative state; the discharge is also varying constantly from a species of extravasation to the new-formed matter peculiar to suppuration. The matter removes further and further from the nature of the blood, losing the yellowish or greenish pus, and becoming white, and more viscid and creamy. By the formation of this new substance, the coagulable lymph, which was extravasated in the adhesive state, and adhered to the sides of the cells, either on cut surfaces, as wounds, or on the walls of abscesses, is pushed off, and if there be a cavity, is pushed into it, so that we should find in the cavity both coagulable lymph and pus; or, if on a cut surface, it is thrown off, and is generally removed, along with extravasated blood, &c., with the dressings.

This is the process which takes place in the first formation of pus in an abscess, or from the surface of fresh wounds.

On the internal surface of canals the parts are not obliged to go through all these steps; they run into suppuration almost instantaneously.

THE MEDICAL JURIST.

No. 4.

INSANITY.

Mental diseases are either idiopathic or symptomatic:—the first comprehend all those diseases which are generally spoken of under the term—*Insanity*; while the symptomatic are those which

obviously depend on bodily disease. The nomenclature of these subjects is so vague as to prove the low state of our knowledge respecting them: the great difference between a madman and an idiot is, that the former reasons soundly on false principles, whilst the latter reasons falsely on sound principles—thus there may be much reason displayed in madness, but not in idiocy. Lord Eldon has endeavoured to make another division, under the appellation of “unsoundness of mind;” but it is very vague. It is only a minor degree of idiocy.

All insane persons are distinguished from healthy persons, by a want of controul over their feelings and actions. Most authors have said that insanity is a want of perceptions of what is morally right and morally wrong; but it will often be difficult to tell whether insane persons may not have this perception, and in order to exculpate them from blame, this want of perception must be evidently seen in many of their actions, if not in the whole tenor of their conduct. Some attempt to prove the fact of insanity from the very act which has brought the prisoner to trial, but he is not likely to be excused on this ground. I cannot agree, says Dr. Christison, with the Continental Jurists, who say that an act may be so atrocious, as itself to prove the insanity of the person who has committed it, without any bodily disease being present: but when the latter produces insanity, as in the case of epilepsy, hysteritis, or puerperal fever, madness may really exist without any previous symptoms having existed to warn us of it.

It is thought by some that suicide always results from insanity. One man married his mistress in order to legitimize the children he had had by her, and then killed himself. It was endeavoured to prove his insanity by his last act, but there was too much “method” in the previous act—his marriage. A man named Nicholson was executed in 1813, for the murder of Mr. and Mrs. Bonner; he was previously on good terms with them, and seems to have had no motive for the deed, which he declared was from a sudden impression, felt about five minutes before he committed the crime. A corporal determined to get himself hacked to death, in order to atone for his sins, and begged a comrade to chop off his arms and legs: the latter did so, thinking it was no crime to obey the request of his friend—he was beheaded. A man jumped into the water in order to prove to his friend that

a man of sound mind might commit suicide. Georget relates the cases of persons going out to murder others, and giving no proof of madness, except their not concealing the deed. This is called monomaniac homicide; but the safety of society demands that all such persons should be confined.

In many cases, insanity continues without interruption, but in others there are intervals of health, called “lucid intervals,”—persons subject to them are “lunatics,” properly so called, but the term is now used more generally. In lucid intervals persons are capable of performing all the duties of life, and are responsible for their actions. They are less easily cured than those whose madness is uninterrupted.

Insanity may be either partial or universal. The former is called “melancholia” by Cullen and Pinel. It may be expressed by the term “monomania.” There is no action, however extravagant, that persons afflicted with it will not attempt. The first delusion we shall mention, as one to which monomaniacs are subject, is as to their own persons—they often fancy themselves kings, queens, emperors and prophets. Some have thought themselves barley-corns, and were afraid of going out of doors for fear of the birds. The second delusion is as to their circumstances, which they generally imagine to be of a melancholy nature. They are often in dread of conspiracies. A third delusion is, as to their future state, which they always paint in gloomy colours. It is sometimes difficult to distinguish this state of feeling from that of many religious persons whose minds are sound. A fourth delusion is, as to their being in ill-health. All the patients affected with these delusions are rational on all other subjects; and sometimes succeed in concealing their particular hallucinations. There was one gentleman who thought that Buonaparte was Jesus Christ; but before his examination came on, his hallucination changed to his being Christ himself, and when attacked on the former delusion, was perfectly rational. It is a question how far the act of a monomaniac can be excused, when it is not immediately connected with the subject of the hallucination. One man had a delusion, which led him to dress himself like a woman. His will was set aside, but the propriety of doing it is very questionable. Another was a man whose understanding was acute on all points, except that he thought himself the owner of the winning

horse in every race. In a case of murder a partial madman would escape punishment, although the act might not be connected with his hallucination; but he ought to suffer in such a case. As to wills, if not proved to be connected with the hallucination, they should themselves be looked to, in order to decide on their propriety, from their own internal evidence.

We must not conclude that a man is insane from one act; and therefore it is wrong for barristers to make medical men give their opinion on successive single acts. Madness generally *begins* gradually, but often *terminates* suddenly; as in the case of a gentleman who thought he had a glass leg, but whose servant cured him in a quarrel, by proving that this leg was able to bear the blows of a poker. Another person was speedily cured by finding that what he took for a canvas partition, was a stone wall. Madmen may be either manageable or furious, and a cure, in idiopathic cases, is not so rare as is generally thought. Death seldom occurs from the madness; the patients are often remarkably healthy in other respects; and but slight morbid appearances, in most cases, can be discovered on dissection.

Somnambulism is a state closely resembling that of madmen who acts correctly on false principles. Dr. Christison never knew a case of a person committing a crime while in a state of somnambulism; but Fodere tells us of a priest, who stabbed the bed of a person he disliked; but it is not certain that he was not awake at the time. A woodman, waking up suddenly, killed his wife with an axe. He said he thought the devil was come, that he struck at him, and hit his wife by accident.

Insanity may be pretended from various motives; and in many cases the pretence has been successful. The kind of insanity chosen, is usually general madness of a furious description, or partial madness of a gloomy cast. In suspected cases, we must first trace the history of the case from the time of health to the present date. There is much to be learned from the countenance, but it requires great experience to judge of it; and idiots have sometimes shrewd countenances. The next thing to be observed is the voice, which is of a peculiar kind in real insanity. In the latter, also, you have preternatural strength, violent exertion without perspiration, &c. Pretended madmen generally return incoherent answers

to every question; which is not often the case with real madmen. The best way to detect them is to tell them suddenly some news about their case, observing the effect on the pulse. Cases of real insanity are more easily cured while recent, than if neglected. Cures are also more frequent in youth than in age, and in females than in males. Monomania is oftener cured than other kinds of insanity, although the contrary is maintained by Esquirol. He says idiosyncrasy is never cured, and the fatuity of old age is likewise considered incurable. Sudden cases are more easily cured than gradual ones. Reports of cases of insanity are generally defective in many particulars.

We may be called upon to decide on the insanity of an absent or a dead person. It is seldom that a man can conscientiously give an opinion here; and he must not pronounce on separate acts. There is reason to think that furious fits of mania, may take the place of epileptic fits. Cases of this kind are mentioned by Haslam and Burrows. Insanity is often not so much an *accompaniment* of bodily disease, as a *sequel* of it: one symptom becoming more prominent than the rest, and remaining after they are gone. Sometimes, however, insanity is one of the attending circumstances of diseases. The deaf and dumb, whose state of deprivation in these particulars is accompanied by a kind of mental disability, are reckoned among the insane, unless they are educated by the modern system; in which case they will be considered as responsible agents.

Bodily disease is often accompanied by a kind of mental imbecility in which men are easily excited, and owing to the former practice of leaving estates to the Roman Catholic Church, there is an old Scotch law against the disposity of heritable property on a death-bed. It is absurd to keep up this law now. There are many lingering diseases in which the judgment remains sound. The time is now limited to sixty days. If the person lives beyond that time, after making his will, the latter is valid. It is also valid if the person who made it paid his accounts *before* signing it, or afterward; so that fifteen minutes would have made all the difference. Such a distinction must be absurd. A question may also arise, as to whether the man at the time he made his will, was ill of the disease of which he afterwards died. As the statute is so absurd, its conditions ought to be fully proved before it is put in force. It is sometimes alleged

that a man recovered of one fit of his disease, but died of another fit, as in a case of epilepsy, for instance. Suppose that a man, while making his will, labours under paralysis of one side of his body, and that he dies within sixty days. But did he then, at the time of making his will labour under the disease of which he afterwards died? Such a question must be decided on metaphysical grounds.

Sometimes the line between health and insanity is so slender as to require great judgement to discriminate between them. Hall long ago remarked on the difference between total and partial insanity. The great difficulty is with respect to the latter which is now called monomania. Dr Haslam says, no specific direction can be given for pronouncing with certainty on a supposed case of it. Monomaniacs are sometimes very cunning, and they will then avoid giving direct answers. One of the best plans is to allow the patient to detail his case, and the ill-treatment which he alleges he has suffered; and never to interrupt him in his digressions. Want of sleep is a very frequent symptom; and likewise a restless, wandering eye; and if asked the reason of these phenomena, the patient will often ascribe them to the malice of his enemies. Insane persons often fancy they see and hear things which have really no existence. The maniac thinks they are real, but the monomaniac knows they are not. Some persons exhibit in their conduct such peculiarities, and to incur the suspicion of monomania, and yet act so well, that it is dangerous to deprive them of liberty, or free them from responsibility. Lord Cudworth used to indulge in eccentricities of dress, and they tried to set aside his will on the ground of insanity; the case went before the Lord Chancellor, who decided in favour of the will. It was a good rule laid down by Lord Erskine, that if the insanity does not affect the act in question, that act should be considered valid. If the person, however, should labour under any idea, which might lead to mischief, he is a proper subject for restraint. When I went to Liverpool, says Dr. Traill, I found a man in the asylum, who had been confined for ten years for threatening his neighbours; but the only peculiarity which could be discovered in his conduct, was his keeping the seventh day holy instead of the first; as he thought he had no right to change the Sabbath. He was a strict Christian, and attended worship on Sundays in compliment to the rest. Finding he had

given up all idea of doing harm, I set him at liberty, and kept sight of him for eight years. He went on quite correctly, still keeping the Jewish Sabbath. He remembered me with gratitude, and as a mark of it, came to me with a hare as a present. Lord Mansfield thought a man was responsible for his acts, if he could tell good from evil; though he might be incapable of managing his affairs. He said that if a man committed a crime, in the intervals of occasional insanity (properly called lunacy), he would be responsible for it. It is not easy to draw the line on the general question. Cases must be decided each on its own merits. The impunity for crime which is attached to insanity, makes a great impression on the mind of all lunatics. In 1800, Margaret Nicholson was acquitted of attempting to murder the king, as it was proved she had a fit of lunacy the day before; and Lord Kenyon thought it highly improbable she could have got well in the short interval.

A late act of parliament has several provisions to prevent the disgraceful abuses, which were proved, by parliamentary investigation, to have existed. All asylums must be licensed; a plan of them must be furnished to the magistrates, who may appoint visitors, from whom it is a misdemeanor to conceal any patient. No patient can be admitted into an asylum without a certificate from two medical men, who must have examined him at different times, and within seven days prior to admission. A medical man cannot sign this certificate, if he has any interest in a lunatic asylum; or if his father, or son, or brother, or partner should have such an interest.

There is better hope of patients with high maniacal fury, than of monomaniacs, especially if the latter be of a despondent class. The existence of an hereditary taint, renders the case unfavourable; for then slight causes will bring back the attack. In the case of insanity produced by intoxication the first attacks are generally cured easily. If insanity arises from pregnancy, it is generally cured in six weeks, and almost always within a few months. Of cases of insanity from drinking, of long standing, the majority are quite incurable. Monomaniacs require from four to six months, or even two years for their cure, especially if they exhibit a tendency to suicide. If the attack should last longer than this, it is seldom cured. By an examination of the French tables, it appears that the greater number

of cures take place within four months. The greatest misfortune in this disease is the tendency to relapse after recovery: this relapse is common when the disease is hereditary, and where it arises from drink, the habit is but too liable to recur. If it arise from distress of mind, when the patient is left alone, he is apt to ponder on the painful subject. Intoxication is sometimes characterized by the symptoms of delirium, of hysteria, of epilepsy, and of apoplexy. Hypochondriasis, in a severe form, is generally attended by dyspepsia.

A lucid interval is not a mere remission of the disease, but an interval between the paroxysms, in which interval the mind is in a perfect state. The law allows a lunatic to make his will in a lucid interval; but it does not recognize the will of an idiot. Dr. Traill does not think a *perfect* lucid interval exists in insanity. He has known convalescents remain collected for months, if the morbid subject has not been touched upon. While he had charge of the Liverpool Asylum, the burning of York Minster took place; but the incendiary was very properly acquitted on the ground of insanity. The newspapers were admitted into the convalescent ward, and the accounts of the trial caused great sensation. One of the patients told the doctor, that if he were to kill him, he should not be hanged; since either he was mad or his detention in the asylum was unlawful: reasoning, by-the-bye, which was perfectly correct.

A young man was brought into the same asylum one night, with a certificate from a medical man, who had granted it on the representation of his friends, without having seen him personally. He was only intoxicated, and on coming to his senses was much surprised at his situation. In a few days he was dismissed, with an assurance that the life he had lately led would render him a fit object for a permanent residence in the asylum.

Hypochondriasis is apt to degenerate into insanity. Hysteria, if often repeated, tends to produce mental imbecility. As drinking is a volutary act, the law makes a person responsible for the acts committed during intoxication. This was ruled by Lord Eldon, in a case in which the prisoner was quite rational between the fits of intoxication, although the latter were almost constant. Lord Ferriars decoyed a man into his study and shot him. It was proved that he was subject to fits of lunacy, and had had one the day before; but he was executed. It is

thought that if he had not been of so high a rank he would not have been executed, but confined. In Pinel's cases of recovery from mania and monomania, only one-sixth relapsed.

Cox's remarks on feigned insanity are very good. Pretended madmen think it is only necessary to be extravagant. They do not copy consistency, or draw logical conclusions from the false premises. They cannot imitate the watchfulness of real insanity, but will generally sleep soundly, if left alone, and if put into a chamber where they can be watched without their knowledge, will generally betray themselves. There is a want of that peculiar expression of the eyes which characterizes insanity; and of that peculiar odour which is very perceptible about the insane, especially after they rise in the morning. The way to detect them is to tell them to relate their own story. They make it far too favourable for themselves, and afford opportunities for contradiction, which would irritate them if really insane. Real maniacs lose hope and fear in the predominance of the morbid idea; but those who feign madness may often be acted upon by them, and are thus detected.

Has insanity increased in Great Britain? It is generally thought that it has; but Dr Burrows, who treats the subject very ably, shows that although there has been a great increase in the consumption of spirits, and of speculative adventures in business, insanity has really not increased. This opinion is supported by Willis and Heberden. Many insane persons who were formerly allowed to wander about the country are now shut up in asylums, and this swells the apparent number of the insane.

Let us now take a glance at the researches of the phrenologists on this subject. They allege that insanity was little understood before their science was introduced, but is much more likely to be properly understood now. Those who feel an interest in the subject, considered in relation to phrenology, will find it ably treated in the best article on the subject, in one of the best practical treatises on medicine, which our time has produced; "Dr. Mackintosh, on Pathology and the practice of Physic." Mr. Combe was taken to the lunatic asylums at Dublin, and told the hallucinations of the patients correctly, from feeling their heads. Every derangement of the brain is a disease; but temporary delirium is not called insanity, because it disappears when the fever

declines, or the bowels are put into order. When any important organ of the body is diseased, the brain must suffer, either from the blood not being properly changed or from what is called *sympathy*—a certain influence conveyed by the nerves. When insanity takes the form of furious violence, the strength of the patient is often very great. The latter may be wrong in everything, or eccentric in one particular only; fancying himself a teapot, or that he is made of glass, or having some curious fancy, as for a peculiarly shaped hat or coat. This last kind of insanity, which is called monomania, could not be explained satisfactorily before the introduction of phrenology. Men used to think themselves kings or prime-ministers, while perfectly sane on all other particulars; and it could not be understood how the brain could be wrong in one particular and not in another, till different feelings were assigned to different parts of the brain; any of which parts, of course, may be diseased independently of the rest. I was walking, says Dr. Mackintosh, with a man who had been quite sane up to that time, but who suddenly exclaimed that he was a great man, and he was to marry the Princess Charlotte, and to conquer Buonaparte. He fasted and prayed three days and nights, and thought an angel visited him, and gave as a sign that a plant in the room should die or revive at his wish. I got his bowels opened, and he recovered for that time, but he has since been placed in an asylum. Another gentleman had some large hæmorrhoids excised, and the discharge from them being suddenly cut off, and as he lived high, he became maniacal, and was caught firing his pistols in his bedroom. When Dr. Mackintosh was informed of this, knowing the conformation of this gentleman's head, and in particular that the organ of caution was largely developed, he told his friends that the gentleman thought himself beset by conspirators, which turned out to be correct.

Females advanced in life sometimes think themselves pregnant by some great person. Dr. Mackintosh knew a married lady who fancied herself with child by George the Fourth, and who stuffed anything she could lay hold of up the vagina, in order, as she said, to prevent the young prince from escaping. This she did for years, and is now in confinement. Some monomaniacs fancy a post is transformed into a king, and make speeches to it, and pay various marks of respect to it

accordingly. Some write very cleverly on the false impression that ministers have been peculating, or that a fraud has been committed on some bank. Dr. Mackintosh new an instance in which a real case of the latter was found out by a monomaniac, who at first only guessed at it. Some fall in love, and pester the lady with letters, till the police is called in, which aggravates the disease, and generally consigns the patient to a mad-house. Others become suddenly insane, and run into ruinous speculations, or perhaps murder their friends. Dr. Mackintosh mentions a man now in confinement who murdered two keepers, and who talks of nothing but murdering millions of people. He remembers an old lady on her death-bed who was quite rational, except that she thought that her husband and brother (who had been dead a long while) were in the room with her, accompanied by angels. She spoke to them cheerfully. Many patients talk about suicide, being afraid of some persons coming after them. Some who have been religious all their days are blasphemous in their language when they come to die, and vice versâ. These phenomena are attributed by some to deranged circulation through different parts of the brain. We cannot ascribe them to organic lesion, for the brain is often found unaltered in such cases. Indeed men recover sometimes, after having been insane for years, and the brain is found perfect after all.

While some insane patients are bold and inclined to do mischief, others would shrink into a nut-shell, and often commit suicide to escape from imaginary enemies. Sometimes hatred is felt towards their dearest friends, supposing them to be in a conspiracy to confine them. A gentleman had the small-pox in a violent form: on recovering from it he suddenly became insane, and while Dr. Mackintosh was writing for him, aimed a blow at him with a stick, and threw a chair and other articles at him, though without doing him any mischief. At the great fire which took place at Edinburgh, in 1824, a man acquitted himself so well that he obtained a sum from the town, as a reward for his exertions. He took to drinking, which ended in violent mania. He thought that devils attacked him in the night; tore all his clothes and blankets to pieces, and scratched his body all over. Some physicians predict, from the habits and phrenological development of persons whom they know, that the latter will some day be confined in a mad-house. Some of

the patients become very emaciated and consequently weak, but in the paroxysms of the disease their strength is amazingly increased.

Dr. Mackintosh gives an interesting account of his visit to the Asylum for the Insane at Chatham. Some old musicians played a jumble of parts from all kinds of tunes, taking two or three bars from each. There was an old weaver who was constantly going through the motions appropriate to his trade. Soldiers, though insane, fell into line, and performed their exercise with tolerable correctness. They all thought the rest of the patients were mad, but not themselves. Some thought they saw in the air engagements between ships. One man there was never sure of anything, even in the days of his sanity, he had always doubts. Some were walking about making love-sonnets. Some, who had been medical men, were holding disputations. Many medical men went mad during the Peninsular War, for after a battle, instead of going to sleep, like the other officers, they were obliged to dress wounds, and the anxiety, labour, and want of rest brought on insanity. Many of them committed suicide. One medical man popped a child into water as soon as it was born. He was put into an asylum, and was constantly arguing with a lawyer there.

The desire for women among insane persons, sometimes rises above all other passions; but this is, perhaps, not very common. The inmates of an asylum generally regard each other with dislike; and this prevents their combining, or no keeper would be able to controul them. Many years ago a doctor went into a ward alone, and was locked in, as was then the custom. The pot was on the fire, and the patients proposed to singe the doctor first, and then to make soup of him. He kept them in conversation about different things, and thus kept them at bay till he heard a keeper at the door. He then called out to the latter, or he would have been seriously injured. Many patients are hypochondriacal, and these should never be laughed at; for either there is organic disease somewhere, or they really feel great distress. You meet with many ladies in this state of mind. They are generally unmarried, and have long been looking for husbands without success. We are sometimes called to patients who will not eat; and to others who pretend they cannot. Dr. Campbell, of Edinburgh, had a patient of this kind, who was very fond of good living; and, though sup-

ported by the charity of friends, indulged in salmon, ducks, and other expensive articles of diet. He was one day called to attend her, and found her feasting on a duck; the whole of which she eat, and drank a bottle of porter, with some wine, complaining all the while that she could not eat! There was a gentleman who fancied himself afflicted with scirrhus-pylorus, and many other diseases, and had blistered himself all over. He said he could not eat; but would take a fancy at midnight, for a boiled chicken, and then for other things, which his cook would have to dress in the night. He would have half a dozen kinds of wine to this supper. He was irritable, that if a cinder fell out of the fire, the noise put him into a rage. Dr. Mackintosh pronounced him insane, which his friends would not believe it; but it was proved by the sequel. One day he thought he had stone in the bladder, and collected fifteen medical men to consult on his case. Dr. Kellie, of Leith, passed a sound into the bladder; found no stone; but, by means of his finger introduced into the rectum, detected enlarged prostate. The gentleman afterwards fancied he had disease of the rectum, and used to preserve the feces passed from the bowels, in eight or ten vessels; stirring and smelling them occasionally, to detect the progress made by the disease. He soon afterwards died, when the stomach was found diseased; the dura mater thickened, and numerous arteries ossified.

REVIEW.

On the Nature and Treatment of Diseases of the Heart, with some new Views on the Physiology of the Circulation. By JAMES WARDROP, M.D. to King George IV., Lecturer on Surgery, &c. &c. 8vo., London, 1837. John Churchill.

It must be obvious from our last notice of this work, that the author has not only followed the footsteps of the illustrious Harvey, but has explained many phenomena of the circulation untouched by that immortal physiologist. The truth of this assertion will appear to all acquainted with the imperishable work on the circulation, after the perusal of the succeeding extracts. Mr. Wardrop writes so graphically and logically, that it is utterly impossible to abridge his language,

and this is our apology for our long quotations from his excellent and original work. Thus we should do him and our readers injustice, unless we inserted his own words in describing what he has aptly termed, the *Musculo-cardiac function*; and we assure our readers that they will gain much instruction and valuable information from an attentive perusal of it.

"The Musculo-cardiac Function."—However difficult it may hitherto have been to explain the phenomena of the living bodies, yet, whenever we have gained a step in physiological science, we are struck with the remarkable simplicity in the means which nature employs for accomplishing what had to us appeared a most complicated function in the animal economy. In endeavouring, therefore, to explain any of those phenomena of living beings which have hitherto evaded research, it may be anticipated, that, if such inquiries be successful, they will not lead to the discovery of *new laws*, but unfold the same simplicity of means for performing those operations of the economy, which have already been disclosed by human intellect. It has been indeed justly observed, in allusion to the progress of chemical science, that it has shown 'from what a small store of primitive materials have all that we behold and wonder at been created!' And in like manner we perceive that as physiology has advanced and we have been able to explain any of the phenomena of living animals, the laws which govern them are found to be equally few and simple; so that it is by no means improbable that some such general law as that of *gravitation*, which governs the material world, will be discovered to govern and regulate all the phenomena of organized beings.

"In the arrangements of the animal economy it may be frequently observed that one organ is destined to perform several distinct functions—functions indeed so dissimilar and apparently so unconnected with one another, that it would not be anticipated they could be executed by the same physical apparatus.

"Thus, for example, the muscles of the jaw are not only employed to masticate the food, but they at the same time evacuate the salivary glands and squeeze the saliva into the mouth by the pressure they produce during their contractions on the salivary apparatus. The urinary organs of the male, moreover, are employed for the transmission of the seminal fluid, as well as to afford a passage for the urine.

And the bones not only support the body like a framework, but they afford fixed points for the origin and insertion of the various muscles, and also form walls of defence for the internal organs, as the brain and the thoracic and pelvic viscera.

"The functions of the respiratory apparatus are still more multiplied. Besides arterializing the blood, conveying odorous substances through the nasal passages of the organ of smell,—assisting the return of the venous and expelling the systemic blood,—and producing the voice; they also, as I shall subsequently endeavour to demonstrate, are employed in modifying the supply of blood to the heart. In birds we find that the functions of the respiratory apparatus are even more numerous, the air passing into membranous sacs within the chest and abdomen, as well as into their hollow bones, in order to assist their flight.

"In like manner we shall find that the *muscles*, besides being the active organs of motion, destined to perform the various movements of the body, are essential auxiliaries in the circulation of the blood, in the arteries as well as in the veins, performing these offices merely by the pressures which they produce during their contractions on the adjacent vessels.

"A general view of the means by which the circulation of the blood is carried on throughout the animal creation, as well as the phenomena of diseases, points out the errors of those physiologists who have endeavoured to explain the *systemic* circulation by the action of the heart alone. The momentary flushings of the cheek, and the diseased changes in the cutaneous *capillaries* of a common pustule might surely have been deemed sufficient to show that those vessels are endowed with powers and perform functions in the circulation which are independent of the central organ.

"The fact that the circulation of the blood is carried on in some of the lower animals, as in worms and in insects, without a heart, and only by the most incessant motions of their bodies, might have indicated that muscular contractions have at least *some* influence on the circulation of the blood in the arteries as well as in the veins.

"So important indeed is the influence which the muscular movements have on the circulation of the systematic blood, that in various tribes of animals, the heart is found developed more and more perfectly in proportion as the body is less exposed to motion. Whilst, therefore,

the restless *insect* requires no heart to impel its blood, the *shell-fish*, fixed and mot onless on its rock, is provided with a central organ or heart, to carry on the circulation. In man the duty required of the heart must therefore vary with his bodily pursuits, the sedentary habits of some causing this organ to derive little or no assistance from those of locomotion, whilst the active occupation of others will materially aid the circulation of the blood.

"When the respiratory apparatus is healthy, and the circulation through the right heart undisturbed, the pulmonary veins afford a sufficient supply of arterialised blood to the left heart for the ordinary purposes of the systemic circulation. During sleep this must be strictly true, but when the heart is suddenly required to act with unusual vigour, a circumstance which is constantly taking place whilst we are awake, an increased supply of blood then becomes necessary, the energy of the heart depending on the quantity of blood with which it is supplied. This important office we shall find is fulfilled, not only by *accelerating* the flow of the venous blood into the right heart, but, as I shall endeavour to show, also by *impeding* the exit of the arterial blood from the left heart, and both these purposes are admirably effected simply by the change of form which the muscles undergo during their contractions.

That the velocity of the circulation in the veins of the extremities is accelerated by the contraction of the muscles of the limbs, and consequently that muscular exertions assist in propelling the venous blood towards the right heart, is a fact long since pointed out and generally admitted by physiologists. It was consi- by HALLER, and has never been contradicted by subsequent writers,—as alone sufficient to explain both the increase in the heart's action and the frequency of respiration which follow muscular exertions.

But whilst the pressure caused by muscles during their contraction propels the blood onwards in the contiguous veins, it seems never to have been contemplated what must be the effect of that compression on the adjacent arteries, although these vessels are doubtless alike exposed to its influence. It will however be shown that the effect of muscular contractions both on arteries adjacent to, as well as on those imbedded in, the substance of muscles, must be to compress these vessels, by which compression the flow of blood through them will be necessarily impeded,

—hence, the contraction of muscles will increase the accumulation of blood within the heart in two ways,—by *accelerating* the flow of the venous blood to the right heart, and by *impeding* the transit of the arterial blood from the left heart.

Mr. Hyslop having bled a lady to syncope, became alarmed at its long continuance, and on accidentally raising her from a horizontal position by grasping her arms and supporting by them the weight of the body, she rapidly recovered. Surprised at this, more particularly as the change from the horizontal to the erect posture might have been expected to have had an opposite effect, Mr. H. was led to reflect what could be the cause of so sudden a restoration of the heart's action, and he became convinced that whilst elevating the body and allowing its weight to be supported on that part of the arms along which the brachial arteries pass, he must have compressed those vessels, the effect of which compression was an impediment to the flow of blood through these arteries, and consequently an increase in the quantity of blood in the heart. He thence concluded that the rapid recovery of this patient from syncope was analogous to the artificial process of transfusing blood. Subsequent experiments enabled him to prove the accuracy of his observations. He found that by the application of a tourniquet on the brachial artery he could increase the heart's action about ten pulsations in five minutes; an ingenious mode which he proposed to adopt in cases of syncope or apparent drowning in order to revive the heart.

"This interesting observation, as I shall endeavour to show, leads not only to a satisfactory explanation of some phenomena of the circulation, but in particular it explains how the quantity of arterial blood, and, consequently, the vigour of the heart's action, are increased by muscular exertions.

"The effect of muscular contractions in compressing arteries and consequently in impeding the circulation of the blood through them, may be demonstrated by experiment as well as by an examination of various phenomena.

"If the radial artery of a person who is powerfully contracting the muscles of the arm be examined, its pulsations are soon found to become feeble, and, at last, they are scarcely perceptible; whilst the moment the muscles are relaxed the artery is perceived to beat with its natural force. By the same experiment it may also be shown, that the effect of impeding the

transit of the blood in the arteries is to increase the action of the heart, it being found that in proportion as the strength of the pulsations of the radial artery diminishes, so is the impulse of the heart increased.

“Next let us consider the position of arteries in their relation to the muscles and learn the mechanism which enables the muscles, on contracting, to compress the contiguous blood-vessels in such a manner as to *impede* the systemic circulation.

For performing this important function, and which I have denominated the *musculo-cardiac function*, we perceive several simple and beautiful contrivances; whilst we also find a striking illustration of this peculiar office of the muscular system in the mechanism which nature has adopted in order to *prevent* the compression of some arteries, when such compression would be injurious to the proper performance of the functions of those organs which such arteries supply. For although it appears that it is not requisite that some organs should be at all times supplied with an equal quantity of blood, there are others wherein any alteration in the supply of blood, would be prejudicial, or even fatal, to the great functions of life; and hence whenever the heart requires an additional quantity of blood, that office is fulfilled by impeding the flow of the arterial blood through the arteries of those organs only which do not at all times require a uniform supply of the sanguineous fluid.

“In accordance with these positions, we find that the arteries of all organs of the first denominations are so placed that they must inevitably be more or less compressed by the contractions of the adjacent muscles; whilst the arteries of the other class of organs are so situated, that they are protected from all pressure from the movements of the muscles contiguous to them.

“For a demonstration of the first of these conditions, we must look at the arteries of the limbs, while those of the brain, heart, stomach, and iris, each exemplify particular contrivances, by means of which the quantity of blood in these organs is not subject to any variations from muscular movements.

“There are, indeed, several points, in the anatomy both of the muscles and of the arteries, which seem to be specially subservient to the musculo-cardiac function. Arteries accompany the veins where it is intended that *both* these systems of

vessels shall be influenced by muscular contractions: yet, long as the period has been that the relative position of the blood-vessels and muscles of the limbs has been pointed out, no rational explanation of the utility of such an arrangement has been given. It is, however, evident, according to the preceding views, that by such a disposition of the two systems of vessels, the velocity of the blood is equally influenced in the veins and in the arteries whenever the adjacent muscles are contracted;—that whilst muscular contractions assist in propelling the blood in the veins forwards to the right heart the valves preventing its regurgitation, the same pressure impedes the current in the contiguous arteries, and thus diminishes the exit of blood from the left heart.

“Here, then, we have an anatomical fact, affording additional proof of the simplicity and wisdom which nature displays in all her works, employing one organ to perform at the same time more than one function,—veins and arteries accompanying each other in those situations where it is intended that the circulation of the blood, both venous and arterial, shall be influenced by the contractions of muscles; at the same time those vessels which are *not* liable to compression from muscular contractions are not similarly disposed, either with relation to the muscles or to each other;—thus in the internal viscera, such as in the brain, lungs, and liver, the veins do not accompany the arteries.

“Besides this ingenious contrivance to enable the muscles to assist in accelerating the return of the venous blood to the right heart, and to impede the exit of the arterial blood from the left heart, we find that the relative position of the blood-vessels and muscles to one another is such, that whenever muscles are thrown into action they necessarily cause the adjacent blood-vessels to be more or less compressed, the heart, under such circumstances, requiring additional vigour.

“No arrangement could be better adapted for such compression than the course which is allotted to the femoral and brachial arteries, these being in some places completely encircled and embedded in the large muscles of the extremities, so that on every movement of the limbs they must suffer compression, and the current of the systematic blood be therefore more or less impeded.

“Whilst it is interesting to examine Nature's contrivances in order to *impede* the flow of blood through the arteries, when she requires to increase the quantity

of the sanguineous fluid in the heart, it is no less instructive to observe the means which are employed to *prevent* muscles from compressing the arteries and veins of certain organs any interruption in the supply of blood to which would be injurious.

"In those arrangements where such compression from the muscles is to be avoided, we either find circles of *anastomosis* established between different arterial trunks, or the vessels are so placed that they are completely protected all that pressure which would be produced by the contractions of the adjacent muscles.

"Of the first of these provisions we have examples in the coronary arteries of the stomach and lips, and in the circles of anastomosis of the arteries of the iris,—the effect of all which free inosculation is obviously to render any obstruction in the arterial circulation in these organs impossible, a circumstance which would be constantly taking place from their unceasing movements, had not such anastomosis been established.

"The other provision is expliſied in the heart and in the brain. In order to prevent any interruption to the circulation in the vessels of the heart, there is not only a free anastomosis between both coronary arteries, but also a peculiarity of structure to which I have alluded,—those vessels passing along a tendinous furrow or groove between the auricles and ventricles in such a manner that, during the unceasing contractions and relaxations of these cavities, the circulation of the blood, neither through the veins nor arteries, can be in any way interrupted.

"And again, if we look at the brain, we observe that its vessels are also protected from all muscular compression, independent of having a free anastomosis established between them. The vertebral arteries pass along a bony canal, where they are so protected that the current of the blood in them can never, like that in the carotids, be interrupted by the contractions of the muscles of the neck during the very frequent and varied positions of the head; whilst the anastomosis established between the carotids and vertebral arteries secures a constant supply of blood in all the arterial ramifications within the head.

"The mode of securing that regular supply of blood to the brain, as well as to the substance of the heart, indispensable for the due performances of their functions, is indeed a striking example of the consummate skill and simplicity al-

ways evolved whenever we succeed in unfolding Nature's works. The passage of the two vertebral arteries in such a situation as not to be susceptible of compression by the contractions of the cervical muscles enables those vessels under all circumstances to supply the brain with an uninterrupted stream of blood, whilst any irregularities in the supply of blood to the branches of the internal carotid arteries are also amply provided against by the free communication of these vessels with the two vertebral arteries by means of the basilar artery,—so that by this simple mechanism the branches of the carotids are as well supplied with blood as those of the vertebral arteries.

"If such a distribution of the arteries of the brain did not exist, and if the vertebral arteries, like the carotids, were constantly exposed to compression from the contractions of the muscles of the neck, and from alterations in the position of the head, or if there were no free communication between the vertebrals and carotids, then the quantity of arterial blood within the head would be exposed to constant variations, and the functions of the brain would be liable to incessant disturbance,—accidents which the mechanism I have now described is, however, ingeniously calculated to avert.

"But an equal and uninterrupted return of the *venous* blood from the head is of no less importance in the due performance of the brain's functions than a regular supply of *arterial* blood; hence the importance of that peculiar structure,—the unyielding parietes of the veins or sinuses, for warding off the effects of that very compression which is provided in some other veins for the purpose of *accelerating* the return of the venous blood.

"The circumstance of the cerebral arteries being distributed and protected in such a manner as always to ensure a regular supply of blood to the brain may, perhaps, along with the peculiar structure of the veins, be considered as the cause of this organ suffering more than most others when the heart is diseased, a circumstance which I shall subsequently have occasion fully to explain.

"From what has been said, it is evident that, except in a few organs, the supply of blood must be more or less irregular, their varied functions not requiring the same nicety in the regulation of their supply, and when, the heart's action is disturbed, any temporary irregularity in the distribution of the blood to these organs is not therefore injurious. With the

brain, however, it is essentially different; and the mechanism by which the sensorium is provided with a regular supply of blood becomes, as I have already remarked, the very means of rendering it more liable to derangement whenever the function of the heart is disturbed. On such grounds I shall endeavour to account for the unnatural sounds, false images, vertigo, inability to balance the body, and various disturbances in the cerebral functions, which so frequently, nay, almost invariably, accompany diseases of the heart.

"The effects which I have described of the contractions of the muscles of the extremities in compressing the brachial and femoral arteries will suffice to point out what is here requisite to be noticed as regards the influence of the *voluntary* muscles in increasing the vigour of the heart; but we also find that the *involuntary* muscles perform an equally important share in modifying the circulation of the blood.

"I have already shown that the arteries which supply the heart, and likewise those of the stomach, lips, and iris, are each so situated that the circulation in them can never be interrupted by the movements of these organs. Neither are the arteries of the brain nor those of the lungs, subject to pressure from the contractions of the voluntary or the involuntary muscles, the anastomosis and the protection which is afforded to the cerebral arteries warding off the influence of any movements of the neck; and the pulmonary vessels are affected only indirectly by the movements of the parietes of the chest.

"But when we examine the alimentary canal, we there find an illustration of the function performed by the contraction of the *involuntary* muscles on the blood's circulation. The vermicular motions of the stomach and intestines during the process of digestion must doubtless have a very considerable influence on the circulation of the blood, both in the veins and in the arteries of these organs, and hence, during the movements of the alimentary canal, we observe an increase in the impulse of the heart, indicated by an increase in the frequency of the pulse. In this respect, the circulation of the blood in the intestinal canal in part resembles that which exists in *norma*, the almost unceasing movements of these animals being sufficient, as I have before noticed, to circulate their blood, unaided by a heart.

"In the next place I shall proceed to

show, that the Musculo-Cardiac function enables us to explain many important phenomena which are constantly occurring in the living body, and which could never have been explained, until a knowledge of this function of the muscles had been discovered.

"Some muscular movement will be observed to precede every effort which we make to increase the action of particular organs, because, for such a purpose, it is first inquired that the vigour of the heart shall be increased. Hence we find that, unless when the body is in a state of perfect tranquillity, which can scarcely ever happen but during sleep, the circulation of the blood throughout the system is constantly varying, any muscular movement, however slight, increasing the influx of the venous blood, and at the same time impeding the reflux of the arterial blood. Thus in some organs the quantity of blood is diminished, and in others increased, by every motion of the body, those which are called upon to perform particular functions receiving an increase, whilst other organs whose office less urgent, experience a diminution in the supply of the sanguineous fluid.

"It is, indeed, interesting to contemplate the contrivances which are employed in or to fulfil this office in the various organs, and observe the injurious effects which result from deviations in the due execution of this function of the circulating apparatus. No more satisfactory illustration can be indeed given of the office of the muscles in modifying the circulation of the blood, or of the Musculo-Cardiac function, than by glancing over the development of those phenomena which may be observed in a living being, at the moment of awaking from sleep, and by reviewing the various functions successively as they are evolved.

"The first indication of a person passing from sleep into a state of watchfulness, is *some movement of the body*. He changes the posture in which he has been slumbering; the limbs begin to move, and, almost at the same moment, and just when he is becoming conscious of existence, the muscles of the extremities are thrown into contraction; he stretches the limbs and yawns, and, finally, the intellectual powers awake!

"These phenomena are so uniform, though they may vary in degree, and so universal throughout the animal creation, that it would be unphilosophical to suppose that they were not a link of some chain, which, however inexplicable, could

not reasonably be supposed to be the result of chance, or the effect of habit.

"All these muscular movements can, indeed, be satisfactorily explained by contemplating the effects on the circulation, which as I have endeavoured to demonstrate, are produced by muscular contractions.

"The almost instantaneous effect of a person stretching the limbs whilst awaking from sleep, is that of rousing the powers of the mind, and this arises from an accumulation of blood in the heart, which such motions necessarily create, and which, by increasing its action, enables it to propel an additional quantity to the head.

"Scarcely has a man awoke, and the brain received this additional quantity of blood, ere the mental powers are resuscitated, and having been refreshed by "balmy sleep," they almost immediately resumed their wonted vigour!

"The powers of the mind having revived, man is now befitted for his varied avocations, in the execution of which the Musculo-Cardiac function continues to perform an important share.

"Observe how the strength and vigour of the body is increased when we require to make any great exertion! In order to produce a temporary increase in the heart's action, I have already remarked that it is requisite to give to that organ an additional stimulus. This is at once effected by throwing into action such muscles as shall, by their newly acquired forms, compress the contiguous arteries, and thus impede the transit of the arterial blood.

"If, by way of illustration, a man be about to make a great exertion, such as running or leaping, he prepares himself, as it were, by first vigorously contracting the muscles of the arms and clenching his hands. For the same reason, when a person is subjected to pain, as that of a surgical operation, he prepares himself to endure it by throwing into action almost all the voluntary muscles, grasping firmly with his hands, and pressing the feet against some resisting body. And when the female, during parturition, is about to make a powerful expulsive effort to assist the uterus in giving birth to the infant, she in like manner, throws into violent and long continued contractions the muscles of the extremities, clenches the jaws, and squeezes with a convulsive effort whatever may be within her reach.

"Muscular exertions are also employed to effect a similar purpose in those who, from diseases in the urinary passages or

rectum, have great difficulty in voiding their contents; so that, before endeavouring to accomplish such evacuations, they forcibly contract some of the voluntary muscles,—muscles whose actions are totally unconnected with those which are employed to perform the evacuations.

"No less remarkable is the influence of this function of the muscular system on a person who is recovering from a state of *syncope*. Having passed into a condition where the last spark of life had been apparently extinguished, the first symptoms of recovery from fainting are ushered in by a series of convulsive movements of the voluntary muscles. Long protracted inspirations are succeeded by powerful expirations; the limbs are convulsed, and soon afterwards the intellectual powers are resuscitated.

"The influence of muscular contractions in increasing the vigour of the heart also explains, in a very satisfactory manner, the salutary effects which children derive from their almost constant movements, and the benefits which arise from all kinds of bodily exercise. How a person, when he feels sluggish and inert after mental fatigue, or from want of sufficient bodily excitement, is revived and invigorated by walking; it also accounts for the exhilarating influence of dancing, or driving rapidly in a carriage, and fully explains the "intoxicating effects" which, according to the poet, the Arab experiences while galloping across the boundless desert!

"On the Orator this influence of muscular movements is no less striking. His gestures keep pace with his mental excitement, and the gesticulations become more and more extravagant in proportion as he becomes impassioned; the heart thus acquiring an increase in the quantity of its blood, and, consequently, the brain receiving a proportionate increased supply.

"All these phenomena can be explained now that we comprehend how muscles during their contraction increase the quantity of arterial blood in the heart; and it is only surprising that physiologists, when endeavouring to account for the beneficial influence of various exercises, and having shown that they increase the return of the *venous* blood to the central organ of the circulation, should not have advanced a step further and considered, what must be the effect of muscular contractions on the adjacent *arteries*.

"My attention was directed to some of these phenomena and to the physical ex-

planation of them which I have now given, when attending a patient who had frequent attacks of gout, and who had been sometime before affected with an arthritic inflammation of the pericardium. After that illness he suffered from palpitations of the heart every morning just at the moment when he awoke, but they continued only a few minutes. On enquiring if he was in the habit of yawning and stretching his limbs, he then stated that he always did so whilst in the act of awaking, and that it was immediately afterwards when he felt the palpitation. He further observed, when interrogated on this point, that, if he accidentally awoke during the night and stretched himself, palpitation of the heart always ensued.

"The effect of yawning and stretching the body in disturbing a diseased heart I also observed in a person who had for many years suffered from symptoms of Hypertrophy, and who was recovering from a febrile illness, for the relief of which an antiphlogistic treatment had been pursued. When convalescent, this patient had no uneasy feelings remaining except a pain in his head, which came on every morning immediately after he awoke, but did not continue longer than ten minutes. From the circumstance of this headache occurring only after he awoke, and from his stating that he was in the habit of yawning and forcibly stretching his limbs whilst he was awaking, it appeared to me probable that the increase of blood in the irritable heart caused by those movements, produced the headache in the same manner as it had in the former instance caused *palpitation*.

"The influence of the Musculo-Cardiac Function explains how there is such a remarkable difference in the number, as well as in the strength, of the heart's pulsations when the body happens to be in the recumbent or in the erect postures,—a difference particularly striking in all invalids, and which must have led to the advice so commonly urged, of preserving bodily tranquillity in the treatment of diseases. The difference in the pulse is indeed sometimes so considerable in the different positions of the body that it is usually necessary, before being able to for a correct judgment of the state of the circulating system, to examine both the heart and pulse when the patient is in the recumbent as well as when he is in the erect posture.

"If therefore the influence of muscular

contraction on the *arterial* circulation be admitted, it not only enables us to give a rational explanation of many phenomena which take place in the healthy state of the body, but it opens a most important field for the researches of pathologists. It explains the hurtful effects of severe bodily exertions in over exciting the heart. It explains also the beneficial influence of bodily tranquillity in all those ailments wherein the circulation is hurried or disturbed. It accounts for the great frequency of some diseases of the heart in two very opposite classes of persons,—in those whose avocations expose them to violent muscular efforts, and in those whose organs of circulation, in consequence of taking little exercise, obtain little or no assistance from the musculo-cardiac function.

"The various involuntary movements which occur in some diseases, such as those during convulsive, epileptic, and hysterical fits,—the permanent muscular contractions in those afflicted with trismus, and the temporary movements in chorea, must all have a greater or less influence on the action of the heart, and can only be explained by a reference to the musculo-cardiac function.

"In like manner we can account for those differences so remarkable in the vascular system of the two sexes. As the circulation of the blood in the female, in consequence of her inactive habits, derives little assistance from muscular contractions, the arteries consequently become more lax and capacious than those in the male; whilst the veins of the male are proportionably much larger than those of the female, the venous circulation being greatly influenced by all those muscular exertions to which men are so much exposed. In proof of these differences in the vascular system of the two sexes, it is only necessary to compare the distended and tortuous veins of an artisan with the delicacy and beauty of the surface of the female.

"Before concluding this part of the subject, I may notice, as a further proof of the effect of muscles compressing arteries during their contractions, an ingenious mechanism in some animals, which is calculated to guard against compression where such pressure would be injurious. In those of the feline tribe, and which use their paws not only for climbing, but for grasping their prey, in order to prevent the pressure which is unavoidably made on the limbs from impeding the flow of blood through the brachial arteries;

vessels pass through a bony canal formed in the humerus at that part where they would be most liable to compression, and thus the circulation of the blood goes on without interruption, though these animals continue even many hours, firmly grasping their prey. In the lion also a provision is found in the distribution of the arteries of the head so that the muscles of the jaw can be kept for a long time in a state of powerful contraction without the circulation being interrupted.

"For a like purpose a peculiarity is found in the trajet of the aorta in some fishes. After having supplied the abdominal viscera that vessel in the shark passes along a channel formed by the bony processes of the vertebrae, so that the circulation can never be disturbed in the powerfully muscular tail, during any of its movements.

"Here, then, as well as in the brain and heart, is an example of arteries passing along a course by which they are protected from muscular pressure, whilst we have found other vessels so placed that they are subjected to muscular compression in order to fulfil a very important function in the animal economy."

Mr. Wardrop next describes the respiratory organs and the "Pulmo-Cardiac Function," as well as all the phenomena connected with the respiratory organs and heart. Here our readers will find much information. The extracts which we have given afford complete evidence of the value of this work. It will greatly add to the justly earned fame of its author as a pathologist and physiologist. It is one of the most valuable productions of modern times.

The London Medical

AND

Surgical Journal.

Saturday, September 30th, 1837.

HINTS TO MEDICAL STUDENTS.

THE METROPOLITAN MEDICAL SCHOOLS.

AT this time, when the lads are fast arriving "green and fresh from the country," to use the language of an eloquent contemporary, we cannot better employ the

pages of this journal than in offering our young friends a few hints which may serve to guide and protect them against the snares which they will find laid for them in every direction. There is no trade in this metropolis which is carried on with more *spirit* than medical education, and the great competition which exists amongst the different medical schools, whilst it has induced some to bestow more pains and qualify themselves better for the task of teaching, others, and these by far the majority of the teachers, have resorted to a variety of arts and stratagems to extort money from the student, making a number of promises which they neither can or ever intend to perform, and giving a false and deceitful account of advantages which their schools do not possess.

First of all, let us warn the unsuspecting youth of the arts and stratagems which different schools have unblushingly adopted, in order to make it appear to the student that their commodities are to be had at the *cheapest* rate. The Joint Stock Company of Gower Street, are fully justified in claiming the privilege of being foremost in the rank of impostors, for they had the ingenuity in preparing their "bill of fare" of last session, to fix a low price for their hospital, and make up the *deficiency* by so mystifying the other items of their "account current," that it was absolutely the most expensive school in London.

As another illustration of the same system of imposture, we need only pay a visit to their next-door neighbours, the modern Sydenhamian Professors, who, in the hope of seducing some of the "customers" of the Gower Street Company, have been mean enough to offer, as a bribe, that they would generously deduct that integral part of the North London Hospital fee, which the *liberal* junta of

the University College have had the long-sightedness and consummate wisdom to impose on those students whom they could not induce to attend their lectures, but who merely wished to fee their *cheap* hospital for the purpose of getting their diplomas.

King's College, it is but justice to say, has ever been consistent in the quality of the "goods" which it has offered to the student since its establishment. Founded on the true principles of ULTRA-TORYISM, it had great difficulties to contend with, one professor succeeding another in such rapid succession, as to bear unequivocal testimony of the difficulty of their labours; it would be, however, ungenerous not to state, that there is no article in their "bill of fare" which bears the character of an imposition; neither is there any article offered at a cheaper price than their brother-tradesmen of the exclusive order, unless the attendance at chapel, which the student may have three times a day, without any additional fee or remuneration.

The Borough Hospitals require great circumspection from the inexperienced student. The name of Sir Astley, once of itself a tower of strength, is still artfully introduced into the "bill of fare" of Guy's Hospital; but the student must not expect to derive a great fund of practical knowledge from the clinical observations of the "Consulting Surgeon," as his visits seldom exceed one or two per annum. The name of the "Surgical Leviathan" is therefore ingeniously introduced into the prospectus of Guy's School, for the purpose of entrapping any of those unfortunate young men who are not aware of the *intimate* union of the worthy baronet with the hospital.

The School of St. Bartholomew's "is not backward in coming forward," in competing with its adversaries in "thim-

ble rig" performances; and the student must take care not be cajoled and *battered over* by certain teachers in this establishment. As we observed regarding Guy's Hospital, the teachers have inserted in their "bill of fare" the name of a distinguished individual as one of their lecturers, but who merely gives a very few lectures sufficient to prevent the professors, as a body, being guilty of a gross fraud—we allude to Mr. Brande.

The ILLUMINATI of St. George's, having formed themselves into two divisions, have found themselves in so many difficulties, and the school in such jeopardy, as only to have contrived as yet one clap-trap for the lads, green, raw, and fresh from the country. Sir Benjamin having proffered his services to deliver an occasional "Clinical Improvisatore," upon terms which will receive universal approbation—terms very inadequate to the merits of the orator!

The Westminster School, though last not least, but little merits the vigilance of the youthful student in medicine, for besides contemplating the *lowering* system of the hospital fees to *their own students*, in strict imitation of the praise-worthy and *liberal* conduct of their northern contemporaries in Gower-street, Mr. Guthrie has, with the same laudable spirit, also imitated Sir Benjamin, and promises the "innocent youth" twenty intellectual repasts, suitable to the most fastidious palates, and on the same liberal terms as those of the eminent and distinguished clinical professor of St. George's.

There is one other institution, though insignificant and contemptible in itself, yet ought to be pointed out to the student as one of unusual audacity—we allude to the CHARING CROSS HOSPITAL SCHOOL. The undaunted staff of that hospital having again failed to procure a recognition from the Royal College of Surgeons,

now hold out as an inducement to the ignorant and unwary, that those entering their school shall have a *free* admission to their wards of that hospital, the infamous history of which will long be remembered by the profession.

The *reputation* of the Middlesex School is so well established, that we are not aware that they have thought it expedient to have recourse to any of those base resources so prominent in the prospectuses of most of the other schools; and though the "funds" suffered severely the last two sessions, by an unprecedented diminution in the number of "young gentlemen," who "walked their wards," in consequence of the North London Company reducing their fee to "half price;" it is now probable that the "Middlesex sufferers" will this year be, to a certain extent, reimbursed, as the fee they require is almost the same as that which the Gower-street extortioners now crave from those who will not condescend to attend their soporific discourses. Though the student may not have here an opportunity of being a witness to all the quackery of ANIMAL MAGNETISM and KREOSOTE, he will have the superior advantage of attending a large and comparatively well-regulated institution, and wherein, with all its imperfections and mal-practices, he will have an opportunity of seeing the practice of several different individuals, from which more useful lessons may be derived than from "experimental inquiries" and sanguinary exhibitions!

In offering these hints to the inexperienced, we are quite aware that a very different version of some of the nefarious practices to which we alluded will be given by an "independent" hireling, and by those who are bound, both by principle and duty, to countenance and support the old and antiquated system of medical education.

TRIBUTE TO THE MEMORY OF THE LATE DR. UWINS.

THE first meeting of the Medical Society of London was held on Monday last, at which the members were chiefly occupied in conversation respecting the late Dr. Uwins, and came to the determination to place on the records of the society the high opinion they entertained of the character and attainments of their late worthy Fellow.

ANNIVERSARY DINNER OF THE BRITISH MEDICAL ASSOCIATION.

It will give much satisfaction to those who, like ourselves, are deeply interested in the rapid progress which has been making in the Association, to see that their Anniversary Dinner is fixed for this day, the 30th instant.

THE WORKING OF THE ANATOMY BILL.

THE London Inspector of Anatomy, and his secretaries, have removed his offices from No. 5. Saville-row, to No. 5, Upper Bedford Place, Russell Square. This change has become imperative, from the great mass of students congregating in that district of the metropolis, in consequence of the advantages held out by the North London School of Medicine, Sydenham College, and the Middlesex and North London Hospitals.

EFFICACY OF ERGOTA IN EXCITING UTERINE ACTION AND ARRESTING HÆMORRHAGE—ARREST OF FLOODING BY EXTERNAL COMPRESS'ON OF THE AORTA.

To the Editors of the Medical and Surgical Journal.

Gentlemen,—Having observed in your Journal of the 16th instant, some remarks on the beneficial effects of *Secale Cornutum*, or as it is now termed, "*Acinula Clavis*;" also in the *Lancet* of the 9th instant, some observations, attributed to Professor A. T. Thompson, of which the following is a short extract:—"I need not inform you that the ergot is now much used in promoting the actions of the uterus in parturition; and as it has been erroneously supposed to operate in causing uterine action, it has been employed in every period of pregnancy to produce criminal abortion, and has caused poisonous symptoms, in these cases, of the most alarming kind, which, in some instances have terminated fatally. In a case to which I was called, where the object was to expel a blighted fœtus, fever was induced, with flushed face, a rending sensation of the head, and the other symptoms which I have described as characterizing its poisonous influence."

I have to remark that, I have administered, and seen the medicine given, in, I may say, some hundreds of cases, and where it had been retained on the stomach I have always seen its exhibition followed promptly by increased uterine action, and never, in any case, have I observed any unpleasant symptoms result from its administration; indeed, so well known where its beneficial effects, by the nurses and patients themselves, in that part of the country where I had the opportunity of seeing it used, that, when called to a case which happened to be at all tedious, the patient herself used to request "*some medicine out of the little bottle*," to use her own words, and felt disappointed if the request could not be complied with, in consequence of the presence of any indications unfavourable to its administration.

When given in the form of powder, it has been often found inert, owing to the evaporation of its active principle, from being kept perhaps for some considerable time in this state, and thus offering a large

surface to the action of the atmosphere, or when administered in the form of powder, from its bulk, being likely to be rejected by the stomach.

I gave it in the form of tincture, after the following formula:—

R.—*Secalis contusi*, ʒi.
Aque bullientis, lbiss.
Coque ad dimidium, cola et adde.
Tincture lavendulæ compositæ, ʒi.
ʒiss. contains nearly a ʒi. of secale.

When called to a case in the country, I generally took with me ʒiss. of the tincture, or decoction, whichever you wish to name it, and if indications favourable to its administration were present, I gave half this quantity in a little warm drink, and the remaining portion in a quarter of an hour's time, if necessary; indeed, I seldom found it requisite to give more than the first dose.

This preparation possesses several advantages over the powder.

1st. Its activity may always be relied upon.

2ndly. It is not so likely to be rejected by vomiting as the powder, for you will find very few stomachs able to bear ʒi. of secale, suspended in ʒvj. of tepid water, the dose administered by your correspondent Mr. Wardleworth.

3dly. The dose of the medicine may be administered in a more concentrated form, and

4thly. It is always ready. The surgeon need not be detained from his patient an instant; whereas, if you use the powder, which should be prepared only when wanted, it takes some considerable time to pulverize it finely, or if you prefer the decoctions commonly in use, you must have recourse to the dignified process of cooking and messing the affair in a saucepan borrowed from the kitchen, and, in many cases, particularly in the humbler walks of life, under the eyes of your patient.

I extract from my note book and send you one or two cases, in which it had been useful in arresting or preventing *after hæmorrhage*.

Yours, obediently,
W. ROSE.

I was summoned to attend Mrs. B., of Stone-street, Maidstone, on the evening of the 10th of August, 1834, in labour of her fifth child; the pains were strong, propulsive, and frequent; the os uteri fully dilated, and the presentation natural; the membranes soon ruptured, and in about twenty minutes after arrival she

was delivered of a healthy male infant. Having detached the infant, and applied a roller tightly round the abdomen, I passed my hand over the hypogastrium, and found the uterus contracted firmly; the placenta was then removed from the vagina.

Immediately after I observed her face become completely blanched, she threw her arms violently about, and seemed gasping for breath; blood was gushing from her in torrents. I instantly made firm pressure on the abdominal aorta* against the lumbar vertebrae, with my left hand, and succeeded in arresting the hæmorrhage. I then had recourse to the other means usually adopted in these cases, viz., throwing open the doors and windows, the application of cold waters to the parts, and exercised pressure on the uterus with the right hand. This organ was now quite relaxed, and felt almost as large as before the birth of the child; the pulse was scarcely perceptible at the wrist. My efforts failing in re-establishing the contraction of the uterus, the usual dose of the tincture of *secale* was administered in a little hot brandy and

water; the pulse being still scarcely perceptible, more than half a pint of pure brandy was given, in small and frequently repeated doses; in about a quarter of an hour she had a second dose of *secale*, and after the lapse of a few minutes the uterus was again firmly contracted. I was only now able to remove my pressure from the aorta. She was not able to leave her bed for a fortnight, and recovered slowly.

She afterwards informed me that all her previous labours were attended with hæmorrhage, in one or two instances to a very alarming extent, and that her life was saved with much difficulty.

The idea occurred to me that, if I should be called upon to attend this woman in any future confinement, taking into consideration the regular recurrence of hæmorrhage, a dose of *secale* administered before the completion of the second stage of labour (even though the action of the uterus should still be as powerful as in the present labour) would be likely to succeed in preventing hæmorrhage altogether, which was always to her a source of very great alarm, so much so, that whenever she found herself *enchein*, from that time to her delivery she indulged a good deal in melancholy forebodings.

She was so much terrified by these repeated attacks, that she vowed "*never more to have a child*;" however, by some *unaccountable accident or other*, "this her vestal vow took wing," and she again became pregnant during my absence in India. She was attended by my friend Mr. Sedgwick, of Maidstone, one of the most experienced obstetricians in that part of the country, who has since informed me that, approving of the suggestion alluded to above, he had given her a dose of the tincture of *secale* immediately before the birth of the child, although the pains were strong and frequent. She was safely delivered of a healthy female infant, the placenta was thrown off immediately after, and the uterus contracted firmly and permanently. She did not lose a table-spoonful of blood, much to her surprise and satisfaction. She was out of bed in a few days, and able to resume her usual domestic occupations, without the occurrence of a single unpleasant symptom.

SECOND CASE.

On the 20th of July, 1834, I was called upon to attend Mrs. B. of the West Borough, Maidstone, a strong healthy woman, mother of several children. On examination the os uteri was fully dilated,

* This, I am convinced, is the speediest and most effectual method of arresting uterine hæmorrhage. The abdominal aorta can be compressed against the last lumbar vertebrae with great ease and facility, by the left hand of the obstetrician, leaving his right hand free to make pressure over the region of the uterus, or to adopt any other sort of manipulation he may think proper.

Making pressure on the aorta is attended with several advantages:—

1st. It speedily arrests the hæmorrhage.

2nd. It gives time to induce the contraction of the uterus, either by the administration of *secale*, or any other means you choose to adopt.

3rd. It is very often effectual in arresting, or altogether preventing, those frightful fainting fits, generally attendant on hæmorrhage, by confining the blood within a narrower circle, and having it sent to the sensorium in greater quantity; and

4th. Pressure can be made effectually here, even by the merest tyro, in consequence of the great relaxation of the abdominal muscles and integuments.

This pressure may be adopted in syncope, arising from any cause, either in the male or female subject, with great advantage.

the presentation natural, and the pains propulsive. She had been in labour for three hours; in about twenty minutes after my arrival she was delivered of a full-sized male infant. On passing my hand over the abdomen it appeared nearly as large as before delivery, and on examining per vaginam, I found the uterus containing another infant; presentation natural; uterine action trifling. I ruptured the membranes; this rendered the uterine contractions somewhat stronger; in about fifteen minutes after I perceived blood streaming from the vagina, which I attributed to the partial detachment of the placenta belonging to the first child; a dose of secale was instantly administered; in a few moments strong uterine contractions succeeded; the second infant was born; both placentæ thrown off together, and the uterus contracted firmly and permanently without further loss of blood.

The administration of the ergot was, in my opinion, the best course which could be adopted in this case; for the introduction of the hand into the uterus, the seizing and bringing down the feet, was impracticable, owing to the contractions of the viscus, without having recourse to an unwarrantable degree of violence; and although the discharge of blood was not very alarming, yet I fancy any hesitation in giving the medicine would be injudicious and culpable.

[We fully agree with Mr. Rose as to the judicious plan he pursued in both cases, and are very much surprised how any obstetrician can doubt the efficacy of the ergot. It is very much to be regretted that a public lecturer should deny the power of a medicine, which is well established by the observation of all practical obstetricians, as that of opium or any other well known remedy. The experienced obstetric practitioners will however agree with us, that the ergot, when good, does excite uterine action, relieves the woman from tedious and useless suffering, expedites parturition, arrests hæmorrhage, and saves a vast deal of time and loss of rest, both to the medical attendant and his patient. The proposal of Mr. Rose, to compress the abdominal aorta, in the cases mentioned, is, in our opinion, truly scientific and valuable, and entitles him to much credit for its recommendation.—EDS.]

HINTS FOR THE PHYSICAL MANAGEMENT OF INFANTS.

The new-born infant, while it is being washed and dressed, may have some butter and sugar, though this food is by no means necessary, and it may be applied to the breast, when there is milk, in half an hour or an hour after delivery, or, so soon as the mother has recovered from the fatigues of parturition.

The infant ought to be applied to the breast every two hours, or as often as it awakes from sleep.

Lactation or suckling generally prevents sore breasts and nipples.

A wet nurse ought to avoid spiced, salted, smoked, and oily animal substances, and also crude vegetables, pickles, unripe fruit, and spirituous or vinous liquors, unless when delicate.

Light broths, milk, whey, coffee, home-brewed ale, or porter, are the best drinks, and a pint or a pint and a half of the two last is sufficient during twenty-four hours.

Tea and coffee may be used moderately.

A wet nurse ought to attend most closely to the infant committed to her care, and avoid all crowded assemblies, balls, theatres, &c.

A hired wet nurse ought to be healthy, good-tempered, careful, fond of children, watchful at night, patient, sprightly, cheerful, active, have a good supply of milk, and a healthful infant of her own.

She ought to be treated most kindly by parents who entrust their infant to her care.

The best substitute for human milk is, that of the ass or cow, with a sixth part of tepid water, and some loaf sugar. Three table-spoonsful are sufficient for each repast for a new-born infant.

The milk should not be boiled, or repeatedly heated.

The inferior animals of the mammiferae are nourished with milk only.

The infant ought to be kept warm, clean, and changed whenever it wets or soils itself, and in such cases dried or washed, and powdered, and a clean napkin applied.

John Hunter well observed, "give children plenty of milk, plenty of sleep, and plenty of flannel."

Farinaceous aliments ought to be used sparingly at first, and mixed with milk. They are most appropriate before the time of weaning.

Ablactation or weaning may be accomplished when the infant is vigorous, after

the appearance of the milk teeth, which varies from the sixth to the twelfth month.

Weaning ought not to be attempted when the infant is delicate, teething, or labouring under any severe disease, as the breast is the best sedative for infants, even if the milk is deteriorated. It ought not to be commenced during winter.

Weaning should be commenced gradually, and not suddenly, the infant being first accustomed to ordinary food; for in the last case, it becomes fretful, peevish, and rapidly out of health.

Children have their likes and dislikes as well as adults, and ought not to be compelled to use any food which they disrelish. Light puddings, eggs, fresh fish, gravies, soups, or broths mixed with arrow-root, mealy potato, bread-crumbs; ripe fruits, such as apples, pears, oranges, strawberries, grapes, &c., the pips or seeds being removed, may be used in moderation by infants from the second to the fifth year.

Boiled or roasted meats are best for children; fried, broiled, stewed, or minced, are less proper.

The drink ought to consist of milk, milk and water, barley or common water, tea, coffee; toast and water, a small quantity of ale or porter, as half a wine-glassful; a tea-spoonful of sherry diluted with water, when the infant is delicate.

Solid animal food is improper for young children, as they do not sufficiently masticate it, and it produces irritation in the stomach and bowels. Too much food is generally given to infants, but they ought to be left to their own discretion or inclination.

The infant ought to be allowed to sleep and wake whenever it pleases. All violent rocking is injurious to the brain and to the general health.

It should be kept warm, and so placed that it cannot slip or fall out of bed.

It ought to be placed on the right side in bed, to facilitate the passage of the milk or food from the stomach into the bowels. It may also be turned on the left side, and of all positions, the back or face is the worst.

The clothing should always be suited to the season, and cold avoided. Exposure to cold and improper food, are the most prolific causes of diseases of infants.

It is computed that half mankind perish from cold before the end of the third year.

Air and exercise in the nurse's arms, or in a carriage, or on foot, are as necessary for children as for adults.

An infant is exercised by being carried in the arms, rocked in a cot or cradle, by rubbing its body or limbs at the time of dressing or stripping, by dandling, by its laughing and crying, by riding in a carriage, by crawling, walking, jumping, running, dancing, &c.

The infant finally acquires power to assume the erect position, to stand alone, walk along chairs, &c., when it ought to be carefully watched and assisted.

It ought to be placed on the carpet, with its toys about it, when it will move about to collect them.

It is now exposed to falls and injuries, which often destroy its life.

All soothing syrups ought to be prescribed by medical practitioners only, unless when these cannot be procured.

Cleanliness and bathing are essential to infants. Frequent washing with tepid water, either locally or generally, is highly beneficial. This is beneficial at all times, and indispensable in cold weather.

Cold bathing is now universally condemned for delicate or feeble children.

Exposure to the air is necessary, but hardening, as it is popularly termed, is most injurious, and often induces fatal inflammations of the respiratory organs. The clothing should *always* prevent the bad effects of the weather.

Dentition or teething is a natural process, and unaccompanied by pain when the infant is in perfect health, and properly managed as regards diet, clothing, cleanliness, sleep, air, exercise, &c.

But it is in general a painful process, as few infants are properly managed, or in good health.

Incision of the gum over a projecting tooth is highly beneficial. Other diseases, which are sympathetically excited by teething, as cough, diarrhoea, &c., are to be treated on ordinary principles.

Every healthful infant ought to be vaccinated after the sixth week, to prevent the danger and mutilations caused by small-pox, and too often death itself.

Children ought to be treated with kindness, and all corporal chastisement avoided until reason is developed. "Spare the rod and spoil the child," is now an obsolete maxim. Moral management is universally preferred by all enlightened individuals.

Severity towards children is cruel and most injudicious. When correction is necessary it should be inflicted with regret and gentleness, and never with a display of anger.

A feeling of jealousy ought never be

allowed to exist between children, there should be no marked preference.

The infantile constitution is frail, and easily injured by external agents, and hence the frequency of diseases.

The diagnosis of the complaints is difficult, as the sufferer cannot, in some cases, give any, and, in others, a proper account of the symptoms.

Literary education ought not to be commenced until the age of six or seven years; but the nature and uses of external objects should be always explained to children.

Infant schools are very superior to the old-fashioned establishments, as they combine exercise, amusement, and competition with instruction.

Much knowledge may be communicated by the representations of pictures or figures of birds, beasts, fishes, insects, herbs, trees, fruits, and mechanical inventions.

The utmost regard for truth, and abhorrence for falsehood, should be always inculcated.

An open and candid disposition ought to be applauded, and an acknowledged fault rebuked with mildness, and then forgiven.

All questions put by children ought to be clearly answered, and the nature of surrounding objects explained to them.

An affable, modest, and polite behaviour should be cultivated and applauded.

The memory and intelligence must not be too much excited, as disease of the brain and bad health may be rapidly induced.

Children who are prodigies in learning, music, and other pursuits, are generally destroyed by premature disease of the brain, water in the head, and many other complaints.

They should be taught to maintain a lively and cheerful countenance.

Attention should be paid to a correct articulation and pronunciation.

They ought to be constantly cautioned against hurting themselves with surrounding objects, and the danger, pain, and bad consequences explained to them.

The greatest judgment is required in treating the diseases of children, and medical aid ought to be procured whenever it can be obtained.

The science and practice of infantile medicine, require deep study and extensive observation.

Large volumes have been written on the subject, and a long course of lectures is necessary to comprehend it.

The delicacy, peculiarity, and sensibility of constitution, the predisposition to a vast number of diseases, the want of speech and of reason, the difficulty of detecting disease and fixing appropriate doses of medicine, render the study and knowledge of infantine medicine much more difficult than is generally imagined.

MEETING OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, AT LIVERPOOL.

WEDNESDAY, Sep. 13th.

MEDICAL SCIENCE.

Dr. Roget took the chair at eleven o'clock.

Dr. Mackintosh, of Edinburgh, then proceeded to give demonstrations and exhibit morbid preparations of *dysmenorrhœa*. He had peculiar pleasure in addressing the section. He should introduce a subject which was a great source of business to medical men generally, and to accoucheurs particularly. He had himself given up the practice, but still attended much to the subject. It was very interesting to watch progress in discovery. He believed that no man ever made a discovery in midwifery, without his mind was continually working on the point. He was following a course of observations and investigations on the *mucous membrane* of the bowels, when a friend of his went to India. His friend returned in two years, and found him still in the same stage of observations; he had been so much engaged in other things, that he had made no progress in discovery. Soon after, a friend of his came into the museum, and presented him with a preparation, saying, there is a *uterus* without a mouth for you. He examined the *uterus* at the mouth, and found a slight opening, and on squeezing it, there was a slight *mucous* discharge. It immediately occurred to his mind, could this be a case of *dysmenorrhœa*? Science had now progressed to that stage that they demanded facts; he had plenty of facts to bring before them. He began from that moment the investigation of the subject, and he had now collected a vast number of preparations in illustrations of the subject. But he had his difficulties. He had supported a dispensary which gave advice gratis to about 5000 people annu-

ally; and amongst his patients he had found a sufficient number of cases where young patients were pining away from diseased action of the *fluxus menstrualis*. And in the course of a few years, he had seen the strongest constitutions broken down. Hitherto the practice had been only, if possible, to alleviate the sufferings of the patient. When a young man, he had kept what he called a *black book*, in which he marked down all cases which he could not understand, in order that he might at some future time investigate them. He would strongly advise all young practitioners to avoid making an examination, until it was absolutely sought for by the patient. They would remember the case in this very town, where an amiable man had been persecuted, and absolutely destroyed, for making what in his (Dr. Mackintosh's) conscience, he believed to be an absolutely necessary examination. (Expressions of indignation and applause.) He then proceeded to exhibit a number of preparations, showing stricture in the *os uteri*, causing disease in the *catamenia*. Some of the specimens exhibited a false membrane absolutely formed over the *cervix* of the *uterus*. In one specimen complete obliteration of the *os uteri* had taken place, and a deposition of *mucous* matter had accumulated in the *uterus*. It appeared that Dr. Mackintosh had been highly successful in his mode of treatment, to overcome the stricture. He exhibited a Portuguese instrument, an ivory tube and piston, by means of which, leeches had been applied to the *cervix* of the *os uteri*, and which had been of great service in some cases.

Some discussion followed this communication, in which Dr. Granville, Dr. Copland, Dr. Holland, and Dr. Yelloly, took part.

Experiments on the Connexion between Nerves and Muscles. By Dr. W. Harris Madden. Communicated by Dr. Alison.

The author begins by observing that this subject has engaged the attention of physiologists to a considerable extent, but that the result of their investigations has been unsatisfactory. Drs. Whytt and Henry advocated the idea that irritability was dependent upon some influence derived from the nervous system, supported by the fact, that after death by narcotic poisons (which are allowed by all to exert their greatest influence upon the nervous system), the muscles very speedily lose their contractile power. It is affirmed

by Smith, on whose observations Cullen founded his singular hypothesis concerning the identity of the muscular and nervous fibres, that sedatives applied exclusively to a nerve destroy the irritability of the muscles to which it is distributed. And, lastly, Whytt endeavoured to show, from his experiments, that irritation of the nerves, or spinal cord, is effectual in exciting contractions, when all direct stimulation of the muscles themselves has ceased to produce any change. With a view of testing the accuracy of this opinion, he performed ten experiments upon frogs with narcotics, from which he has drawn the conclusion, that the results described by Whytt are by no means uniform; that narcotics do not, in all cases, produce any appreciable effect upon the contractile organs; that sedatives applied to nerves exclusively are absolutely inert; and that muscles exhibit distinct signs of irritability long after the nerves have lost their power of exciting them. Hence he concludes that great doubt exists with regard to the inferences which have been previously drawn, and that his experiments add strength to the doctrine of independent irritability.

A few of the experiments may be detailed:—

Experiment 1.—A frog was killed by injecting tinct. opii into its stomach and intestines. All the muscles of the body and limbs contracted vigorously upon application of the galvanic wires. One of the legs was then amputated, the sciatic nerves carefully separated from all contiguous structures, and immersed in the tincture. Six hours afterwards the muscles of the trunk and attached leg perfectly retained their contractility. The muscles of the leg whose nerve had been immersed in the opiate contracted violently when the galvanic stimulus was applied, either directly to the muscular fibres, or to the nerve and muscles, but no effect was produced when the nerve *alone* was irritated.

Experiment 3.—At fifteen minutes before ten, A.M., I introduced two drops of the essential oil of bitter almonds into the mouth of a frog; it was apparently dead in ten minutes. At twelve minutes past ten, A.M., the heart was still pulsating. At four, P.M. the heart was insensible to mechanical stimuli. At eleven, P.M., the contractility of all the muscles was quite destroyed, even galvanism being ineffectual in exciting their action. The result of this experiment, so totally at variance with all that I had previously observed,

indeed with the published observations of the majority of experimenters, astonished me not a little; and I accordingly determined upon its repetition.

Experiment 4.—At five minutes before ten, A.M., I introduced two drops of the same oil into a very large frog's mouth. In four minutes it became evidently much affected; the eyes were soon insensible; convulsive action of the abdominal muscles ensued, and at five minutes after ten it was apparently dead. The chest was opened, and the heart found acting vigorously, but much distended. 12h. 20m., muscles still pulsating; ventricle inactive. Three P.M., heart quite insensible to galvanism, but voluntary muscles readily excitable. 6h. 30m. P.M., muscles still retain their irritability. At ten next morning the muscles were still quite irritable upon direct galvanic action of their fibres, but could not be excited through their nerves. In order to make this experiment more conclusive by comparison, another frog was killed at the same time, by destroying its brain and spinal cord. After several hours the muscles contracted upon direct irritation, but not when the nerves alone were stimulated.

These experiments appear to the author to throw doubts upon the confident assertions of neurologists, that the irritability of voluntary muscles is destroyed by the remote action of powerful narcotics and sedatives.

(Concluded in our next.)

ANIMAL MAGNETISM IN LONDON IN 1837.

[The following admirable account of Animal Magnetism, which we have extracted from our able contemporary Blackwood's Magazine, will be perused with all that interest which the subject demands.—Eds.]

Our readers are, perhaps, aware that the Mesmerian controversy, after an interval of nearly forty years, has revived again with the greatest bitterness in France. A great change, certainly for the better, has taken place in the philosophy of animal magnetism. Instead of being brought forward as something altogether supernatural, and setting all reasoning and experience at defiance, it now comes before us as a science founded upon natural laws; gathering round it new proofs the more closely it is examined,

and substantiating its claim to be the greatest blessing ever vouchsafed to mankind. In Paris the advocates of the doctrine were so numerous and so distinguished in their profession, that it was impossible to pass over its claims in silence. Men of science and literature—surgeons and physicians of the highest eminence—declared that animal magnetism was not the dream of a madman, as it had formerly been considered, nor the trick of an impostor. They professed a belief in its virtues, and introduced it into their practice. On this the medical section of the French Royal Academy of Sciences thought it necessary to interfere, and appointed a committee, under the presidency of Bourdois de la Motte, to make enquiries on the subject, and report to them the result of their labours. This duty was entrusted to men of the most unprejudiced opinions—some of them had given a cursory attention to the claims advanced by the magnetizers, and considered them unfounded;—others had been impressed with two great a contempt for any thing so wild and startling, on its first announcement, to consider it seriously at all,—and not one member of the committee had compromised himself by having written or spoken one syllable in support of the new doctrine. Another thing which weighed with them, and with most of the thinking men in Europe, was the decided reports against the system of Mesmer delivered to the Academy of Sciences and the Society of Physicians in the year 1784. From their decisions there appeared to be no appeal, or at least, most people considered themselves justified in making no farther inquiry after the researches of such men as Benjamin Franklin, Le Roi, Bailly, De Bori, and Lavoisier. Many circumstances, however, were advanced in explanation of this verdict. Some of the committee are alleged to have been unwell, and not to have attended the meetings; and all were prejudiced, from the beginning, against the introducer of the novel system. Mesmer undoubtedly gave great ground for his suspicions. His accessories—such as darkened rooms and hidden music—looked more like the aids of a travelling conjuror than the accompaniments of a true science; and the boldness with which his discoveries were promulgated, as also the pecuniary success with which they were rewarded, armed against him the pride and the personal interests of the professional gentlemen by whom he was to be judged. The committee of 1831

resolved to keep themselves as much as possible unbiassed by the assertions of the contending parties, and to examine into the subject for themselves. The result of their labours, long and and patiently pursued, and of their experiments, to which it seems impossible for any deception to have had access, is a report confirming the claims of animal magnetism in the most ample manner. This report is ably drawn up, and is probably in the hands of a great many of our readers, as it has been translated, upwards of three years ago, by Mr. J. C. Colquhoun.

We do not propose to take any farther notice of that work, as it will be perceived it has been frequently alluded to in the English report, which we are happy to have been able to obtain. This report was not intended for publication—and we are indebted to the kindness of the President of the scientific section of the Association for the original paper as read at the general meeting. We owe the members of the committee an apology for venturing to print an account of their proceedings without their direct sanction, but we know they will pardon the liberty we allow ourselves in consideration of the interests of science. Mr. Brown, their eloquent and ingenious secretary, will also, we are persuaded, accord us his forgiveness for using his very talented report. It is not often that a philosopher, who has the genius to conduct a scientific examination has at the same time the power of describing it so well.

The Metropolitan Joint Stock Medical, Scientific, and Literary Association has not been long established. But we may venture to observe, that no body of men have done more for the furtherance of the ends for which they are associated than the eminent individuals who compose this society. We will not particularize any names, nor institute a comparison between their labours and those of the chartered body of physicians, or of any other institution. We merely wish to accord our high opinion of the usefulness of the Metropolitan Association as a school of philosophical enquiry, and as an uncompromising advocate of the truth. Where societies of longer standing, and reposing on the respect of the public and the strength of their own characters, have abstained, perhaps too guardedly, from interfering with the new discoveries in medicine or science, the Metropolitan Association has eagerly rushed forward, and hailed with generous warmth the appearance of any novelty. Its honorary

diplomas to Dr. Morison, the discoverer of the properties of the vegetable pill, and to Dr. Turnbull, for his profound treatises on the virtues of Veratrina, attests its readiness to pay honour to disinterested skill, wherever it may be found. Its medal to the philosophical gentleman who has established his reputation by an essay, containing proofs of the unity of the body, shows no less zeal in rewarding metaphysical distinction, than its former proceedings had displayed for the encouragement of medical utility.

(To be continued in our next.)

TO CORRESPONDENTS.

S. H.—The serious impositions to which an editor is exposed, we alluded to in a late number.

A Constant Reader will always find one of us at the office every morning.

Jurist.—If a person is supposed to be murdered by the hands of an assassin, or by mal-treatment, the coroner is bound to hold an inquest.

Justitia.—We believe Mr. Lawrence was a supporter of the bye law.

Craniologist.—The hat shop recommended by Sir Benjamin is in Vigo-lane.

Churchwarden.—The Inspector is only allowed one clerk.

A King's College Student.—An introduction from Professor R. B. Todd to his friend Mr. Lane, medical agent, Adelphi, would prove quite satisfactory.

Calculator.—It was one hundred guineas Sir Astley subscribed for the Duke of Wellington's monument, a sum considerably less than the worthy baronet had received for fees at Apsley-house.

St. George's Student.—Mr. Walker will deliver the whole course. The services of all others are dispensed with.

A Young Operator.—In performing amputations without a tourniquet, the loss of blood is sometimes so considerable as to endanger the result.

Molares.—We only know of two in the mill at present. The Council expect several others individuals to come forward.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

E C Z E M A .

Prognosis.—Eczema usually constitutes a slight disease, especially when it exists in the acute state, but when having become chronic it occupies, at the same time, a certain extent; it then constitutes a very troublesome and very obstinate disease. The prognosis is worse when the eczema continues for years, and new eruptions cause it to re-appear at the very moment when every thing seemed to announce an approaching termination. Without endangering the life of the patient it embitters his existence, when it thus continues for an indefinite period. It may co-exist with lichen, and especially with the itch. It is often complicated with pustules of impetigo, or ecthyma, &c., &c.

Treatment.—The treatment of *eczema simplex* consists, in most cases, in the simple use of cooling drinks, weak and acidulated lemonade, and some warm baths. These means are in general sufficient to remove the eruption in a very short space of time. But when the disease is continued for a considerable time, and is accompanied with intense itching, especially when the eruption is very extensive, it is sometimes useful to administer some laxatives, and to have recourse, at the same time, to alkaline baths (four or eight ounces of subcarbonate of potash or soda for an entire bath, according to the age of patient and the state of the eruption).

Eczema rubrum and *eczema impetig-*
No. 297.

ginodes do not require a different treatment from that of the acute phlegmasiæ; diluent drinks and strict regimen, when it is local and of small extent; but when it occupies a great surface, and is accompanied with a little elevation in the pulse, and more especially when the patient is young and vigorous, it becomes necessary to bleed generally, or locally, by applying leeches in the vicinity of the eruption. Sometimes it is necessary to have recourse to these two means. If the disease was very extensive, the general bleeding might be repeated with advantage.

Lastly diet, plain or emollient baths, local baths of marsh-mallow water, &c.; potatoe cataplasms, and of some emollient decoction, when the broken vesicles have exposed an excoriated and painfully red surface, are the only means to be adopted in acute eczema. We should carefully avoid sulphurous preparations, so frequently and so unseasonably employed in the cure of all diseases called *dartrous*. The same may be said of mercurial preparations. We have frequently seen patients enter the Hospital St. Louis, in whom the *eczema rubrum*, being exasperated and kept up by these improper means of treatment, had passed into the state of *eczema impetiginodes*; oftentimes also it was accompanied with real pustules, either of impetigo or of ecthyma, and continued for whole months, when, on the other hand, cases of acute eczema, which occupied the entire surface of the body, and seemed to constitute a very serious disease, yielded in twelve or fifteen days to a judicious antiphlogistic treatment.

In all cases the first object is to remove the cause; thus frictions are to be avoided, and the patient is to be withdrawn from his usual employment, if it be considered calculated to originate the eruption. In one man employed in a pharmaceutical business, we have seen

eczema simplex constantly re-produced almost as soon as he resumed his work.

Chronic eczema, which has not attained this degree of severity, where it becomes a serious and very troublesome disease, generally yields to the employment of the following means:—

Acidulated drinks and baths generally succeed very well. Thus we give from a scruple to a drachm of sulphuric or nitric acid in a pint of barley-water; the nitric acid is more energetic than the sulphuric acid. They are chiefly applicable in cases where there exists a very copious exhalation of serum, accompanied with severe itching. The patient should sip, and even swallow, immediately after, a little plain water, when the stomach is not yet accustomed to these acidulated drinks.

The baths must be from 25° to 27° (Reaumur);* the patient is to remain about one hour in them; they are to be rendered emollient by the addition of mucilage, gelatine, &c. The quantity of gelatine necessary for one bath, is about half a pound.

It is often necessary to have recourse to laxatives; they may be employed alone or alternately with acidulated drinks. Thus we should give, by way of pisan, veal broth, infusion of chicorey, &c., with the addition of *sulphate of soda* (half an ounce to the pint), or else *sulphate of potass* in the same dose, which may be increased or diminished according to the indication; *whew*, with the addition of two drachms of the *acidulated tartate of potass*, &c.

Alcalies are employed with much advantage, both externally and internally. They are useful externally when, in spite of the employment of emollients, the itching is very severe; then local baths, with the addition of from half an ounce to two ounces of *subcarbonate of potass or soda*, evidently diminish this itching. The patient must take them before lying down. Internally the *subcarbonate of potass* is given in the dose of from half a drachm to a drachm to a pint, most usually in a bitter pisan.

When the eruption is of longer standing, and when it occupies a greater extent of surface, it is necessary to have recourse to more active means, such as purgatives, sulphurous waters, baths and vapour douches.

Calomel may be administered in the dose of four grains, in the morning fasting

for a week or two; the patient may take one or two *Plummer's pills*, or pills of *aloes, jalap, gamboge*, so as to produce purging; regard being had, however, in all cases, to the state of the digestive organs. *Sedlitz waters* may be employed for the same purpose, in the dose of one or two glasses every morning.

Sulphurous waters may be administered externally or internally; they are applicable only when the disease is of some standing, especially when the eruption, seated in the lower extremities, presents a purple tint.

The waters of *Barrege, Enghien, Canteretz*, &c., are those most generally employed. These may be formed artificially, by adding to each simple bath, two or three ounces of sulphuret of potash, the quantity of which is varied according to the excitement which we wish to produce. In all cases it is good to advise simple baths with the sulphurous baths. When we administer sulphurous water internally, it is well to dilute it at first with two thirds of barley-water, or of milk and water, and the quantity of the mineral water may be gradually increased until the patient comes to take it pure.

Local or general, simple or emollient baths, are, as we have shewn, the only ones applicable at the commencement, and every time the inflammation becomes more acute. In these cases, also, whatever be the means employed, it is very useful to apply some leeches to the parts around the eruption.

Vapour baths are sometimes very useful in cases of chronic eczema; but the patient must not expose himself to too strong a heat; he should also keep at some distance from the point whence the aqueous vapour issues. Vapour douches are often of great use when the disease is local.

When the eruption is limited or reduced to a small extent of surface, the cure is sometimes accelerated by ointments of pomade in which the ammoniacal protochloride of mercury in the dose of from a scruple to half a drachm to a drachm of oxunge.

In the course of the treatment, we must often employ, in order to appease the severe itching, either lead lotions, or an emulsion of bitter almonds, or else a decoction of some plants, such as *dulcamara, henbane*, &c.

In some cases the chronic eczema, which is much more severe, resists these different means, and it becomes necessary

* From 88° to 95° (Fahrenheit).—Ed.

to have recourse to others of a more active kind, provided, however, that there does not exist at the same time any chronic affection of the digestive passages.

It is in these cases of obstinate eczema that we have seen the following means succeed in a manner truly surprising: 1st. *tincture of cantharides*, especially in women; 2d. *some preparations of arsenic*, by means of which M. Bielt has often removed very inveterate and bad cases of eczema, with remarkable rapidity.

The tincture of cantharides is given at first in the dose of three, then five drops, every morning in a little pisan, and every six or eight days there is an increase of five drops. In this way the dose may be raised without any inconvenience to twenty-five or thirty drops, care being taken to interrupt the use of it at intervals more or less remote, and always beginning with minim doses.

Among the arsenical preparations, those which seem most frequently to succeed are *Fowler's solution*, *Pearson's solution*, and the *solution of arseniate of ammonia*. The base of the first is arsenite of potass; it is one of the most energetic medicines we possess; it is given in the dose of three drops at first in some inert vehicle, in the morning fasting; then every five or six days we increase the dose by two or three drops only; after a great many trials M. Bielt has come to the practice of not exceeding fifteen drops a day.

Pearson's solution is milder and more manageable; it is fitter for females, and persons of an irritable temperament, and it is the only one which should be employed with children. The base of it is arseniate of soda, in the proportion of an eighth of a grain to each drachm. It may be administered from a scruple to a drachm and more.

Lastly, the *solution of arseniate of ammonia*, introduced into practice by M. Bielt, was employed by him for the first time in 1818, with a success which cannot be denied. It is given in the same doses as the preceding. These three solutions are substituted advantageously one for the other, and oftentimes Pearson's solution succeeds, where Fowler's solution had failed, and *vice versa*.

The employment of arsenical preparations demands much attention on the part of the physician; they must be given up, if any symptoms of irritation of the digestive canal come on; but a little indisposition which the patient may feel at the commencement of its use is not to be taken for such, as this indisposition soon

disappears. It is often of advantage to discontinue the use of them, as in the case of the tincture of cantharides, for a few days, to resume them afterwards.

Frequently, in cases where the eczema occupying only a certain extent of surface, has almost assumed the squamous form, when the skin is dry, chopped, slightly thickened (as is seen particularly on the hands), we must have recourse to means of a somewhat more active nature.

In these cases it is often useful to employ frictions over the eruption itself, either with the *proto-nitrate of mercury* (a scruple or half a drachm to the ounce of axunge), or with the *proto-ioduret* (a scruple to the ounce of axunge), or the *deuto-ioduret of mercury* in the dose of from ten to twelve grains to the ounce. To these ointments a little *camphor* may be added to calm the itching.

These mercurial preparations, thus employed externally, have often produced very good results; but the advantages of those which have been recommended internally are, to say the least, doubtful, and even their use is frequently injurious.

Lastly, it is chiefly in these cases that it is useful to employ sulphurous baths, whether local or general; but still it is probably vapour douches whose good effects are best ascertained.

Cauterizations should never be resorted to in the treatment of eczema, in which affection however it has been strangely abused; the employment of stimulating ointments is preferable.

Before concluding the subject of eczema, we shall make a few remarks of some cases where, having its seat in certain regions, it presents some important peculiarities.

LECTURES ON SURGERY.

BY JOHN HUNTER, F.R.S.

Mode of Formation of Pus.

Pus is formed by some change, decomposition, or separation which the blood undergoes in its passage out of the vessels. To carry on this process, either a new and peculiar structure of vessels must be formed, or a new disposition or mode of action of the old must take place. This new structure of vessels, or new disposition of vessels, I shall call glandular, and consider pus as a secretion.

Dissolution of the living solids of an

animal body into pus, and that the pus already formed has a power of occasioning their further dissolution, is an old opinion, and is still the opinion of many.

But if this idea were just, no sore which discharges matter would be exempted from continual dissolution; and I think it must appear inconsistent that matter which was probably intended for salutary purposes should be means of destroying the very parts which produced it.

The circumstance of internal circumscribed cavities, as the abdomen, thorax, &c., forming pus, and where they might often have seen pints of matter, without any breach in the solids to produce it, (which is proved beyond controversy to take place,) should have taught them better; and the prevalence of this idea certainly shows a barrenness of knowledge and observation. Such an idea might be forgiven when it was thought that the discharge in gonorrhœa arose from an ulcer; but now that it is known that there is no ulcer in the urethra, it can only continue from mere stupidity.

The moderns have been more ridiculous still; they have put dead matter into pus, and have thought that it has been formed into pus, and have thence inferred opinions similar with the former. In this case they have been putting dead and living animal matter on the same footing. But what is still further, they might have seen that extraneous matter cannot be formed into pus, by observing that in wounds, and in suppuration with extravasation, blood and pus are found separately in the same cavity, and that in extravasation of blood in sound parts no pus is produced. In abscesses from violence and erysipelas they might have seen sloughs of dead cellular membrane, hanging like wet tow, and not melting down into pus, although exposed to the action of matter for a long time. The same observation holds good with regard to dead bones, when exposed to the action of pus; besides, if, in consequence of the decomposition of these parts, some of their parts are mixed with pus, it is altered in its properties, thereby attaining a very ill smell. But if there is a loss of substance in a dead piece of bone, for instance, it is produced by absorption; in proof of which we see that the loss is on that side where it unites to the sound parts, and where alone the absorbents can act.

The chemists found no difficulty in explaining the formation of pus, and this

they supposed took place by fermentation. But fermentation necessarily implies that there should be something to ferment; and, according to this idea, there are three effects which contradict the notion of fermentation flatly. First, internal canals, where mucus only was formed, take on the formation of pus without previous loss of substance or previous fermentation, and they leave off the action in the same way. Secondly, internal cavities take it on without loss of substance. Thirdly, abscesses already formed leave it off. If fermentation was the cause in the first, what solids enter into the matter discharged? for the whole penis could not afford matter enough to form the matter discharged in a gonorrhœa. And how or by what power was the fermentation commenced? and how should it ever cease? for there is the same surface secreting its mucus whenever the fermentation of pus ceases? In the second case, what solids were destroyed when fermentation began? by what power is the first particle of this fluid formed in an abscess or sore, before anything exists capable of dissolving solids? And according to the third, an abscess shall form matter, become stationary, perhaps for months, and at last be absorbed; and what become of the ferment during the time it remained stationary?

We may safely, then, discard these notions, and say that pus is formed from the fluids alone, by the action of the living solids.

Pus appears to consist, when examined by the microscope, of globular bodies, such as compose cream; these may be white, or not so, as we find glass appears white when powdered, though not really so. The globules swim in serum, or a fluid like serum, and most probably there is a little coagulable lymph mixed with it. The proportion that those white globules bear to the other parts depends on the health of the parts which form it; and when in larger proportion, the matter is thicker and whiter, and is called pus, that is, the solids that produced it are in health, for these appearances in matter are no more than the consequences of certain salutary processes, which are going on in the solids, the effect of which is to produce a disposition on which both suppuration and granulation depend.

Pus has a sweetish mawkish taste, as is known when it is formed in the mouth, and it coagulates by heat. This is the same, whether from an irritated natural surface, as the membrane of the nose and

other outlets and canals, or from an incrated surface.

These discharges from canals or outlets have been termed mucus, and not pus; and the surfaces yielding these discharges have been termed mucous membranes. A test has been recommended for distinguishing these when their appearances have been so exactly similar as to afford no visible difference, and when, as I observe, they are in fact one and the same fluid. This test was the chemical solution of the fluid in menstrua, and its precipitation therefrom, a proposal which was unphilosophical on the very face of it, and which I treated from the first as absurd. I did conceive that all animal substances when in solution, either in acids or alkalies, were in the same state, and that the precipitation from them would be the same. But as it was so strongly asserted, and supported by experiments said to have been made, I, to satisfy myself, made several experiments with animal matter, both solid and fluid; these I dissolved in different acids, vitriolic, muriatic, &c., and made precipitates with several alkalies, both fixed and volatile, but all these precipitates appeared the same, even when examined with the microscope, exhibiting universally a flaky appearance.

The quality of the matter always depends on the nature of the part secreting it; whatever specific quality the part is affected with, the pus will possess the same; hence we have venereal matter from venereal sores, cancerous matter from cancerous sores, &c.: but though it takes on these qualities when the part yielding it is so affected, yet it does not derive these qualities from the constitution if it is so affected, unless that part is also affected. A circumstance which serves to show that the part which yields it is of the same nature with the matter produced, is that it does not prove an irritator to the surface yielding it, though it may to another; hence no suppurating surface can be kept up by its own matter. The gonorrhoea, smallpox, &c., curing themselves is a proof of this, for were not this the case we should have constant pain from the irritation and much more difficulty in the cure. We do, indeed, sometimes find that pus will irritate its own surface; but this may be the effect of some extraneous matter, as blood, &c., in the pus: the intestines will sometimes produce a discharge which stimulates them very considerably; but this may be secreted by the diseased sur-

face, and prove an irritator to the sound part of the canal only. What I have hitherto said refers to natural pus only; but when a specific nature is added, then the secretion is altered. The first alteration is a greater quantity of serum and salts, producing a thinner discharge, called sanies; this discharge has sometimes appeared to affect the solids, and has thence been called corrosive, a property which it does not possess, the parts only receding from the irritation; and where this is the case, perhaps, the decomposition and new combination necessary to the formation of pus is not perfect, in consequence of the vessels having lost that structure which is proper for the secretion of pus; and this is probably the case, as healthy granulations are not produced when such matter is secreted. By what particular organization matter is produced we can no more determine than we can the nature of any other glandular organization,

Pus appears to have a greater tendency to putrescency than the other secretions have, but I do not think this is in the degree that has been supposed. It is brought into a putrescent state by circumstances independently of the pus itself. If the air is admitted to it by a small opening in an abscess, or it is placed near the intestinal faeces, or some parts of the solids which have sloughed, then it will be fetid; or if any dead blood, as in recent sores, is mixed with it, it is fetid; but if perfectly confined in an abscess it is always sweet, and will be long time in putrefying. In erysipelatous inflammation, however, where there is an internal inflammation, there will be putrefaction; but this is probably from the solids themselves first putrefying. Hence we find, in most cases of specific disease, that the pus is offensive, because blood is mixed with it. Where there is dead bone also pus becomes very offensive.

The final intention of this secretion of matter is not, I believe, yet understood. Some say it is carrying off humours from the constitution, or that it is a constitutional disease changed into a local one, and so discharged or thrown out of the body, either in the form of pus, or with it, as in those cases called critical abscess. Or it is presumed to carry off local complaints from other parts, by way of derivation or revulsion; hence sores or issues are made in sound parts to allow other sores to be dried up. But I am apt to believe that we are not yet well, or at all, perhaps, acquainted with its uses.

We might naturally suspect that it was on the surfaces of sores to keep them moist, but this will not account for its formation on internal surfaces.

Absorption of whole parts in consequence of Disease.—The immediate effects of absorption of the body in consequence of disease may be said to be of two kinds. The first is only a wasting of a part, or the whole, without any breach in the structure or form, and this I call the interstitial absorption; the second consists of the total removal of a part, as if by art, and this is the progressive absorption. The interstitial absorption may be considered in two lights: 1st, where it leaves the part affected still a whole, though wasted; 2nd, where it entirely removes it, which latter resembles the natural process by which useless parts are removed, as the thymus gland, the membrana pupillaris, &c.

The process of removing entire parts of the body, either by the second interstitial or the progressive absorption, answers very material purposes in the machine. It is by means of the progressive that bones exfoliate and sloughs separate, that pus is brought to the skin, and that while new bones are formed old ones are removed; and although in these cases the process arises from disease, yet it is somewhat similar to the modelling process in the natural formation of bone. It is this last that removes useless parts, as the alveolar processes when the teeth drop out, or when children are shedding teeth, which allows these to drop out; and it is by these means that ulcers are formed. It is many cases a substitute for mortification (which is another mode of loss of substance), for it is a degree of strength or vigour superior to that where mortification takes place; and in many cases it finishes what mortification has begun, by separating the mortified part.

The progressive is that absorption which begins at one side of a part to be removed, and goes on till the whole is removed, as spreading ulcers.

These two modes, the interstitial and generally going on at once, which may be called the mixed. This operation of absorption, like many other processes arising from disease, would often appear to be doing mischief, by destroying parts which are of service, and where no visible good appears to arise from it, as in those cases where the external covering is destroyed by ulcers or sores; but in all cases it must be reduced to necessity, for we may depend upon it that those parts have

not the power of support, and it becomes a substitute for mortification. In many cases we shall see both ulceration and mortification going on, ulceration removing those parts which have power to resist death.

New-formed parts, or such as cannot be said to form a part of the original animal, admit more readily of removal than those parts originally formed: probably this arises from the principle of weakness. It is on this principle that all adventitious new matter is more readily absorbed than that matter which forms the substance of old tumours.

Remote causes of absorption.—The remote causes of absorption are various. The most simple appears to arise from a part's becoming useless, as the thymus gland, the ductus arteriosus, the alveoli after the teeth drop out, the crystalline lens after couching, the fat of the body in fever, either inflammatory or hectic, all which are removed by the absorbents as useless parts. Another cause is want of power in the part to support itself under certain irritations, which may be considered as the basis of every cause of removal of whole parts, as calluses, cicatrices; also of parts pressed on. From all which it would appear that parts are liable to be absorbed from five causes: first, parts pressed on; second, parts, considerably irritated by an irritating substance; third, parts weakened; fourth, parts rendered useless; fifth, parts become dead. The two first appear to me to produce the same irritation; the third, an irritation of its own kind; and the fourth and fifth may be somewhat similar.

Immediate causes of absorption.—The immediate causes of absorption of the body itself must be of two kinds respecting the parts, one passive the other active. The first of these is a consciousness in the parts to be absorbed of the unfitness or impossibility of remaining under such circumstances, the action excited by the irritation being incompatible with the natural actions and existence of the parts, whatever these are; therefore they become ready for removal, or accept of it with ease the second is a consciousness in the absorbents of such a state of part; and both concurring to do the same thing, they fall to work. When the part to be absorbed is a dead part, or extraneous matter, the whole disposition is in the absorbents. Pressure from without rather stimulates than irritates, for we find it produces thickening of parts; but if exceeds the stimulus of thickening, it

becoms an irritator. If pressure is from within, parts rather appear to give way, and absorption takes place.

Interstitial absorption.—This is of two kinds with respect to the effect, or, rather, has two states. The first, where it takes place only in part, as in the wasting of a limb, where disease of the joint has rendered it useless; in a broken tendon; a divided nerve going to a voluntary part; or when it takes place in the whole body in consequence of disease, as atrophy, fever, &c. The second, when entire absorption takes place, and no vestige is left; and this would seem to be of two kinds, one where it takes place only in consequence of another disease, and is a necessary and useful effect of that disease, assisting in bringing parts to the surface, &c.; but the other appears to arise from disease in the part itself, as a total decay of the alveoli without any disease in the teeth or gums, as also the wasting of the testicle. The first or second division of absorption of entire parts is taking place in a thousand instances; it is gradually taking place in that part of the body between many encysted tumours and the surface, and is generally slow in its progress.

Progressive absorption.—The removal of those surfaces immediately contiguous to the irritating cause, which is an absorption of necessity, is effected by progressive absorption. Absorption from pressure is the removal of the part pressed, which may either be the surface of an abscess in contact with pus, or of that part of the surface of the body in contact with some body constantly pressing, as the buttocks or hips of those who lie long on their backs.

Of the relaxing process.—Besides the modes of removing parts above mentioned, there is another process, called the relaxing or elongating process, carried on between the abscess and skin. It is possible that this process may arise in some degree from the absorption of interior parts; but there is certainly some other cause, for the skin which covers an abscess is certainly looser than it would be from mere stretching; and it is very beautiful to observe how Nature goes on in her own way to produce an effect. In consequence of the pressure of pus in an abscess, Nature set's up three processes to let it out: first, progressive absorption; secondly, interstitial, by which the progressive is assisted; thirdly, the relaxing process, making the parts yield to distention. In women, the relaxation of parts

is very considerable before the birth of a child; and the old women in the country know when a hen is going to lay by the softness of those parts. The following cases exemplify those processes of absorption.

A lady, after inflammation of some of the abdominal viscera, had the belly swell: some time after, a kind of pointing was observed in various parts of the belly, and on opening the largest a very considerable quantity of fluid (matter, I think,) was discharged; this opening was near the sternum, and the ends of the recti muscles were quite ragged. The patient died. Here was an instance of the effects of absorption, by which an exit was obtained for the matter. Suppose an abscess to go on for a long time with a smooth surface, yet if any part takes on the absorbing process the matter will be very rapid in arriving at the skin, although this process may have taken place in the thickest part. This process may be induced by an irritation in any part of the surface; thus, after opening an abscess, if matter is permitted to collect at the most depending part, it may bring on this process, whence a fresh opening will be made.

ANIMAL MAGNETISM IN LONDON IN 1837.

(Concluded from our last.)

It is not, therefore, to be doubted that, on the first re-appearance of the Mesmerian Philosophy, its advent was warmly welcomed by the Association. Allusion was made to it, so long ago as 1830, in a very luminous paper by the late Mr. St. John Long. But other topics of absorbing interest at home occupied too much of the attention of the scientific world to allow the subject to be prosecuted at that time. At intervals, however, the magnetic theory has incidentally been introduced in the discussions arising at the quarterly meetings; but no formal proposition to enquire into it fully and and completely was submitted to the Association till the beginning of this year. The public, however, seemed to take little interest in the matter till about two months ago, when the arrival in London of Baron Dupotet, the principal professor of animal magnetism in Paris, was announced in the newspapers. An invitation was published by the Baron to any

gentleman who desired instruction in the doctrines of animal magnetism to visit him any day, between two and three at his house in Maddox Street, Hanover Square. Before laying the more scientific report of Mr. Brown, as read at the last meeting of the Metropolitan Association, before our readers, we may be allowed to describe a visit which we paid to the Baron in compliance with his invitation. On entering the room, No. 8, Maddox Street, we saw a party of twelve or thirteen gentlemen standing on the floor. Baron Dupotet, a man of very prepossessing appearance, with fine dark intelligent eyes, was seated in front of a gentleman who had offered himself for experiment. After keeping the points of their thumbs together for some time, till the temperature of both was the same, the Baron pressed his hands on the patient's shoulders, and passed lightly over his arms till their hands again touched. He repeated this two or three times, and then spreading forth his hand with the fingers closed, he moved it gently, with a downward motion, over the patient's face, at about two inches distance from his nose. He then continued the waving action of the hand down the stomach and legs, and, having finished the whole length of the body, returned to the brow. This was continued for a quarter of an hour, and the patient persisted in saying he experienced no change. At last, however, he seemed to feel some of the effects the Baron had foretold; his colour disappeared, and he confessed that his heart beat in a way that he had never experienced before. The Baron continued his manipulations with renewed activity, and shortly told us he had acquired a certain degree of influence over the patient, which a few more days of the magnetic operation would complete. He now stood up and informed us that the attraction established between himself and his patient was already so great, that it would be impossible for the magnetized to resist following him to whatever part of the room he went. He then, in five or six long deliberate steps, proceeded to the lobby at the top of the stairs, looking round all the time at the patient, who struggled with himself for some time, but yielded to the influence, and cried out for us to hold him, or he must follow, as if he were dragged by a strong chain! As the gentleman appeared considerably excited, the Baron did not think it right to carry the experiment any farther. Some of the company being extremely anxious to see

the effect of the magnetism upon a somnambulist, the Baron introduced his domestic Julie, and made her sit down on the sofa. Julie seems a quiet, simple peasant, of about forty years of age, not good-looking, and rather fat, but withal of a prepossessing appearance, and very modest retiring manners. After a few minutes' conversation with several of the spectators, in answer to whose questions she said she had not been in good health, but felt herself greatly benefited by the Baron's treatment, the experiment was begun. Standing about three feet from the sofa, the Baron stretched forth his hand, and kept waving it downwards all along her face and body. In a few minutes her eyes began to close, her head nodded as if in the beginning of slumber, and, at the end of less than five minutes, her chin fell upon her breast, and she was in a profound sleep. To outward appearance the sleep was natural and calm; the breath came tranquilly, and she seemed unconscious of every noise. The Baron addressed her, and to all his questions she replied immediately, but remained dumb when spoken to by any one else. As we were told that it needed to be put in magnetic "rapport" with Julie, in order to have any conversation, we offered to undergo the process. Our hand was placed in Julie's, which closed strongly and firmly on it, with a gradually increasing pressure, till at last it fairly assumed what is called the magnetic grip. We now addressed the fair sleeper, and told her we had a head ache, and asked her how it was to be cured. She said by taking castor oil, and eating chicken-broth. The broth was to be composed of half a chicken, two carrots, and a quarter of a pound of barley. A gentleman now endeavoured to separate our hands, but the wrath of the somnambulist was roused, her veins swelled with passion, and a perseverance in the attempt would have thrown her into hysterics. Large quantities of snuff were put into her nose without producing the least effect; pins were stuck into her arms and legs without being noticed, and it seemed impossible to make the slightest impression on her senses in any. The Baron released our hand, and after a few more wavings before her face, ordered her to open her eyes. In a moment the lids were lifted, and the eyes were seen directed upwards, and void of all expression. A handkerchief was suddenly waved close to them, but she did not wink, nor was there any movement in the pupil. After many

endeavours to produce some movement by striking with great force within an inch of the iris, the Baron ordered her to shut her eyes, and the lids fell down with the rapidity of a porteullis. He now took a little walking-cane, tipped with silver, and pointed it for a minute to Julie's nose, and she instantly began sneezing from the effects of the snuff that had previously been introduced. After a short time he touched her on the knee, moved his hands crossways before her face, as if tearing aside something that covered it, and exclaiming "Awake! awake!" presented Julie to the company, looking as simple and unconcerned as when she first came into the room. She said that she was quite unconscious of all that had passed, and would scarcely believe that she had taken any snuff, and had no recollection of the chicken-broth and the castor oil. In all this there was no apparent desire to do any thing in an underhand way. Every thing was fair and open, and the Baron in all his operations followed the suggestions of any one who chose to offer them. The rod was pointed to the nose in perfect silence, without a word having been said which could let Julie know what was about to be done. Noises were made at her ear enough to produce a start on the stoutest nerves without effect, and however prejudiced may be the observer, it must be confessed that if there is not something extraordinary in magnetism itself, there is something very wonderful indeed in Julie's acting.

We now proceed, without farther preface, to the remarkable paper of Mr. Brown.

"At a meeting of the Metropolitan Joint Stock, Medical, Scientific, and Literary Association, held in the hall of the Hygean College, on Thursday 27th July, 1837—President, Dr. Deprati; the secretary of the committee of enquiry into the state of animal magnetism was called on for his report. Mr. Brown read as follows:—

"Gentleman—Before entering on the subject which you committed to our investigation, permit me to express my regret that your committee were deprived of the assistance of several distinguished individuals whose names you put upon it. It adds to our regret on this occasion, that the reason of withdrawal advanced by some of them appears little consonant with the spirit of enquiry which ought to distinguish a philosophical mind. Dr. Belluomini and Dr. Quin, whose celebrity

as practitioners of the Hahnemaniac system of medicines, attests at once their talent and respectability, refused to belong to the committee, and assigned as their reason that the very enquiry into a system so strange and unsupported, was an encouragement to quackery and imposture. Dr. Granville also, whose fame extends from the snows of Petersburg to the watering places of Germany, refused his co-operation to your committee, though without giving any reason for his refusal. With diminished numbers, therefore, but undiminished anxiety to discover the truth, we proceeded on our task. In all our investigations we took for our guide the course of examination pursued by the medical committee on the same subject in Paris. And in this, as we had the invaluable advantage of the presence in London of the same operator who bears so prominent a share in their recorded experiments—we allude to M. le Baron Dupotet—we had little more to do than to verify the cases recorded by our foreign predecessors. But besides the Baron Dupotet, we had likewise the great assistance of the celebrated German professor of the same science, Dr. Von Schurke of Vienna, whose contemporaneous presence in this city we cannot help considering as almost a providential arrangement by which our deductions are established beyond the possibility of a doubt.

"Adopting the point at which the French committee arrived as that at which we should commence our verification, we took the four following divisions (in the 120th page of the English translation of their Report) as the groundwork of all our enquiries:—

"1. Magnetism has no effect upon persons in a state of sound health, nor upon some diseased persons.

"2. In others its effects are slight.

"3. These effects are sometimes produced by ennui, monotony, by the imagination.

"4. We have seen them developed independently of these last causes, most probably as the effects of magnetism alone.

"The first of these we shall pass over very slightly, as there is little worthy of being noticed when no sensible results are produced. Your reporter submitted himself frequently to the operation, and had the patience to sit nearly an hour without motion—perusing a newspaper—and during the manipulation experienced no kind of effect, though the ennui of his

position, and the absolute silence he had recommended to be observed, might have been very capable of producing sleep. Dr. Von Schurke of Vienna, determined to make an experiment on a person in still more robust health than your reporter; and for that purpose proceeded, in company with three members of the committee, to a hotel kept by Mr. Thomas Cribb, the champion of the prize-ring. It may perhaps appear somewhat below the dignity of philosophy to frequent such a locality; and a less entire devotion to truth than that we hope entertained by your committee, might prompt us to bury in silence the painful result of this experiment. Dr. Von Schurke placed himself in front of a very stout, ruddy-faced man, who was smoking a long pipe, and drinking a combination of gin and sugar in hot water; and without giving any notice of his intention, proceeded with the magnetic manipulations. He laid his hands on the gentleman's shoulders, enjoining him at the same time to be silent, and, after passing down to his fingers, applied his thumb to that of the patient, and allowed the remaining fingers to rest on the back of the patient's hands. There were many other persons in the apartment, who looked on with considerable surprise. Dr. Von Schurke having established a community of heat between the thumbs, drew out his hand, and let it fall gently along the line of the patient's face. We sat round watching the effect. The patient gazed most earnestly on all the proceedings of Dr. Von Schurke, but made no remark. When, however, the manipulation had continued for some time, the patient having finished his pipe laid it on the table, and buttoned up his coat. Dr. Von Schurke proceeded with redoubled zeal, and waved his hand faster than ever about half an inch from the patient's nose. But when the Doctor was about to return, by means of the dorsal manipulation, to the patient's shoulders, the gentleman sprang up in a furious access of passion, and seizing the nose of Dr. Von Schurke between his finger and thumb, squeezed it till the Doctor roared out for commiseration, in the greatest corporeal pain. The patient, however, did not listen to his cries; but dragging him by the nose to the door, opened it, and applying the point of his great toe to the extremity of the os coccygis of Dr. Von Schurke, lifted him half-way across the street with the power of the impulse, and returned into the room. Applying, in the same manner, his finger to the nasal

excrecence of Mr. Moat, one of the most active members of your committee, he went through the same process, with the exception of the kick, the absence of which he supplied by a slap with the open hand upon the pit of the stomach, which caused Mr. Moat to eject all the food he had eaten during the day. In the mean time your reporter was happy enough to discover a back way, by which, in the company of Dr. Jephson of Leamington (another member of your committee), by clambering over several walls, he effected his escape. In all succeeding meetings of your committee, Dr. Von Schurke has been accommodated with an air-cushion to his chair, and has worn sticking-plaster over his nose, which was nearly separated from his face. Mr. Moat has not again made his appearance, being convinced that, along with his breakfast and lunch, he vomited a large portion of his intestines.

"But leaving this and several other experiments, which produced no magnetic results whatever, we go on to those cases in which we perceived, though in a slight degree, the presence of the magnetic power. But here again our remarks shall be very cursory, as we are not certain that the effects produced were altogether unaccountable on some other hypothesis. According to the plan we had laid down, we referred to the English translation of the Parisian Report; and at page 122 we found two or three instances stated of the pulse having been reduced many beats by the manipulation, and on one or two occasions headach (cephalalgia) and a nervous pain (neuralgia) being sensibly diminished. In order to verify these effects, we saw several persons magnetized who were suffering from rheumatic pains. In one instance, on the third day, the pain removed from the shoulder to the elbow—on another, the Baron manipulated a person labouring under toothache, while her tooth was being extracted by the dentist, after which there was no recurrence of the twinges. The case, however, in which the strongest effect was produced, without being decidedly magnetic, was the following:—A gentleman, who had travelled all the way from Exeter on the outside of the mail, arrived at about eleven o'clock at night, in a house where Dr. Von Schurke was at supper. The gentleman complained of headache and fatigue, and the Doctor recommended him a broiled chicken, with some hot potatoes, a pint of Burton ale, and two glasses of brandy and water. He then made him lie down

on the sofa and began his manipulations ; and in about two minutes and a half, the magnetic power was so great that the gentleman fell sound asleep, and, on waking next morning, had no remains of his headache.

"The third resolution of the French Report is, 'The effects are frequently produced by ennui, by motony, by the imagination,'—Page 125.

"With regard to the two former causes we made various experiments, which corroborated them in the most ample. We availed ourselves of a public meeting, at which the celebrated Mr. Joseph Hume and various others were expected to address the assembly. Dr. Von Schurke placed himself in the gallery, and proceeded to magnetize the whole of the crowded meeting. Before Mr. Hume had spoken twenty minutes, the ennui and motony, in combination with the magnetic influence, produced the effects stated in the French report. There was universal drowsiness and inattention, which ended, in ten minutes more, in a profound sleep. And to prove that these were not entirely the effects of magnetism, but of the causes specified above, there were two gentlemen in the assemblage perfectly deaf, who kept their eyes open the whole time.

"We wish to be perfectly accurate in every thing we advance, and think it right to state explicitly what are the conditions—as stated both by Baron Dupotet and Dr. Von Schurke—of the magnetic influence. The first condition is, that the magnetizer shall impress his own mind with a strong desire to magnetize ; and the second condition is, that the recipient shall impress his own mind with a strong desire to be magnetized. It results from these two conditions that the imagination must occasionally have a very powerful effect. Dr. Von Schurke goes even farther than the French philosophers, and maintains that it is the will alone which gives efficacy to the manipulations,—that is, that the soul is the possessor of the magnetic properties, and by a strong voluntary effort ejects a portion of them through the external skin. He maintains that that the same manipulations, if unaccompanied by a powerful *wish* to magnetize, would be perfectly ineffective ; and that in cases where the will is strong enough, it needs no intervention of the external organs to render itself perceptible, but can produce its effects at a distance from the patient in another room, and even in a different quarter of the

world. This will more properly come under the fourth head, to which we now proceed.

"The greatest triumph of animal magnetism in the examinations at Paris, was the case of Paul Villagrand, a student of law—born at Magrac Laval in the year 1803—who had been under medical treatment for an attack of paralysis for upwards of seventeen months. Your committee think it right to lay an analysis of this case before you, as it was in verifying its principal features that the extraordinary effects we are about to detail came under our observation. When the magnetic treatment began under the direction of M. Fouquier, in charge of the Hospital de la Charité, Paul's infirmities were very considerable. 'He still walked upon crutches, being unable to support himself on the left foot. The arm of the same side, indeed, could perform several motions, but Paul could not lift it to his head. He scarcely saw with his right eye, and was very hard of hearing with both ears ; and besides all this, there were evident symptoms discoverable of hypertrophy of the heart.' He was magnetized frequently in the hospital, with no other effect than involuntary sleep, and a power of prescribing the mode of treatment most effectual for his cure. But even this degree of the magnetic possession was attended with such salutary results, that he cast away his crutches and walked back to his ward, climbing up a great number of steps without assistance. M. Foissac, however (the magnetizer), determining to carry his experiments as far as possible, procured his dismissal from the hospital, and went on with the treatment in Paul's lodgings. His strength, during the manipulation, was greatly increased, and his confidence in the system grew so strong, that he renounced all medical treatment, and begged to be kept in a magnetic sleep from the 25th December to the 1st of January. During this sleep he went out of the house of M. Fossaic, and walked and ran along the street with a firm and assured step, and on his return he carried, with the greatest facility, one of the persons present, whom he could scarcely have lifted while awake. On the 12th of January, the French committee, accompanied by three gentlemen of distinction, met at the house of M. Foissac. Paul was set to sleep, and a finger applied to each of his closed eyes. A card taken at random from the pack was immediately named by Paul. While his eyes were held by M. Segalas, a volume was placed

to his stomach: He read upon the title-page 'Histoire de France;' and wherever it was opened he could read it perfectly. He recognised the figure of Napoleon, and read on a slip of paper the name of Maximilian Robespierre, which the gentleman who drew up the report wrote at the moment.

"1. A patient, whom a rational medical treatment by one of the most distinguished practitioners of the capital could not cure of a paralysis, found his cure from the administration of magnetism, and in consequence of following exactly the treatment which he prescribed for himself when in a state of somnambulism.

"2. In this state his strength was remarkably increased.

"3. He gave us the most undoubted proofs that he read with his eyes closed.

"4. He predicted the period of his cure, and this cure took place.

"In addition to these effects of somnambulism, displayed in the case of Paul Villagrand, a power of judging of the complaints of those in magnetic 'rapport' with her was shown by Mademoiselle Celine Sauvage. Your committee quote this case at length, page 183.

"The committee found among its own members one who was willing to submit to the investigations of this somnambulist. This was M. Marc. Mademoiselle Celine was requested to examine attentively our colleague's state of health. She applied her hand to his forehead and to the region of the heart, and in the course of three minutes she said that the blood had a tendency to the head; that at that moment M. Marc had pain on the left side of the cavity;* that he often felt oppression, especially after having eaten; that he must often have a slight cough; that the lower part of the breast was gorged with blood; that something impeded the alimentary passage; that this part (pointing to the region of the xiphoid cartilage) was contracted; that to cure M. Marc it was necessary that he should be copiously bled; that cataplasms of hemlock should be applied; and that the lower part of the breast should be rubbed with laudanum; that he should drink

gummed lemonade; that he should eat little and frequently; and that he should not take exercise immediately after having made a meal.'

"Founding our experiments on these two cases, and on several others having great similarity to them, we endeavoured to prove, beyond any cavil or dispute, whether or not those very peculiar results of the magnetic agency were producible either in kind or degree by Baron Dupotet or Dr. Von Schurke. Your committee lay the result of their enquiries before you, without believing for a moment, that you will allow the impossibility of many of the effects obtained from magnetism to lead you to so unphilosophical a deduction as that they, therefore, must be illusory. Your committee saw with its own eyes, and heard with its own ears, and on manipulated with its own hands. It took every precaution in its power to render deception or collusion impossible; and in recording the simple facts of which it was a witness, it claims implicit credit to the statement it now makes, that it neither adds to nor diminishes one iota from the truth.

Baron Dupotet, having much occupation, in conjunction with Dr. Eliotson (one of your committee), in endeavouring to effect a cure on a person who had lost both his legs by a fall from a lofty building, proposed that the committee should be divided,—one portion confining its observations to his experiments, and the other to those of Dr. Von Schurke. Your reporter rejoiced to be of the latter number. Baron Dupotet having stated, as the groundwork of the doctrine, that the magnetic power existed in exact proportion to the nervous energy and strength of will in the magnetizer, your reporter could not for a moment doubt that Dr. Von Schurke had a preponderance over his Parisian rival, as his nervous energy is prodigious, and his power of will almost superhuman. From Dr. Eliotson your committee received a report, signed by his colleagues, containing the following results:—

"Patrick Mulhooly, hod-carrier, aged 27, had fallen from a four-story house in October last, and received such severe injuries in both his legs that they were amputated on the following day. Since then he had been totally unable to walk without crutches, or some support in the shape of wooden limbs, into which the stumps of the knees were ingeniously fixed. Baron Dupotet's first object was to draw as great a flow of blood as pos-

* "The author of the report, we conclude, intended the word *cavity* to have reference to the region of the heart; or, perhaps, the 'clairvoyance' of the somnambulist detected some reason for applying this expression to M. Marc's head.

sible to the extremities, in order that a tendency downwards might be created, to be made available in the farther course of the cure. Accordingly, he magnetized Mulhooly on the 10th, 11th, and 12th of July, and on the fourth sitting succeeded in throwing him into a state of somnambulism. On the 14th of July the extraordinary effects of this treatment began to develop themselves, Slight excrescences, similar in form to very young radishes, protruded from the end of the limb, the glow of health returned to the cicatrix of the wound, and the intellect, imagination, and memory of the patient were increased in a most astonishing degree. Baron Dupotet asserted that while in this state of somnambulism Mulhooly possessed all the faculties of any person with whom he was put in magnetic 'rapport,' and proposed as a proof of this, that some gentleman peculiarly skilled in any walk of science or literature, should join hands with him, and ask what questions he chose. Dr. Hamilton Roe, who possesses an intimate acquaintance with the Seraphic language, submitted to the experiment, and having taken his hand, addressed him in the unknown tongue. To the amazement of every one present Mulhooly conversed in it with the utmost fluency. The only limit to the satisfaction of the company was, that from the unfortunate circumstances of Dr. Roe not being himself in a state of magnetism, he could not understand the replies of the somnambulist. But the committee having been informed that several apostles and seven angels had recently arrived at the New Church near Oxford Street, one of Cloud's omnibuses was sent to bring them to the scene of the experiment. In a short time the twelve apostles and all the angels arrived in the conveyance, sixteen inside and three out. One of the angels, a native of Tipperary, undertook to interpret the replies of Mulhooly, and the branch of your committee present at this case comes to the unanimous conclusion that the assertion of Baron Dupotet is verified by the result.

"Dr. Roe having asked in the unknown tongue, 'Who am I?' Mulhooly answered, 'ochan yeerab rothoval oy!' which the angel interpreted to mean, 'a pillar of the elect; upon which the Doctor professed himself satisfied, and said it was the truth.

"At another sitting the excrescences, originally so small, had assumed the appearance of well defined toes, —a heel and sole were afterwards developed, and at

the eleventh sitting the cure was completed. The celebrated dancer Mademoiselle Taglioni, having been invited to enter into the magnetic 'rapport' with Mulhooly, touched his hand, and then fixing a thread round the patient's thumb, held it, at the other extremity of the room. She then lifted up one of her graceful feet, and holding it out on a level with her breast, spun round with the velocity of a gig-wheel—Mulhooly unconsciously imitated every attitude, and seemed to have a greater power over his limbs than the beautiful sylph herself. He placed his right foot on his own shoulder, and spun round for more than a minute at that height, holding his leg in an horizontal position all the time. He then leapt down from his shoulder, and danced the cachucha dance, in exact imitation of Taglioni. In one of the pirouettes towards the conclusion, he exerted himself so prodigiously that having struck the mouth of Mr. Gardener, one of the committee, with his heel, a tooth was displaced with great violence, the extent of which may be judged of from the fact of the tooth being driven backwards through the palate, grazing the spinal column at the back of the neck, and severely wounding Dr. Eliotson in the abdomen at a distance of fourteen feet. Mr. Gardener being luckily in possession of an infallible secret for setting himself to sleep, pulled out his night-cap, and made such use of his recipe, that the wound was completely cured, and a new tooth nearly full-grown before he thought proper to awake.

"In this case, also, the existence of the cerebrum abominale, or rather of the transference of all the senses to the epigastrium, was completely established. The power of reading, however, was not confined to the epigastrium in Mulhooly, but was equally developed in the elbow and tip of the ear. Mr. Balfour having brought to one of the meetings an exact transcription of the writing on the Rosetta stone, Mulhooly, having his eyes held by two of the gentlemen present, pulled up his coat-sleeve, and applying his elbow to it read the inscription with the most perfect ease. The same experiment was repeated with the tip of his ear. What adds, if possible, to the wonder of this experiment is, that till that time Mulhooly was unable to read, his early education having been totally neglected.

"Your reporter now begs to direct your attention to the proceedings at which he was personally present, which were conducted by Dr. Von Schurke. A few

words in explanation of those points in which this professor differs from Baron Dupotet are necessary to the complete understanding of what is to follow. When we use the expression 'differs,' we mean not that there is any disagreement between these two philosophers, but that Dr. Von Schurke practises in a higher department of the science than the Baron, and pursues a different mode of experiment. In the English translation, to which we have so repeatedly referred, are found many statements of the applicability of animal magnetism to other beings than man; to inanimate objects, and even to the elements. The assertion of such propositions is certainly startling; but after the strange effects of this system, of which you have already heard a description, you will not be deterred from accompanying your committee in its enquiry into the validity of these extraordinary claims. With regard then to the efficacy of magnetism on the lower animals, we proceed to relate the experiments which were made on the blue-nosed Joco, in the Surrey Zoological Gardens. Mr. Simpson, a celebrated lecturer on the necessity of teaching infants logarithms, allowed himself to be put in 'rapport' with the Joco, which instantly commenced a lecture on the subject of education, from which Mr. Simpson, with the noble simplicity of humble genius, confesses he derived many valuable hints for his future exhibitions. There was a splendour of diction and a refinement of illustration in the discourse of the Joco, which evidently owed their origin to the magnetic affinity which it enjoyed with the distinguished orator. An ass was afterwards put in 'rapport' with a gentleman of the name of Grote, and immediately delivered a speech in favour of the ballot, which brought tears into the eyes of the whole committee.

"But your reporter hopes you will excuse a longer notice of experiments of this nature, as they differed very little from each other, and the fact is as clearly settled by one well ascertained instance as by a dozen. The next class of experiments to which your committee request your attention has reference to inanimate objects. A few words of explanation will introduce the account of our observation more intelligibly. Dr. Von Schurke maintains, along with all the distinguished professors of animal magnetism, that magnetism is a vital energy seated in the will of the magnetizer, and propelled in an imperceptible manner from the points

of the fingers, or generally from the surface of the body. The *modus operandi* on inanimate nature is this. He impregnates his own soul with a superabundance of magnetic energy—a portion of which, by a strong effort of the volition, he injects into the object to be magnetized. Thus, if a degree of magnetic power represented by the number 9 is required, in order to magnetize two objects, one of which can work up its own volition to the amount of 3, the magnetizer needs only to exert his will to the amount of 6, in order to be effectual. But when this power is needed to operate on a non-sentient being, who is incapable of volition, it is necessary for the magnetizer to impress himself with the full energy of nine, and then, by an additional effort, to bestow the surplus 3 on an inanimate subject. With this explanation your committee goes on with its report.

"Don Von Schurke procured a fowling-piece and a small quantity of powder, and proceeded to the shooting-gallery of a person of the name of Laing. Your committee accompanied him. He laid a small quantity of the powder in the hollow of his hand, and pointed to it with his other fingers for several minutes. He then loaded the gun with it, and having excited in himself a considerable degree of nervous power, he directed the fingers of his right hand to the touch-hole, and in an indescribably short space of time, your committee saw the powder take fire and flash in the pan. The gun was again primed, and Dr. Von Schurke, being somewhat irritated at the failure, accumulated such a superabundance of nervous power, that, on the second experiment, the gun could not resist the impulse, but shattered into a thousand pieces. Happily no accident occurred. Your reporter cannot describe the pleasure and surprise with which your committee witnessed this astonishing effect.

"The day on which this occurred was Monday, the 24th of July, which, your committee begs to remind you, was the most stormy day we have met with for many years, as had been foretold by our distinguished colleague, Francis Moore, Physician. Availing itself of this circumstance, your committee proceeded, along with Dr. Von Schurke to the top of the monument on Fish Street Hill. Having arrived there, and finding the wind most propitious for the experiment, the magnetizer looked the north wind fixedly in the face, till it was evidently overcome, and vered off a little to

the eastward, as if to avoid the influence. At last, however, the whole compass was so completely saturated with the energy, that it was as obedient as a well-disciplined servant. The success of these two experiments produced so great an effect on your committee, that a strong desire was expressed to see the power of magnetism exercised on the most fierce and indomitable of the elements—the element of fire. Your committee finding itself so near the Mansion-house, took the liberty of calling on the Lord Mayor, who, with the noble devotion to science worthy of the chief magistrate of the greatest city in this or any other world, immediately, on ascertaining our wish to have a conflagration on a large scale, deputed Alderman Wood to enable us to make our experiments, by setting fire to the river Thames. The worthy Alderman, by some process known only to himself, excited the combustibility of that majestic stream, and soon produced one blaze of flame from Blackwall up Westminster Bridge. High rose the spiral columns of the destroying fire, and cast a glare against the sky that made the cerulian heaven lurid and red as the vast concave of hell at the Surrey Theatre. The genius of destruction seemed to ride the smoky whirlwind, and direct the ruddy storm towards the steam-boats at Tower Stairs. All was agony, and grief, and wo, and ejaculations, and despair. Your committee was itself cast into a state of prodigious perplexity. But Dr. Von Schurke impressed the angry billows of thick rolling flames with such a mass of magnetic energy, that in one instant the conflagration ceased, and the eloquent alderman was found coughing and sputtering, half-choked with the smoke he himself had been the means of raising. Your committee feels assured that after this it is needless to go on. Your reporter, therefore, reverts to the French Medical Report, so often quoted, and in the name of his colleagues begs to express his full concurrence in every one of its conclusions. The result, in fact, is irresistible to every logically constituted mind, that if one of the claims of magnetism is well-founded, the others are equally so. For we believe it to be one of the plainest rules in investigations of this nature, that an equal degree of evidence has a right to an equal degree of belief; without reference to the absolute credibility of the thing in dispute. Thus, if the same men who depose to the efficacy of magnetism, to the extent of setting to sleep—of endowing with the power of reading without

the organs of sight—of seeing the colour and shape of the viscera of those with whom the magnetized is put in ‘rapport’—how weak, how unphilosophical would it be to refuse belief to matters supported by the same testimony, however unnatural they may appear!

“But it is not for your committee to do more than make its report of what it has seen and heard—the deductions must be left to yourselves. What course of conduct may be pursued on this occasion by the learned and distinguished men to whom this plain unvarnished statement is now read, your reporter has not the vanity or the presumption to suggest. Sufficient for him that he has obeyed your injunctions in tracing, step by step, the progress of your committee’s labours; and whether or not you adopt the system in your practice, and avail yourselves of the means now put into your hands, to render this country, as it ever has been, the greatest and richest field for a discovery of this nature, your committee (who are convinced by the use of their own senses of the reality of the effects of this noble science) will console themselves with the reflection that, in coming to this conclusion, they have shown a freedom from the trammels of reason, of education, and of knowledge, which the graduated practitioners of this country—the Clerks—the Chamberses—the Thomsons—have not yet reached, and probably have no desire to attain to.

“THEOCRITUS BROWN.”

MEETING OF THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, AT LIVERPOOL.

WEDNESDAY, Sep. 13th.

MEDICAL SCIENCE.

(Concluded from our last.)

The remaining experiments are principally directed to elucidate the effects produced by the same class of agents, when applied directly to the nerves.

Experiment 7.—A frog was killed at half-past three, P.M., by destroying its brain and spinal cord. Violent contractions were produced in the trunk and limbs by every species of irritation. One of the legs was then amputated, and the separated nerve immersed in an aqueous solution of opium. At this time it was

observed that *feeble* contractions only of the muscles of the thighs could be produced by galvanising the toes; while the most violent action was excited by the direct application of the wires—a result totally at variance with those obtained by Whytt. At ten next morning, eighteen, and a half hours after death, the muscles still exhibited contractility when galvanised directly, or when the ankle was completed by means of the nerve and muscle; but no effect was produced by galvanising the nerve alone, even in the popliteal space. There was no appreciable difference between the irritability of the leg, whose nerve had been immersed in the opiate, and that of the other which had remained attached to the trunk. In connexion with this experiment, I may remark a singular error into which observers have fallen, in believing that the contractions produced by applying one wire of the galvanic battery to the nerve, and the other to the muscles which it supplies, are any evidence of the persistence of the nervous power. The fact is, that the nerve in these cases performs the part only of a conductor; a piece of moistened twine would be equally efficacious. The only one method of determining the point is by applying both wires to the insulated nerve."

There is one circumstance connected with his experiments which the author is unable to explain, viz., the marked difference in the effects of narcotics applied to the internal and to the external surface of the heart. Dr. Henry believes it to be "inexplicable except on the theory of nervous transmission." When, however, we see that narcotics have by no means generally a destructive influence over irritability—when we see that, applied to nervous trunks alone, they produce no change upon the muscular fibre—when we observe that nerves cease to have any power of exciting contraction *long before* the muscles themselves have lost their irritability (as all the experiments now related most distinctly show)—when we remember that the number and size of the nerves distributed to any organ, bear no proportion whatever to its irritability—that any muscles are utterly insensible to any irritation of their nerves, and that a muscle whose nerve had been divided can recover its exhausted irritability in as short a time and as perfectly as one whose nerves have been uninjured—we shall, I conceive, feel the want of far more extensive and conclusive evidence before we can assent to the doctrine which believes

muscular contractility to be, in all cases, dependent upon nervous influence."

On the Order of Succession of the Motions of the Heart. By O'Bryan Belingham, M.D., of Dublin.

The author disputes the accuracy of the succession of the heart's sounds, as given by Dr. Hope, which are—1. The auricular systole; 2. The ventricular systole, the impulse, and the pulse: 3. The ventricular diastole; 4. The interval of ventricular repose, towards the termination of which the auricular systole takes place. Now, if we lay bare the pericardium in a dog, without causing the loss of much blood, the following series of motions will be observed;—the contraction of the auricles, the dilatation of the ventricle, and if we place one finger on it at this instant, we feel the impulse; immediately, and quickly following the dilatation, comes the contraction of the ventricle, without any impulse; then follows the interval of repose, during which the auricular contraction again commences. The heart of the frog is peculiarly well adapted for observing its motions, as the animal will live for a long time with the pericardium and heart exposed; and the parietes and the ventricle are so thin, that we see it become red with blood as it expands during the diastole, and becomes pale and smaller during its systole. The motions are not so quick either as to prevent us from calculating the period which each motion occupies, those on which I experimented beating about eighty in the minute. The time occupied by the diastole of the ventricle is longer than that of its systole, and the interval of repose is about equal to the systole. The author concludes that the motions succeed each other as follows:—1. The auricular systole; 2. The ventricular diastole and the impulse; 3. The ventricular systole; 4. the interval of ventricular repose, towards the termination of which the auricular systole takes place. As respects the duration of these motions, the diastole of the ventricle occupies nearly double the time of their systole, and the interval of repose is about equal to the time taken up in their systole. And in respect to the sound, the first sound is synchronous with the ventricular diastole, and the second with the ventricular systole.

Observations on the Disease called Coca-bae by the Africans; or the Arabian Leprosy; the Ara-apatta of the Caribbees of Guinea; the Radesyge of

Northern Europe, all of which appear to be identical, &c., &c. By John Hancock, M.D.

The author describes the symptoms of the African and American disease, and endeavours to establish its identity with *radasyge*. He takes no notice of the yaws and sibbens, which are the same as the latter, as appears from the elaborate article on the subject in the last number of the *Edinburgh Medical and Surgical Journal*. The author details the Indian method of cure, but as he only supplies us with the Indian names of the plants, and the genera, without identifying the species, the information conveyed is of a very unimportant nature. The paper, however, is a very elaborate one.

THURSDAY, SEPTEMBER 14th.

Dr. James Carson then read "*A Report of a Provisional Committee of the Medical Section appointed to investigate the Compositions of the various Animal Secretions and the Organs that secrete them.*"

This was understood to have been drawn up by Dr. Rees.

Mr. Simpson read portions of a paper "*On the Contagion of Cholera.*"

Causes and Treatment of Curvatures of the Spine, with a Description of an Apparatus for the Use of Persons afflicted with the Disease. By S. Hare, Esq., Surgeon, Leeds.

As it is desirable that each subject introduced before the section should be curtailed as much as possible, I shall omit any introductory matter, and come at once to the origin of the disease, which is owing chiefly to three causes.

1. The improper management of infants and those of a somewhat riper age, and during the period of growth.

2. The impropriety of dress, and want of free exercise, more especially in reference to young females.

3. To inattention to the digestive organs, and the general health of the body.

In accordance with the opinion just mentioned, I shall dismiss the first and third causes and make a few remarks on the second, as being chiefly instrumental in reducing lateral curvature, which is of the most general occurrence. Deformity is, generally speaking, the product of civilization or rather of fashion. In rude communities, or those in a state of nature, it is scarcely known. We have

here an evil, and a serious one too, occasioned by a foolish and persevering disregard to the plain indications of nature. Strange that human beings, endowed with reason, should so blindly follow a fickle, arbitrary, and self-created power, that leads them to displays of the most fanciful and inconsistent nature; it were well if the evil were deserving of censure, merely on account of its extravagance and folly; it assumes, however, a more frightful aspect; it is too often the fruitful source of debility, suffering, and deformity. For, be it remembered, to it chiefly are to be ascribed, as a primary cause, those morbid affections and irregularities of the spinal column which lead, as an unavoidable result, to nervous irritability, dyspepsia, and a train of other maladies which constantly embitter life.

No article of modern female attire is more injurious in its effects on the constitution than that of stays, which are not only improper in themselves as at present made, but are rendered much more so by the excess to which the tightening or lacing them is carried. A very little reflection will show the manner in which lateral curvature is produced. The upper parts of this article of dress are brought close under the axillæ, and embracing the scapulæ, are tightly girt, or laced behind; this causes pressure on those bones which in their motion press upon the spinal column, and by this compound or double pressure the free use of the arm is obstructed. The various avocations of life unavoidably tend to a much greater use of the right than the left hand and arm, by which means the former are enabled, in some measure, to emancipate themselves from the unnatural and disagreeable restraint in which they have been held, the latter continuing comparatively motionless; hence arises that elevation of the right and consequent depression of the left shoulder, which is so generally observed among the higher and middle classes of females.

The apparatus for the correction of this deformity consists of an inclined plane, about six feet six inches in length and two feet in breadth; at the upper end are two pulleys, which are fixed into a piece of oak, the latter being dove-tailed into the board; the two outer pulleys are about four inches, the centre are six inches from the board, the two outer ones being ten or eleven inches asunder; a similar piece of oak, containing two pulleys only, is fixed into the lower end. About one-third from the upper end of the plane,

midway from each side, an opening is made through it; a little below is a thin light board, eight or ten inches long, and five or six broad, attached on each side the plane by means of tape or twine and small tacks, or a piece of carpet fastened with straps and buckles answers very well. A head-strap, composed of soft leather, padded, is attached to a strong tape, which passes over the centre pulley, to which is suspended the weight. The shoulder-straps, made of the same material, attached in the same way, pass over the two side pulleys. Similar straps with weights, are also applied above the ankles, and occasionally only above the pelvis, and passed over the pulleys at the lower end of the plane. The inclined plane is moveable from one room to another; upon it is placed a blanket, or counterpane, of four or six folds; upon this the patient reclines; the head-strap passes under the chin and occiput, similar to the Hinkly collar and others. An opening in the plane is for the purpose of admitting a strong tape strap, and to the other a weight. This very useful when the shoulders project, or in cases of excurvation. There is a number of other contrivances which I think it would be needless to enumerate; it may, however, be well to mention, that the weights are not on any account to be so heavy as to inconvenience the patient, unless the medical adviser have some particular reason for so increasing them.

The next was a paper by Dr. Holland, "*An Inquiry into the Influence of the Mind on the Heart, and other Organs, in Health and Disease.*"

The first inquiry was, as to the influence of the respiratory organs in the circulation of blood in the chest. He had long investigated the influence of respiration on the circulation of the blood. Strong emotions greatly disturbed the respiratory functions, and consequently the circulation. In ordinary breathing, there was no evidence that the heart was influenced by the brain. The expansion of the chest, caused by a deep inspiration, facilitated the entrance of the blood to two different points, the right and the left of it. The contractions of the heart were modified, according to the quality and quantity of the blood it received. An increased quantity having gone to it, invariably augmented the rapidity of the pulse, but decreased its strength. That fact had been often proved. When the increased quantity of the blood was more

stimulating than usual, the contractions were accelerated, and at the same time pulse was augmented in force. The heart was likely to be impeded in its action by any influence which should determine blood to flow to the chest. There was voluntary and involuntary respiration. In one case, an individual immediately fainted from being requested to take a deep breath; in others, the usual effects of taking a deep breath followed, namely, a quickening of the pulse, but incapable of influencing the circulation in the same degree as when involuntary breathing ensued, the result of deep emotions. Expiration was also a voluntary and involuntary action. They could laugh when they pleased, but the effect of this on the system was not nearly so great as from what arose from involuntary expiration. Syncope and palpitation of the heart, were easily explained on this principle.

Dr. Carson differed from what had been stated. It had been stated by the author that the circulation of the blood was much affected by different states of inspiration and respiration. According to his (Dr. Carson's) views, he thought that the circulation of the blood was very little affected by respiration at all. He meant to say as to the force or quantity of it which passed through the vessels. There was another substance to be taken into question, which left the blood in a great manner in the same situation on inspiration and expiration; and that was the reception of air, by which means the expansion of the chest was accounted for without having any effect on the pressure or suction of the blood. It appeared to him that it was a most admirable provision of nature, by which she endeavoured to fill up the different stages of expansion, of expiration, and inspiration. The theory of the oxidation of the blood in the lungs was considered to be exploded by recent physiologists, and that the air passed into blood as it was; therefore that oxygenation did not arise from any change in the blood. When we sighed, a weak person's circulation was improved. What was the cause? By a deep inspiration the lungs expanded with more force; the heart imbibed a larger quantity of blood, and the circulation was improved. He considered, in opposition to Dr. Barry, that by inspiration the blood was not in any degree aided in coming to the chest.

Dr. Mackintosh read a paper from a medical student. He stated that Dr. Thackeray, of Leeds, had published an able essay, investigating the diseases of

different trades, and the object of this short paper would be to ascertain the nature of diseases of the lungs, occurring in the workers of stone near Edinburgh. A. B., aged twenty-five, a worker in stone at Craighleith quarry, was, two years before his death, bled and treated for a common cold. He so far recovered from the attack, that he returned to his work, but was shortly after again seized with an affection of the chest. Percussion gave a dull sound, the stethoscope showed on the right side respiratory murmur, on the left puerile râle. Death took place on the following September. On dissection, there were found in the lungs twenty ounces of fluid in the right side of the thorax, and four ounces in the left; the false membrane on the pleura fibrous, and four inches of union—a rare disease; for Dr. Alison had only once seen it in the pleura or pericardium. Both lungs studded with black tubercles, hard and melanotic—cutting like cartilaginous projections on the pleura; the bronchial glands were large and hard, when cut grating on the scalpel, which was occasioned by a cretaceous secretion like bone. Analysis of this matter showed it to be the carbonate of lime, silica, and albumen. He mentioned that the man morked in the Craighleith quarry particularly, for Dr. Gregory had made an analysis of the stone from this quarry, and found it to be carbonate of lime, silica, and alumina. The legitimate deduction, therefore, was, that the disease was an absolute deposition of the stone taken into the lungs during respiration, and causing disease and death.

Dr. Macartney stated that he could not agree with the opinion that the fibrous concretions were rare; it did not accord with his experience, as might be seen from the number placed in his museum. The disease commenced with a deposition of lymph which became condensed, afterwards fibrinous, and was then converted into carbonate, and finally into bone. His preparations also show that the black dispersions through the lungs, especially at the root, were frequent occurrences, but those he had seen were not hard.

Sir James Murray presented an ingenious contrivance, something like a slipper-bath, which had an air pump for exhausting the air applied to it. The patient was placed in it, and it was then made air-tight, leaving him a breathing communication with the external atmosphere. The air was exhausted from the interior,

and atmospheric pressure removed from the surface of the body. About a pound of atmosphere being exhausted, took off a ton of atmospheric pressure. The consequence was, where the body was before cold and collapsed, the vessels were immediately filled up and rendered turgid, while it did not at all interfere with the process of respiration. He exhibited another application of the same contrivance, of a long tin tube, made air-tight, and with a piece of wet bladder round one end, which was open; at the other end, which was closed up, a small exhausting air-pump was placed. A patient, with a paralytic wrist, put his arm into this; the wet bladder was tied round his arm at the top, to make it air-tight, and the atmosphere was then pumped out of the tube by the patient himself, or any person. The atmospheric pressure being taken off, the limb became turgid, the circulation was increased, and the part affected was soon cured. There was another adaptation of the same contrivance to the limbs, to draw off the effect of congestion of the brain. There was another application to stop hæmorrhage in an injured hand, limb, or other extremity. An exhausting pump was fixed to the end of a bladder, the limb was put into the bladder, and the neck then tied round to make it air-tight. The air was then completely exhausted by means of the pump, which compressed the bladder so close to the skin as effectually to stop even the pores of the skin. The same contrivance of a bladder and exhausting-pump was also applied for the cure of ulcerated legs, by preventing the evaporation of ulcers, by exhausting the air, and making the collapsed bladder adhere tightly all round. There were several other contrivances and application of the same invention, the exhibition of which, and the inventor's happy humour, elicited loud applause.

Dr. Carlisle related two cases of malformation of the brain. One was a female, in whom the skull was found to correspond with the size of the brain. A section showed the mass of brain small—no deficiency in the anterior part; convolutions small, but sufficiently distant; cerebellum only a quarter of the natural size; arbor vitæ, and principal branches from it, membranous-like; cerebral ganglia not distinct; pons varolii small; no grey and white matter; corpora striata small; pineal gland containing clusters of follicles. Organs of generation remarkably well-developed, resembling considerably the organs of lower animals; hymen wanting.

He was unable to obtain any history of the case; but from the absence of the hymen, and the full development of the generative organs, he inferred that she had had intercourse with the male, and that from her unattractive appearance she had solicited the intercourse, rather than been solicited.

Case 2.—He had ascertained the history of this case. The house pupil had ascertained that the man was a mendicant; that he was born deaf and dumb, but had sufficient intelligence to read and write. His muscular structure was well developed, and he had marks on the groin and penis of previous venereal affections. He had a well-constructed brain. The cerebral membrane deficient; and all the vermiform process gone. He had been induced to bring these cases forward, to make inquiry how these could be accommodated to the theory of Dr. Spurzheim. He cited several other similar cases from other authorities besides these, where there was a deficiency of cerebellum, and at the same time strong animal passions. This class of cases had been completely overlooked by the advocates of phrenology. They did not find a large brain always accompanied with great talent, or a small one with deficiency of mental powers. The bone of the race-horse was not so large as the cart-horse's, yet it was much denser and stronger. They knew many persons of but small muscular development, who had greater strength than others who had greater muscular development. The size of the finger did not determine the power of touch. So far from size being necessary, large and small parts possessed equal powers. They were not to look at the size of the brain only as showing power, but to take into consideration the organization of its natural parts. Tiedemann had asserted that the negro brain was perfectly equal in size and in weight to the European; but this was not the way to ascertain the quality of the brain. Up to a certain period he believed that the child of the negro was equal to the child of the white man; but if he was to be taught mathematics he broke down at once, and the white child passed him. He inferred from that fact that the brain of the negro, though equal in size, and corresponding in external relation, yet in the internal structure was deficient. And even further, amongst the brains of Europeans, a great difference in the internal structure was observable between individuals possessing a greater or less degree of intellectual power.

FRIDAY, SEPTEMBER 15th.

Dr. Warren, of Boston, U.S., was then called on for his paper on "*Some Remarks on the Crania of the Mound Indians of the Interior of North America, as compared with the Crania of the South American Indians of Peru.*"

As a stranger, though not exactly a foreigner, he felt it his duty, for the very valuable information he had received at the meetings of that section of the Association, to make some contribution towards the facts which the British Association had so sedulously collected. There were some facts peculiar to that district of the world in which he resided, which, of course, could not come within the cognizance of the members of the Association, and he would endeavour to state them: whether they would be considered important or not, would be for their consideration. A considerable number of years ago, he accidentally came into the possession of a cranium which struck him as an extraordinary one, and on examination he found that it differed from the crania of all the well-known nations, and the individual nations composing those races. He was led by this to make some inquiry into its history, and he ascertained that it came from the banks of the Ohio river, far back in America, in what is called the Western country, and that it was discovered in a cavern on the top of a high and almost inaccessible rock, at the distance of about forty or fifty feet from the banks of the Ohio, by some hunters, who took refuge in the cave. They there found the skull, and the bones of the skull, in a fine state of preservation. The bones were so situated that they might have been there for several ages without decomposition, the calcareous rock which formed the bottom of the cavern, absorbing all moisture. From the inaccessibility of the place in which they were found, it is probable they had remained there for centuries. It was natural to suppose that this head must have been one of the aboriginal Indians of North America; but, on examination, he ascertained that that was not the fact, its whole structure being different to the Indian crania. He suspected that it might have connexion with those races which had been discovered to be deposited in the ancient works or mounds of North America, and he soon obtained heads from that part of the country, and satisfied himself of the fact. He would presently state the particulars in which they differed from other heads.

They had frequently heard of the mounds in the interior of North America. They were exceedingly curious, and were found in the wilds which had scarcely been trod by the foot of civilized man, and were covered by immense forests. They found elevations of earth which were quite extraordinary, and would be so even in any country. These mounds were covered by immense trees, and the observer were struck at once with the great antiquity which must belong to them. There were different kinds of mounds. There were some which had a great resemblance to fortifications, regularly made, and of considerable extent. There was one at Cucum, which was more than a mile in diameter, and which was surrounded by a high kind of wall or fortification, about thirty feet in height, with regular openings in different parts of it, and these openings guarded by interior works, similar to fortifications to defend the entrances to apertures in fortifications in the present day. These mounds were generally situated near the confluence of important rivers; there was one at the conflux of the Ohio and Muskingdom rivers; they were so situated as to command the passage of the rivers. The mounds in the interior of these fortifications were perfectly regular, flat on the summit, and frequently a sort of bowl or centre part on the top of the summit. They were apparently intended for the purpose of interment, and partly for places of worship; probably the excavation found on the summit was a place where human sacrifices were made. Some parts of the work of these mounds were similar to parts found in South America, in the great temple at Calumna. These works were of very great extent, extending a length of 1000 miles, from the banks of the great lakes in Canada to the Gulf of Mexico, and filled all the most fruitful parts of North America. The head he had spoken of as having obtained was taken from one of these circular mounds. The head in question, in common with all the heads taken from those mounds, differed from the Indian and European formation. There was less extension of forehead than in the European head, but it resembled it; the elevation of the forehead being equal to the *Caucasian* race. The vertex also was uncommonly elevated. The seat of the organ of veneration seemed to be very much developed, and it was evident that they were a very religious nation, for there was evidence that they made many sacrifices. The formation of the skull approached to the Peruvian. But the most remarkable fact was the flattening of the occiput, which gave the cranium a particularly rounded form, and some even were quite circular. The occiput also was almost always more flattened on the right side than on the left. Another peculiarity in these heads was, that the palatine fossa was of a rounded form, but this arose from its narrowness. The lower we descended in the scale of races, the nearer we approached the animal formation. They knew that in the animal formation the jaws were very elongated, which gave them greater perfection in taste and smell. There was an approximation to the African race in a small degree in the North American Indian; but as we rose to the *Caucasian* race the palate was shorter and smaller; so that probably taste and smell were inferior in the *Caucasian* races. So that animals probably had a power in discriminating noxious smells and herbs which we had not. After he had been in possession of these heads for a number of years, he was anxious to generalize his remarks. When he was expecting contributions from the interior part of the country—for the mounds were situated very far from the part where he lived—many thousand miles—it was difficult also to obtain these bones, as many of them were found in a state of decomposition—he found one morning three heads lying on his table, the party who left them having gone. He immediately examined them, and stated them to be skulls of the Mound Indians. But a few days after, the gentleman who had furnished them came to Boston, and said to him that these heads were the heads of Peruvians, and that they were taken from an island near the city of Sinia, a place renowned amongst Peruvians, where *Mango Capac* was said to have descended from the sun in order to enlighten the Peruvian race. He afterwards showed the skulls to Dr. Spurzheim, and he said they were all precisely of the same race. He perceived that the organ of constructiveness was peculiarly developed in all these heads. This led him to inquire further into the history of Peruvian heads, and he found three descriptions;—one similar to the one he had been describing, having a flattened occiput, temples wide, and forehead particularly elevated. But there was another description much more common, which was of an oblong form, and very much resembled an egg in shape. In this, the occiput, instead of being compressed and flattened, was very prominent

indeed. Then there was a third kind of Peruvian head, which did not exhibit any marks of compression. The first kind were all remarkably regular, and wanting in symmetry. The heads had evidently been artificially flattened in the occipital and frontal part, and were well-known to belong to the *Inca* race of Peruvians, as they were taken from the place where they were buried; and they also had some specimens of the people amongst them.

[The lecturer here described that a whole family of the noble race of Inca had been buried with their clothes, and every part of them in a surprising state of preservation, just as they lived before the Spanish conquest. The tomb in which they were found, was circular, like a well, lined with bricks, and near the bottom a flat stone was put down, supported at the sides like a floor, leaving a large cavity underneath the tomb drained off the water and damp, and the bodies were thus preserved.]

Having traced the exact similarity between the Mound skulls and the Peruvian skulls of the Inca race, the conclusion was irresistible, that these two people had a cognate origin. Now they were situated at a distance of 1000 or 1500 miles from each other, and the heads of the intervening nations were entirely different from the one or the other. At first this appeared to him very extraordinary. And here he might remark on the great importance of investigations by anatomists to point out the history of these nations, which tradition did not hand down to them. There was a race between these two races, and they had heads almost as flat as a pancake.

[A Peruvian head was here exhibited, which had been subjected to artificial compression, and which was nearly square being perfectly flat behind, and nearly so on the forehead.]

He must say, for the benefit of phrenology, that so far from the intellects of these flat-headed persons being inferior, the Indians who possessed them were quite equal in intelligence to those of the same nation. He had the head of a celebrated chief who had a most extraordinarily flattened forehead, and he was known to have remarkable talent. In fact, no person was thought of any consequence in that country, unless he possessed a flat head. (A laugh.) They then legitimately inferred, that these two nations were closely allied to each other—that was, the nations who inhabited the

mounds, and the Peruvians, because there was no resemblance between the heads of those nations, and any other heads that were known. He might conclude with just intimating, that there had been observed to be a resemblance between these two sets of heads, and the heads of the Hindoo race; the same rounded form, and similar smoothness in the bones of head and face. The conclusion drawn was, that the race of the Mound Indians was entirely dissimilar to the North American Indians; and second, that they were entirely similar to the Peruvian race, which would lead to the inference that these two were one race, which was an evidence also, that the American Indians had emanated from two different sources, one from the South part of America, and the other from the North West Coast.

Professor Evanson read a paper, in which he examined the different methods of determining the functions of the brain. He objected to determining by experiments which injured the brain—by pathology, and by comparisons with parts of the body; but a superior method had arisen with Gall, observations by which the brain was shown not to be a single organ, it was a compound one, and different parts had distinct functions. This had become the science of phrenology.

Dr. Mackintosh was then called upon for his communication on "*Morbid Anatomical Appearances of some Cases of Cholera.*"

He contended that the mere morbid anatomist was not a pathognomist; and that the researches of the pathognomist were infinitely more valuable to science. He had made about three hundred dissections of cholera patients, the whole of which had been conducted by himself. He began his investigations without any knowledge of the disease, further than that there was a lost balance of circulation, and that fever followed. He had not been investigating the subject a fortnight before he found that this was incorrect. The very remedies in use for recovering the lost balance of circulation were positively painful to the patient. The cry was for exposure and cold drinks. One grand circumstance was, that the body was of a dark colour. The question arose, on what that depended. He found the cause of it was, that every capillary vessel was distended with blood, therefore there was no lost balance in the circulation. After death the body still retained its livid colour, and would still bleed. In every examination he found the same dis-

tension with blood in both the arteries and veins. It had been ascertained by Dr. Shaughnessy, that the serum of the blood was deficient in cholera, and the result was that they could not get the blood to flow; it was too thick. There was no doubt but that the blood was deficient in its serum, in the albumen, and in saline particles. The accumulation of blood was not in one organ or in any set of organs, but in the vessels of all the organs they found accumulations of blood. He had taken dimensions of the abdominal aorta in one case, and it was the enormous size of one inch in diameter, or three inches in circumference. The vena cava was one inch and three-fifths in diameter, it was enormously distended with blood. In the brain there was great vascularity, more so than in inflammation itself. So that there did not appear to be such a deficiency of blood as there was bad blood in cholera. The very bones were vascular, and the vessels gorged with blood. Coagulated blood was found in the sinuses of the brain in the collapsed state. He had found the ventricles gorged with a fluid, &c.; by this he had found out that there was a communication between the ventricles and the spinal marrow. The same vascularity was found in the spinal marrow, and even in the fourth ventricle of the brain. The lungs were excessively heavy, being gorged with blood, weighing as much as 3lbs. 9oz. without the heart. It had made his heart bleed to see the wrong manner in which patients were treated. One man had got a medal for smothering his patients between two feather beds. Another had abused him for not bastinadoing the feet of his patients. In some cases they had absolutely seared their patients with hot irons, under the mistaken notion of restoring lost balance in the circulation. He had found the ganglia invariably healthy, but very vascular. Coagulum extended from the right side of the heart into every direction of the lungs. He had also observed ecchymotic patches on the aorta, and on the heart. The heart was also excessively red and vascular. He had found a false membrane lining the whole coat of the arteries, growing more dense as it approached the heart. He was of opinion that this was an effort of nature for the formation of serum. These appearances could not be the result of any morbid change, as he had stood with the knife in his hand after a patient had died, and it would shock non-medical persons to hear the shortness of time in which he

had dissected cholera patients after death; but it had been done for the best possible reasons. The gall bladder was generally enormous, and filled with calculus, from which he inferred the cholera always picked victims from dram-drinkers with diseased livers.

Considerable discussion took place on this, in which Dr. Mackintosh inferred that the blood was thick for want of serum, and that its thickness made it difficult for the heart to pump it, and hence the weak pulse in cholera. The first symptom in cholera was a watery diarrhoea, which he considered to be a pure discharge of serum, which brought the blood into its thick state. During the delivery of the paper Dr. Mackintosh exhibited some very beautiful preparations taken from cholera patients, to show the extreme vascularity which existed.

ANNIVERSARY DINNER OF THE BRITISH MEDICAL ASSOCIATION

It is impossible to contemplate the progress of the British Medical Association, and review its important proceeding, which will be found in another page, without deep interest. Scarcely nine months have elapsed since the origin of this institution, and notwithstanding the venomous abuse which was poured upon it by some, whose worldly interests prompted them to endeavour to check its progress, and, by others, who in the cause of independence, have cautiously pursued a serpentine course to, adapt themselves to any "change of the times," whether in the "council" or in the "senate," this association has surmounted every difficulty which had been cast upon its path, and made a progress more rapid and substantial than its best well-

wishers could have reasonably anticipated. It may now, indeed, be considered as a regularly organized body ; and the members have only to use their sound judgment and discretion in selecting those points for animadversion, and endeavouring to correct those abuses which are most within their power to remove. They must be aware, that in the chaos of monopoly and misrule which exists in the medical corporations, it would be in vain to attempt to improve, far less to alter the *whole* of the present system of things ; and it therefore becomes the medical reformer, to select only those parts of *the system* for his particular consideration, which he is most likely to be able to amend.

The unanimous decision of the Association to petition parliament for the purpose of altering and amending the Poor Law act, appears a most rational and judicious proceeding, and a legitimate object for their interference. It is quite certain that the interests of the sick poor would be long before they claimed the attention of any of our three immaculate medical corporations ; so that this patriotic effort of the British Medical Association ought to be hailed with satisfaction by all those who are really interested in the fate of the sick poor. In accomplishing this great national object, the advantages to society will be two fold, for it will have the effect not only of causing a larger sum of money to be expended by each parish in acts of charity and benevolence, but it will also have the indirect effect of elevating the character of the medical practitioner, by whose hands such acts are best administered. It is impossible to reflect on the working of the present bill, and witness the infamous traffic, of which the sick poor are the unfortunate sufferers, without offering our sincere wishes for the successful efforts of

the Association ; and we trust, before long, that inexperienced and unprincipled adventurers will no longer be permitted to disgrace the profession to which they belong, by undertaking to attend a poor man on his sick bed and providing him with medicine during twelve months for the sum of *one shilling* !

The next great object which has been discussed by the Association, and which many of its members seem very anxious to accomplish, is to render the profession *ONE* and *INDIVISIBLE*, a desire to fulfil which is fraught with difficulties, though not on this account the less worthy of the serious attention and vigorous efforts of the Association, we allude to their "petition to Parliament" praying for the establishment of *ONE FACULTY OF MEDICINE*. There is only one opinion amongst the intellectual part of the profession on the ineffective, corrupt, and degraded condition of the existing medical corporations in this kingdom, but still it would be difficult to induce a government so to remodel them, as to meet the views of all reasonable reformers ; and we therefore cannot help using our endeavour to impress on the minds of all those, who have the interests of their profession at heart, not to look to the interference of a *legislature* for any substantial amendment in their condition ; but rather to place their hope in a warm co-operation and harmony amongst themselves, and to observe such conduct towards each other, as well as to the public, as will ensure the approbation of all classes of the community. In attempting to *elevate* their own condition, let them ever remember, that this cannot be done by any endeavour to *lower* others. The highest of our professional brethren have enough to humble them, and in place of deteriorating whatever good qualities they may possess, let the Members of the British Medical Asso-

ciation endeavour to elevate themselves, only by pursuing that line of conduct, which cannot fail to place them in the same professional rank, with those who now consider themselves in a higher position. To acquire this position, and thus make the profession one body, it is needless to suppose that such an important object can be accomplished, simply by establishing one system of medical *education*, for at the present moment, there are individuals in the most humble walks who have gone through a system of education, far more extended than many, who belong to what is termed the highest "grade" of the profession. The real cause of the existing distinctions amongst medical practitioners, we have no hesitation in affirming, arises from those differences in the modes by which each grade is remunerated; and as long as one class of practitioners, either from choice, or from what they may conceive to be their worldly interest, are remunerated by being paid for *medicines* they *furnish* and prescribe, they must not expect to have the same rank as those who receive only a honorarium for their advice. In this respect, the medical profession resembles all others, for in every avocation in life, a similar distinction of rank is perceptible; and in some even to a greater degree than in medicine. In all branches, the retail dealer does not enjoy the same position in society as the general merchant, neither is the merchant on an equality with the landed proprietor. These distinctions have ever existed, and must ever exist in all civilized society, as they constitute the very essence and form the very basis of civilization, fostering, when duly regulated, the best feelings of human nature, and prompting to the noblest actions.

THE WESTMINSTER HOSPITAL.

REDUCTION OF FEES.

It is gratifying to us to be enabled to announce that the medical officers of this hospital have reduced the fee for medical and surgical attendance, to the comparatively moderate sum of *Twenty-five guineas*. It is now some months since we pointed out the advantages which would arise to the medical officers of both of the Westminster and Middlesex Hospitals, if they would reduce their attendance fee; and the expediency of the measure appeared to us the more judicious at that moment, in consequence of the *liberals* of the North London Hospital having contemplated casting away the benefits which had befallen them from their *low fee*, and proposing to raise it to all students, except those who would submit to listen to some of their prosy discourses. We have every reason to believe, that amongst a certain class of students, the base attempt of the medical officers of the North London Hospital to extort an additional sum of money from pupils, has been received with those feelings of indignation, for which many of the transactions of the Gower Street tradesmen have been so remarkable; and it is, therefore, with much satisfaction we perceive that the Westminster Hospital has now outstripped all the other hospitals in the low amount of the student's fee. We regret to say that the narrow-minded policy of the Middlesex Solons has prevented them, as yet, from profiting by the example of the past; though we feign hope that the additional demand of the Gower Street Company, will send to the Middlesex some of their old customers. The conduct of the medical officers of the Westminster Hospital, considering its intimate union with the Council of the College of

Surgeons, through the medium of two of its members, more particularly by its late President, is deserving of notice, as it augurs most favourably of the intentions of the *liberal* members of that council, and marks their desire to afford the student of medicine of this metropolis the means of acquiring professional knowledge on more reasonable terms. We are indeed prepared to learn that such will be the increase of the number of the students from the reduction of the attendance fee, that "the funds" will wear a different aspect than they have done for some time past, under the old regime. We consider ourselves justified in this prediction from what took place at the North London Hospital, as every one must be aware, that few, if any, students ever would have entered to that institution, had not the commodity, with all its imperfections, been offered at "half price."

NORTH LONDON HOSPITAL.

THE LITHOTRITY CASE.

It may be well to inform those who have written to us, and one correspondent in particular, who has done so in not very courteous language, that the investigation of the Hospital Committee, and the evidence brought before them, will be laid before the public in due time. The investigation has been attended with a good deal of delicacy. For the proppers of the University are quite aware that the question which will ultimately come before them for decision, will be, whether they shall defend the faulty, or endeavour to shelter the honour, and integrity, and skill of one of their own body.

If we could venture, in this stage of the investigation, to give an opinion on the subject, we would augur favourably of

the conduct of the committee, from some observations made by Mr. Cooper in his introductory lecture on the *moral character* of medical men.

REVIEW.

Histoire des Maladies Observées a la Grande Armée Française, Pendant les Campagnes de Russie, en 1812 et D'Allemagne en 1813. Par le Chevalier J. R. S. DE KERCHOVE. Anvers, 1835. History of the Diseases observed in the Great Army of France in Russian and German Campaigns of 1812 and 1813.

The next subject discussed by our author is that of *diarrhœa*, which he states to have been one of the prevailing diseases in the French army at the eventful period of which he writes. He describes it as consisting in liquid and frequent stools, and as having its seat in the intestinal mucous membrane. In some of the soldiers it was preceded, and in others accompanied by anorexia, pains in the abdomen, nausea, sometimes vomiting, a feeling of weight in the intestinal canal, &c.; which symptoms generally abated on the third day. In several of the patients so affected there was violent colic, thirst and dryness of the skin. The intestinal irritation often went so far as to produce tenesmus. In the majority of the cases, there was a bitter taste in the mouth, and the tongue was loaded with a yellowish or whitish mucous coat.

Diarrhœa may be excited by the ingestion of acrid substances, by food of difficult digestion, by excessive quantity of food, by a superabundance of bile, by a peculiar acrimony of this fluid; by external causes; it may, in a word, arise from the use of all those substances capable of irritating the intestinal mucous membrane; from the action of cold on the surface of the body, from the suppression of the transpiration; from causes which may weaken the alimentary canal, &c. It may likewise be occasioned in persons of great nervous irritability by a strong mental emotion; it then assumes the name of *diarrhœa*; this latter variety however does not affect soldiers. Gastric affection is oftentimes the proximate cause of alvine dejections observed in armies, as it is known that mere irritation of the stomach is sufficient to excite vio-

lent watery stools. The diarrhœa often occurred as a secondary affection. In the French army the diarrhœa, being of the mucous or bilious species, was produced by suppressed perspiration, by privations, by the use of coarse and irritating food, by exhaustion, and probably more particularly by an increased secretion of bile which had been rendered acrid by a variety of causes, such as fatigue, bad food, and atmospheric influence. This latter cause our author is strongly disposed to consider as a frequent cause of intestinal irritation.

In the autopsies made by our author he found the intestinal canal ulcerated, and frequently bare erosions of the mucous membrane with actual disorganization.

With respect to *treatment*, the disease frequently passed off without any medicine; mere attention to diet and rest sufficed. But when the employment of medicine appeared necessary, the author gave in the first instance an emetic, which he invariably found to answer his expectation; to use his own forcible expression, "it tore up the evil by the root in very many cases." If the evacuation of the cause of the gastric irritation was neglected, the disease soon became complicated with typhus, by reason of the sympathetic influence subsisting between the brain and the intestinal canal. *Ipecacuanha* he preferred as an emetic to tartarized antimony in consequence of the latter substance being disposed to act on the intestines and so excite purging, whilst the action of *ipecacuanha* is confined to the stomach. Even gastric disturbance did not prevent him from giving the emetic; he employed it with the view of determining to the surface. The derivative of revulsive power also which the emetic exercised recommended it strongly. In order to promote still further the action of the skin he employed pediluvia, and warm baths. Our author is a warm advocate for the use of warm baths in every case. Sudorifics were the medicines employed by him after the emetic, more particularly if the disease appeared to have been caused by suppression of the cutaneous transpiration. Dry frictions along the back and extremities were also employed.

Whenever the disease appeared to be occasioned by general debility, as frequently occurred among the soldiers, he employed a strengthening regimen suited to the state of the patient, combined also with tonics.

When the intestinal irritation was very

severe, marked by severe pain and a continual desire to go to stool accompanied with ineffectual efforts, he then prescribed mucilaginous mixtures, rice or barley water as the ordinary drink, demulcent lavements, emollient fomentations or cataplasms to the abdomen; and if the patient was not too much exhausted he combined with this treatment the application of leeches to the anus, followed by warm baths, hot cataplasms to the legs, frictions over the surface of the body, and strict attention to diet.

When the irritation was on the decline, he found blisters or sinapisms, applied to parts remote from the seat of the disease, productive of much benefit; and with respect to internal medicine, nothing answered so well as a solution of gum-arabic, a decoction of marsh-mallow, of rice or barley, with the aqueous extract of opium, or with laudanum; if the patient complained of pains in the abdomen, he employed opiate frictions over the seat of pain; mucilaginous lavements with laudanum, or lavements prepared with poppy-heads, or marsh-mallow leaves. The same remedies, more particularly the opium, combined with aromatic infusions are indicated in the treatment of the nervous diarrhœa above mentioned.

Whenever the author conceived the diarrhœa to arise from an affection of the liver, to the remedies already mentioned he added mercurial frictions to the abdomen. He considered that these frictions by stimulating the lymphatic system, acted as useful derivatives, and that in several cases they may remove local irritation or inflammation, the character of which may be absolutely acute, or else after the inflammatory acute stage has been sufficiently combatted by blood-letting.

After following this plan of treatment it disappeared in general at the end of six, eight, or ten days; relapses were very frequent; the slightest deviation from strict regimen sufficed to bring it back and to aggravate its cause. When the disease continued beyond the sixth, seventh, or eighth day, it assumed an asthenic character; it sometimes changed into lientery. The disease having continued for a considerable length of time, and the alvine evacuations being still kept up by the relaxed state of the intestinal mucous membrane, a chronic form of the affection remained, the treatment of which our author details in

Chap. 5, under the head of *Dysentery*, which is characterized by frequent and

unnatural stools, accompanied with tenesmus and acute pains in the abdomen. Dysentery, which is more common in hot than in cold countries, is a very frequent disease in camps and armies, when the soldier is badly fed, exposed to moisture or to sudden transitions from heat to cold; and more especially when a large body of troops tarries for a long time in one place, where the rules of hygiene are neglected. This disease generally appears in summer and in autumn, after intense heats, principally towards the end of summer, when bilious affections are most generally observed; or else at the commencement of autumn, if the days are hot and the nights cool.

The occasional causes of dysentery are the same as those of diarrhœa; moreover, these two diseases, at the time of a dysentery, always prevail simultaneously. These causes will produce dysentery in one person who is predisposed to it, whilst in another they will produce only diarrhœa. The distinction generally made between these two diseases, and which is founded on the intensity of the symptoms, our author considers futile.

By dysentery he understands an inflammation the seat of which is in the mucous membrane of the large intestine, and which chiefly affects the colon; an inflammation which follows the stages usually followed by catarrhal affections, and is distinguished by the following phenomena; fever more or less intense, colic sometimes very violent, vain and repeated efforts to discharge the bowels, tenesmus, mucous discharges, which are most frequently bloody and in very small quantity, though the stools are frequent, extreme contraction of the rectum, with a feeling of burning heat in the part, &c.

The ordinary causes of dysentery were the same in our soldiers as those in diarrhœa, only that they acted with more violence on the intestinal mucous membrane. He thought he observed that dysentery appeared rather in those individuals who had great irritability of the intestinal canal, so that the irritation produced on the intestines, either by a suppurated transpiration, or by coarse and bad food, or by the presence of a superabundance of acrid bile, &c., becomes developed with more violence.

With respect to contagion as a cause he does not think that the disease can be transmitted in that way, not even in its complication with typhus. He thinks, however, that dysentery may be caught by remaining in an atmosphere infected

with miasms exhaled by dysenteric dejections.

Dysentery may terminate in the same manner as enteritis. The fever may continue during the entire course of the disease, when it terminates fatally. It occasionally happens that the fever disappears while the dysenteric phenomena still continue. This disease, after having continued for some time, may change into lientery, often into chronic diarrhœa, resulting from ulcerations of the large intestines.

Treatment.—In the first three or four days, which he calls the *first period*, before irritation became developed, our author found the greatest benefit from an emetic of Ipecacuanha. When the disease depended on suppression of transpiration, he prescribed sudorifics after the emetic, hot baths also, &c. Beside these means he employed emollient lavements.

When he had reason to think that the disease arose from irritation produced by the presence of acrid bile in the intestines, he employed mercurial frictions over the region of the liver, and he followed up the emetic with emollient mixtures and mucilaginous lavements. Where the disease was occasioned by indigested substances, he sometimes found benefit from employing a solution of manna, a weak decoction of senna leaves, &c.; he thinks, however, that purgatives so much recommended in the treatment of dysentery, are not only inapplicable, but often injurious by increasing the irritation.

In the second period of the disease, when the irritation is fully developed, emetics and every thing stimulating must be abstained from; the intestinal irritation may then be so intense as to render blood-letting necessary; it should be employed, however, with circumspection. When the patient is robust and the inflammation at its height, general bleeding may be indicated; local bleeding, however, by means of leeches to the abdomen, and principally to the anus. In this period strict attention to diet is necessary; the abdomen should be covered with fomentations and emollient cataplasms; mucilaginous lavements should be given, and by way of deviation pediluvium should be employed, and hot cataplasms should be applied to the extremities; and if there be no febrile reaction remaining, blisters or sinapisms should be applied to parts remote from the seat of inflammation, &c.

Bloodletting practised in the treatment of the dysentery which prevailed at this

time in the French army was generally found to be injurious in consequence of the exhausted state of the men, and by reason of the tendency to typhus, which was found to exist. When the disease is on the decline, or has passed into the chronic state, the application of a large blister to the abdomen has been found beneficial.

Where the dysentery seemed to depend on general atony, as [was marked by the almost total absence of fever, an analeptic regimen was recommended; frictions with volatile linament and laudanum or with aromatic fomentations over the abdomen; blisters to the thighs or on the back; lavements with laudanum: tonics combined with mucilaginous preparations, such as a weak infusion of rhubarb with tincture of canella.

The transition of dysentery into the state of gangrene was recognized by the diminution or sudden cessation of pain, general prostration of strength, alteration of the features, meteorism, cold sweat on the extremities, falling of the pulse, &c. As soon as a tendency to this state appeared, the author employed aromatic infusions, decoction of bark, camphor, ether, with opium, and gum; also aromatic fomentations and frictions with ammonia and camphor over the abdomen; blisters or sinapisms; aromatic lavements containing camphor and laudanum. The same regimen was observed in dysentery as in diarrhoea. When the disease after lasting for some time passes into the chronic state, and the alvine discharges are now kept up only in consequence of the relaxed state of the canal, the disease changes into diarrhoea, and requires the same treatment as the chronic form of that complaint, which our author conceives is best treated with tonico-astringents combined with opium; the opium should be given in a large dose, commencing by two or three grains to be taken in the twenty-four hours, and increasing it gradually up to fifteen or even twenty grains. The author here strictly cautions us to beware of the premature use of opium and astringents, as they never should be employed, as long as the intestinal irritation is of an acute character, nor if the intestinal evacuation is supposed to be occasioned by ulceration in the intestinal canal. An emollient plan of treatment should then be adopted; a seton should be established in the lumbar region or issues in the thighs, as well as mercurial frictions over the abdomen. The author has also found great service

from simaruba bark in the treatment of the chronic forms of the diarrhoea and dysentery, as also rhatany root, and columbo root in decoction, with which remedies he combined opium and mucilaginous preparations.

We shall probably give in some future number further extracts from this really practical work. The near approach of the new medical session will, we trust, serve as our apology for not going farther for the present. The length we have gone will, we are sure, sufficiently mark the importance of the work.

ANNIVERSARY DINNER OF THE BRITISH MEDICAL ASSOCIATION.

A very numerous meeting of the Members of the British Medical Association was held on Saturday last at the London Coffee House, Ludgate Hill, when Dr. Webster the President was in the chair. Among the visitors were Dr. Grant, Dr. Marshall Hall, Dr. Ryan, Dr. Harrison, Dr. Roe of Epping, Mr. Ceeley of Aylesbury, and several other gentlemen. A Report of the Proceedings was read by the Secretary, Mr. Wagstaffe, by which it appeared that the Society had advanced as rapidly as its sincerest friends could have wished. A petition to Parliament praying for the establishment of a Medical Board to advise the Poor Law Commissioners was numerously signed, and another praying for the establishment of one Medical Faculty, or a tripartite Faculty for each section of the kingdom. Resolutions were also adopted, that the Members of the Association should decline to give Certificates to Insurance Companies unless on receiving remuneration, Dr. Marshall Hall, Dr. Granville, Dr. Harrison, and Mr. Hooper, severally addressed the Meeting on this subject.

When the business was concluded the Members and Visitors sat down to dinner, which presented all the delicacies of the season. After the usual toasts, the President proposed 'Success to the British Medical Association,' which was loudly applauded. Dr. Webster gave a clear and eloquent account of the objects of the Association, and acknowledged the obligations which the Society owed to the Medical Press, which was entirely with them, except "the homœopathic portion"

(great laughter). He thanked the other editors in the name of the Association, and concluded by proposing the health of Dr. Ryan and the Medical Press."

Dr. Ryan returned thanks.

The next toast was the "Lecturers of the United Kingdom,"—when there was a general call for Dr. Grant, who returned thanks, after a well delivered address.

The other toasts were—the "healths of the distinguished visitors present," for whom Dr. Granville responded in an eloquent speech—and the health of the Stewards was drank, for whom Dr. Marshall Hall returned thanks.

The last Medical Toast was "The Fathers of Medical Reform," for whom Dr. Harrison returned thanks; Mr. Hilles, Dr. Roe, Mr. Evans, Mr. Wagstaffe, and other gentlemen also addressed the meeting.

The conviviality continued until 11 o'clock, "when the feast of reason and flow of soul" concluded.

USE OF ERGOT OF RYE.

To the Editor of the Medical and Surgical Journal.

Sir, I perceived in your number for September 30th, an article strongly recommending the ergota has a remedy of the highest importance to the obstetrician. In these cases which I forwarded to you for publication, and which appeared in your journal for the 16th of September, there is a typographical error, which I now wish to correct,—the quantity of water mentioned is ʒiv ., I never infuse the ergot in more than ʒj . of tepid water, which I find to be the quantity stated in my note book. Your correspondent, Mr. Rose, appears to think the powder is not so effectual as the tincture. I have tried T. in various forms repeatedly, without observing the least increase of uterine action, and am lead from ample experience to give preference to the powder. The ergot has had many opponents, but I can, with confidence, recommend its administration, having given it in upwards of 1200 cases without any unpleasant symptom having occurred in any one after. It not only saves a great deal of time to the medical attendant, but likewise shortens the duration of the patient's sufferings, and puts in a very short time an end to all those unpleasant feelings which every practitioner must have observed while attending a tedious labour.

I am happy to find the veil of prejudice is rapidly disappearing, and the utility of the ergot becoming more generally known and appreciated. I have not the least doubt that a few years every obstetrician will, like Mr. Rose, acknowledge its efficacy in producing uterine contractility, and I consider it to be the duty of every one in this our enlightened profession, to make public those means by which the sufferings of humanity are shortened or mitigated.

I was called upon to attend on the 10th of March, 1835, Mrs. T., mother of six children, of a strong and robust habit, she had been in labour for three days previous to my being sent for, I found her exceedingly weak from loss of blood, face blanched, pulse quick and tremulous, nausea urgent, pains frequent, but weak. On examination I found the os uteri dilated to the size of a half crown and thin, the placenta was placed over the os uteri, on running my finger round the os, I found a small portion of the placenta detached, and on introducing my finger within the uterus, I found the membranes tense, the head presenting, and the soft parts dilatable. In this case the vital energies appeared to be rapidly sinking, I immediately gave her ʒj . of secale cort. in ʒvj . of neat brandy, in a few seconds after its administration, her pulse became more full and steady, accompanied with increased action of the uterus. I then proceeded to dilate the os externum, os internum (first lubricating the back part of my hand with lard) which I easily effected. On arriving at the os uteri, I did not pierce the substance of the substance of the placenta, as is strongly recommended by some eminent obstetricians, but gently separated a portion of the placenta from its attachment to the uterus, and without any difficulty introduced my hand into the uterine cavity, ruptured the membranes, seized the feet, and in a few moments after, I delivered her of a living girl. The uterus firmly contracted, and the placenta was easily detached from its adhesion to that viscus.

The patient gradually gained strength and in ten days after I found her sitting up, and to use her own expression, said, "that the coffee I gave her in the brandy, had saved her life, and she never felt better," the ergot has got the appellation in this neighbourhood of coffee on account, I presume, of its resemblance to that article of diet.

Mrs. T. became again pregnant, and on the 12th of September, 1836, I was sent

for, and found that she had been in labour for some time; pains had now entirely left her. On examination I found the os uteri considerably dilated and thick, membranes ruptured. She desired me to give her some of my "coffee" and I accordingly gave her ʒj of secale cort. in ʒj of tepid water, pains came on almost immediately after its administration, and in a short time she gave birth to a fine and lively boy; the placenta came away naturally, and in two days after she was out of bed and attending to her usual occupation (which was that of a weaver). |

Yours obediently,

T. H. WARDLEWORTH,
Surgeon.

Pendelator, Oct. 3, 1837.

HOPITAL DE LA CHARITE, PARIS.

10th OCTOBER, 1836.

(Communicated by W. Rose, Esq.)

A Musket Ball contained within the Capsular Ligament of the Knee-joint for twenty-four years.

An interesting *post mortem* examination was conducted this morning by M. Velpeau, on the body of a veteran soldier of Napoleon, nearly sixty years of age, who was admitted about a month since, with an ulcerated wound, from four to five inches long, upon the posterior aspect of the left thigh, about three inches above the knee-joint. He complained also of cough, pain in his chest, and expectorated some muco-purulent matter, but seemed to complain principally of the wound.

On admission, he said that when serving in the late war under Napoleon, he received, about twenty-four years ago, a gun-shot wound in this spot. On examination, the surgeons could not discover the ball, and the wound was allowed to cicatrize. This accordingly rendered him unfit for further service, for although he always had the free and perfect use of the knee joint, the leg remained swollen and painful, and he was consequently invalidated.

Some short time after his discharge, the cicatrix ulcerated, and, after spending sometime in a civil hospital, the wound healed again. He suffered a great deal in this manner, from the frequent ulcerations of the part, and at length, after being

subjected to various treatment, he entered this hospital, under the care of M. Velpeau, with the wound once more in an open state. M. V. examined the wound carefully, but could not detect any foreign body. The ulcer presented a dark unhealthy aspect, and discharged a thin ichorous matter. Straps of adhesive plaster were applied, and his general health, which seemed to have suffered a good deal, was attended to. For the chest affection he was placed under the care of one of the physicians of the hospital, who detected a cavity in the superior lobe of the left lung. After a month's treatment he sunk.

Autopsy twenty-four hours after death.

M. Velpeau examined the limb very carefully; the wound appeared gangrenous, and the posterior surface of the femur opposite the wound, was in a state of incipient necrosis; a small round spot, about the size of a four-penny piece (against which the ball originally struck), appeared quite gone, through which you might pass the probe into the cancellated structure of the bone.

The ball, a lead one of the common musket size, was found resting immediately on the posterior surface of the knee-joint, within the capsular ligament, and was scarcely, or in a very trifling degree, altered from its original form. On the most minute examination, no vestige of the *trajet*, by which it arrived at its present position, could be discovered.

The cartilaginous covering of the condyles of the femur were dissolved, but there was no other appearance of disease about the joint, and its motion was not, at any time, impeded by the accident.

There were one or two cavities found in the upper lobe of the left lung, also a large quantity of serum in the cavity of the peritoneum, and the entire of the left leg was infiltrated with a similar fluid.

M. V. remarked, that death was evidently caused by the chest affection, but that the wound served as a "*point d'appui*" for the disease of the lungs.

KING'S COLLEGE.

CHAPEL ATTENDANCE.

*To the Editors of the London Medical
and Surgical Journal.*

Gentlemen—As the notice which you took in your last number of the atten-

dance of the medical students at CHAPEL three times a day, may prevent some coming forward who are not members of the established church, I trust you will have the candour to state that such an attendance is not in any way *compulsory*; for though all the professors being high churchmen attend daily, they are far from wishing to deter DISSENTERS of all denominations from becoming students of the medical school, more particularly from the empty state of the benches last session.

Your obedient servant and well-wisher.
Z.

King's College, Strand,
Oct. 3rd, 1837.

[Though Dissenters are certainly permitted to enrol themselves in this far-famed academy, we believe that those students who regularly attend CHAPEL meet with due consideration from the constituted authorities.—Eds.]

LONDON MEDICAL SOCIETY.

October 22nd, 1837.

A paper was read by Mr. DENDY, on the axiom of John Hunter, that "no two actions would go on in one part, at one and the same time." The paper embraced a variety of propositions and illustrations respecting this celebrated axiom; and the discussion which followed was rendered most interesting by the introduction of the subject of vaccination and its prophylactic power over variola. The discussion on this point was adjourned.

BOOKS FOR REVIEW.

A Concise Treatise on Operative Surgery, describing the methods adopted by the English, Continental, and American Surgeons; selected for the use Junior Practitioners and Students. Illustrated by twelve plates. By W. P. Cocks, Surgeon. London: Longman and Co., 8vo. pp. 375. 1837.

The Student's Companion to Apothecaries' Hall, or the London Pharmacopæia for 1836. By Edward Oliver, M.R.C.S.L. London: Churchill. 32mo. pp. 189. 1837.

Notice of Patents granted to Joseph Amesbury, Surgeon, for certain Appara-

tus used in the treatment of the Deformity of the Spine, &c. London, 1837, 8vo. pp. 24.

Eloge upon Baron G. Dupuytren. By E. Pariset. Translated from the French, with Notes, by J. I. Ikin, Surgeon. London, 1837. 8vo. pp. 60.

Advice on the Care of Teeth. By E. Saunders, Dentist. London, 1837. 12mo. pp. 107.

An Essay on Pyrexia, or Symptomatic Fever, as illustrative of the Nature of Fever in general. By H. Clutterbuck, M.D. 8vo. pp. 136.

The Theory of Electric Repulsion Examined, in a Series of Experiments on certain Properties attributable to the Elements which constitute Electric Excitation, adduced principally to show the Non-Existence of Repulsion. By Charles Hales. London, 1837. 8vo. pp. 22.

The Nature and Treatment of Diseases of the Ear. By D. Wm. Kramer. Translated from the German, with the latest improvements of the Author since the last German Edition. By J. R. Bennett, M.D., Physician to the General Dispensary, Aldersgate-street. London, 1837. 8vo. pp. 306.

The British and Foreign Medical Review, or Quarterly Journal of Practical Medicine and Surgery. Edited by John Forbes, M.D., F.R.S., and John Conolly, M.D. No. VIII. Oct. 1837. London: Sherwood and Co.

Guy's Hospital Reports. No. V. Oct. 1837. Edited by George H. Barlow, M.A. & L.M. and James P. Babington, M.A. London: Highley.

The American Journal of the Medical Sciences. No. XL. August, 1837. Philadelphia: Carey and Co.

TO CORRESPONDENTS.

A Country Student.—He ought to know that the great Sydenham is dead. His representative only will be found at the new "College"!

Stethoscopist.—When the Stethoscope is not at hand, a mock auscultator has absolutely found a ROLLING-PIN of more advantage.

All communications and works for review to be forwarded, (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.

LECTURES ON DISEASES OF THE
SKIN,*Annually delivered in Paris,*

By M. BIETT,

Reported by MM. Cazenave and Schedel.

CHRONIC ECZEMA OF THE
MAMMÆ,

Is usually confined to a very small extent, it circumscribes the nipple with considerable regularity. As it usually requires a very active treatment, it is almost always very obstinate, we have seen it last for years.

Eczema of the scrotum, and of the thighs, in women is always very obstinate; the same may be said of that which is seated around the anus. Vapour douches, fumigations and sulphurous douches are, together with purgatives, the means from which most benefit may be derived. In robust persons who enjoy in other respects good health, purgatives may be freely employed.

Eczema of the ear, is oftentimes very obstinate, and it is sometimes accompanied with considerable hypertrophy, it may be necessary to place bits of prepared sponge in the meatus auditorius externus, for the purpose of preventing the closing of this aperture.

Lastly, *eczema of the hairy scalp* may present itself with different phenomena so much the more important as it has been mistaken for some varieties of porrigo.

Thus we see in patients affected with eczema which is seated most frequently at one and the same time both in the face and hairy scalp, but sometimes in the hairy scalp alone, an exhalation of serum so abundant, that all the hair is matted with it. Subsequently the serum

concretes, and the scales, at the time of their formation, surround several hairs just commencing to grow. These latter increase, and in a little time, either by a natural degeneration, or in consequence of the latter having been accelerated by this growth, the scales become detached, and there are observed packets of five or six hairs matted together by a scale of greater or less extent, beyond which they pass, both at their adherent extremity, and at their free extremity. This phenomena is less appreciable in women; but it is found in many cases, if the hair be examined near to where it escapes from the bulb. The presence of these scales of a colour resembling *amianthus*, in the midst of the hairs presents an extraordinary and an extremely remarkable appearance, particularly in brunettes.

Sometimes the serous exhalation is much less profuse; the liquid, on becoming dry, gives rise to small white dry *furfuraceous* scales, which are renewed very rapidly, and fall on the least friction in great abundance.

These two varieties do not alter the bulb in any way.

Acidulated ptisans, emollient lotions at the outset, subsequently alkaline lotions, gentle laxatives, such are the only means which these two varieties require. It is sometimes sufficient, in the case of children, to wash the head with a solution of soap, and to pass a fine comb through it several times in the course of the day.

HERPES.

The term *herpes*, for a long time back employed vaguely and in the same acceptance as the term *dartre*, was applied to several eruptions of a nature altogether different, when Willan reserved it exclusively for a genus entirely distinct.

This genus is characterised by an eruption of vesicles uniformly collected in groups on an inflamed base, so as to pre-

sent one or more surfaces perfectly circumscribed, separated from each other by greater or less intervals in which the skin is entirely healthy.

The form of these groups and their seats, constitute species and varieties sufficiently marked to be described individually.

The different species of herpes in general follow an acute course; their duration, which is ordinarily about one week, seldom continues beyond two or three. However we sometimes see varieties of this eruption continue for whole months. The cases in which herpes is accompanied with severe constitutional phenomena are very rare, if they at all exist. In general the symptoms are confined to a little indisposition, slight depression, sometimes loss of appetite, seldom fever. When developed under some uncommon circumstances, under the influence of a direct cause, herpes almost always appears without any appreciable cause, and even in cases wherein it recognized a direct cause, such as cold wind (*herpes labialis*), there exists at the same time a peculiar state of the system, of which the eruption is one of the symptoms.

The union of vesicles in groups, on a circumscribed inflamed base, will always suffice to prevent us from confounding herpes with the other vesicular affections.

It is a disease uniformly of little severity, which generally follows a regular course, and most frequently requires only a simple emollient treatment. Herpes may exist simultaneously with other phlegmasiæ, either of the skin or of some internal organ.

Herpes Phlyctenodes.—By the common denomination of herpes phlyctenodes we are to understand those affections of the genus herpes, which have neither a determinate form, nor any particular seat; the others constitute separate varieties only because they are found in one of these two cases.

Herpes phlyctenodes is characterized by the presence of vesicles which are usually very small, but constantly collected together, capable of appearing over all parts of the body, in some cases over several at the time, and forming by their union an irregular surface, the breadth of which varies from that of a crown-piece to that of the palm of the hand. There are generally found in the same eruption vesicles, some imperceptible, and others the size of a large pea; but the number of small vesicles always far exceeds that of the large ones.

It comes out most frequently on the upper parts of the body; the cheeks, the neck; the chest, and the arms are the most frequent seats of it; it is more rarely seen on the lower extremities.

Herpes phlyctenodes confined in general to one or two groups, usually disappears towards the seventh or eighth day. However, whether its development may have taken place successively over several points, or several groups may have appeared at a very small distance from each other, it may be prolonged to a still greater period, but rarely beyond two weeks, and never beyond three.

When herpes phlyctenodes manifests itself in several separate groups, these are, in general, at a considerable distance; but however near to each other they may be, the skin separating them is always healthy, and presents not the least change.

Symptoms.—Each group, consisting of several vesicles, is developed in the following manner; we observe at the part which is to become the seat of the eruption, a crowd of small red points, almost imperceptible, grouped, the one around the other, the number of which is often very great, though confined to a space which is relatively very contracted. After two days we find a red inflamed surface covered with prominent vesicles, resisting the touch, the size of which varies from a grain of millet to that of a small pea. The redness of each group generally exceeds the vesicles around each patch by several lines. The greatest number of the vesicles generally presents but a very small size. All are hard, resisting, of a globular form and transparent, on the first day of their formation; but on the following day, sometimes even before it, the transparency is succeeded by a milky tint.

A sensation of shivering oftentimes, very painful, accompanies the appearance of each group. The vesicles begin to fade from the third or fourth day, and on the seventh or eighth they are found depressed; some contain a purulent fluid, and others are changed into brownish crusts. Desquamation soon occurs; but we often perceive some slight ulcerations here and there. There always remains for some days after the disappearance of the herpes, a reddish tint which disappears slowly.

Most frequently this affection being but slight is neither preceded nor accompanied by any constitutional symptoms: a state of general indisposition, sometimes loss of appetite, and a little fever, are the only symptoms observed when the disease

occupies a certain extent : the local symptoms are, as we have said, a sensation of shivering and of acrid heat, more or less severe. Moreover, these symptoms as well local as general, occur only at the time of the eruption, and on the two or three first days.

Causes.—Herpes phlyctenodes generally appears in young persons. As it occurs more frequently in meridional climates, it frequently develops itself under the influence of the solar rays. Want of natural rest, excess in diet, mental annoyance, and other causes of this kind have appeared to exercise some influence on its development; but in general it is produced by causes entirely unknown, or at least very difficult to be ascertained.

Diagnosis.—The causes of herpes phlyctenodes already pointed out, which are numerous vesicles grouped together on a red inflamed surface, the extent of which varies from that of a crown piece to that of the palm of the hand, are sufficient to distinguish herpes from the other affections, whether vesicular or bullous.

Pemphigus is the disease with which it may most likely be confounded, and so much the more as descriptions of this disease have been presented under the name of *herpes phlyctenoides*. They may be distinguished from each other by this circumstance that in herpes it is vesicles grouped together on isolated surfaces, whilst in pemphigus it is isolated bullæ. Sometimes, to be sure, we find here and there in pemphigus red surfaces where the bullæ are very close to one another, and almost confluent; but we shall avoid confounding them with herpes, by reflecting that, in this latter affection, we find vesicles, not bullæ. Some of the vesicles may no doubt be transformed into bullæ; but still it is the smallest number, and they are seen only here and there.

Herpes phlyctenodes can be confounded with *eczema* in very rare cases, where the latter affection presents itself with vesicles arranged in groups. However they might be further distinguished by the following characters: the vesicles of *eczema* are less elevated, and redder: it is difficult to ascertain their transparency; and lastly, when they are disposed in groups they are confluent, whilst those of herpes remain isolated.

With respect to the other species of herpes, as they do not differ from this, except in their seat or form, this form and

this seat will serve as the basis of our diagnosis.

Treatment.—Herpes phlyctenodes is a disease of but little severity, which in general merely requires the administration of diluent acidulated drinks, a somewhat strict regimen, mucilaginous lotions, and some tepid baths. If the disease were of sufficient extent, and if it were accompanied by any constitutional symptoms, we might have recourse to a small bleeding.

A.—VARIETIES OF SEAT.

The varieties which differ from herpes phlyctenodes only in having a determinate seat, are two in number: *herpes labialis*, and *herpes preputialis*.

Herpes labialis.

This variety is characterized by groups of vesicles more or less numerous, more or less distinct, disposed irregularly around the mouth.

In general *herpes labialis* occupies only a greater or less extent of the upper and lower lip. It always appears externally, and in general at the point of junction of the labial mucous membrane with the skin. However, in certain cases, it occupies only the external mucous membrane of the lip, whilst, in other cases, it attacks only the skin situate outside the line of junction. Sometimes the groups arranged without order may extend even to the cheeks, the chin, or alæ nasi, and in certain cases they are observed even on the pharynx.

Herpes labialis is sometimes preceded by a slight redness for several hours: at other times the redness appears suddenly. The point where the herpes is developed, swells, and becomes the seat of an acrid, burning heat; there is then observed a red, tumefied and shining surface, painful to the touch; here and there are seen some vesicles beginning to point. The tumefaction of the lip extends beyond the group of the vesicles. The latter are rapidly developed; frequently several of them unite; then we often find on the same group vesicles of variable size, the largest of which however never exceed the size of a small pea, and which are filled with a transparent fluid. The heat is in general less acrid when the vesicles are developed; the transparent fluid which they contain soon assumes a milky appearance, and from the third or fourth day it presents a yellowish aspect; the serous liquid has become sero-purulent; the redness and swelling have then almost

disappeared; crusts soon form, they become brownish, and fall from the seventh to the eighth day of the eruption; when they are torn off too soon, others form, which remain a longer time. After the disappearance of the eruption, a small red surface is found, which disappears rapidly. Its appearance is almost always preceded by some constitutional symptoms which last from twenty-four to forty-eight hours—

Causes.—*Herpes labialis* is very often occasioned by cold; thus it is often observed to appear, when on leaving a warm place persons immediately expose themselves to cold and moist air. It very frequently accompanies coryza and slight bronchitis. The contact of certain acrid and irritating food may sometimes occasion the appearance of this variety of herpes. It is very frequently seen to come on after the fit of an intermittent fever; it sometimes complicates inflammation of some internal organ, chiefly of the chest.

Diagnosis.—The arrangement of the vesicles in separate groups, their regular course, the great size which some of them assume, and which ultimately contain a sero-purulent fluid suffice to distinguish *herpes labialis* from an eczema which might also have its seat on the lips.

Herpes labialis is a disease generally very slight, which scarcely requires any treatment. However in the case where it might be accompanied with an acrid heat, and somewhat painful tension, these symptoms might be mitigated by means of lotions of cold water, to which some drops of sulphate of zinc might be added, or acetate of lead, or of sulphate of copper. Emollients do not produce near so much relief; none of these applications will prevent the eruption from following its ordinary course. In all cases the patient should avoid cold, as also the radiations of too strong a fire.

Herpes preputialis.

Herpes preputialis is characterized by the presence of several groups of vesicles, either on the outside, or on the inner surface of the prepuce.

It manifests itself at first by one or more red spots, more or less inflamed, seldom exceeding the size of a franc, and often much smaller. These spots soon become covered with small globular vesicles, the size of which presents some difference according to the seat.

Thus *herpes preputialis* may be confined to the external or internal surface of

the prepuce; it sometimes occupies both surfaces simultaneously.

The groups which occupy the external surface are but slightly inflamed: the transparent and distinct vesicles follow the ordinary course of herpes; only the liquid is generally reabsorbed; then the vesicles fade, and slight desquamation takes place; sometimes, however, the serum becomes turbid after some days; small scales form, and the disease terminates on the seventh or eighth day, and often sooner.

But in the case of groups situate on the inside of the prepuce, the inflammation is much more severe: the vesicles increase rapidly in size, and often unite two by two, three by three.

They are extremely fine and they are so transparent as to suffer one to see, through them, the red surface which they cover.

The liquid soon passes into the sero-purulent state, the vesicles open, and small scales are formed which soon become detached, either naturally or accidentally, as most frequently happens, and leave behind them excoriations which may be very easily distinguished from syphilitic ulcerations, and which do not leave the slightest trace after them.

A little itching at the onset of the eruption, and a little smarting when excoriations exist, are the only symptoms which accompany *herpes preputialis*.

Causes.—This variety of herpes is hardly ever observed except in adults: the friction of woollen garments, certain chronic discharges from the vagina, the action of this matter which is so copiously secreted between the prepuce and the gland, when it is suffered to accumulate there, may occasion the development of this eruption, which most frequently appears without any ostensible cause. The narrowing of the urethra which may exist at the same time, are symptoms to which herpes seems to hold no other relation than that of mere co-existence.

Diagnosis.—The seat of this variety might throw a little obscurity on its diagnosis, if the physician confined himself to a superficial examination; yet, in whatever state *herpes preputialis* presents itself, we think it would be always difficult to confound it with syphilitic eruptions or ulcerations.

Again, is it vesicular? all the characters of the genus herpes are applicable to excoriations behind it? these, which are all superficial, level with the centre as it, and cannot admit of error even for an

instant. Is it covered with scales? no one certainly can mistake these thin and flattened scales for the prominent and thick crusts of syphilis: lastly, has it left with the circumference, arranged moreover in groupes as the vesicles which have given rise to them, &c. will never impose on any practitioner for syphilitic ulcerations, which are remarkable for their depth, for their hard and elevated edges, for the whitish surface covering them, &c.

This mistake, however, has occurred, and a vesicle of *herpes preputialis* has been very often mistaken for syphilitic ulceration at the onset. In these cases, in order to remove the supposed venereal disease, recourse has been had to cauterization, or, following up the error, mercurial frictions have been employed, etc. Thus, under the influence of this unlucky treatment, the herpes has frequently passed into the chronic state; and from a simple affection, it has been converted into a rebellious, obstinate disease, which continued for years, complicating itself with phymosis, etc. Fortunately, it is always easy to avoid falling into this mischievous error. It is sufficient to know that the venereal ulcer, Hunter's chancre, does not commence, as has been stated, by a vesicle, but by redness, and real ulcerative inflammation.

Treatment.—Barley water or lemonade, injections between the prepuce and the gland, with a decoction of marsh-mallow root, local emollient baths, are the only means necessary to be employed in *herpes preputialis*, which, in the great majority of cases, yields veay readily. However, in some cases, the *herpes preputialis*, having become chronic, resists the most active means. M. Biett has cited several remarkable cases in his clinical lectures, and we have seen several instances of it.

B.—VARIETIES ACCORDING TO THE FORM.

The genus *herpes* includes three more which are very important to be known, which might appear to belong to distinct species, but which, when attentively examined, do not really differ from *herpes phlyctenodes*, except in their precise form. However, as they constitute diseases of considerable frequency, and as there still exists some doubt on the nature of some of them, we deemed it right to describe them separately. These are, *herpes zoster*, or *zona*, *herpes circinnatus*, and *herpes iris*, which constitutes a very rare variety, ranked by Willan among the exanthemata, and which, in fact, sometimes

approximates very closely to a species of roseola, which we have described under the title of *roseole à anneaux multiples*.

Herpes zoster (zona.)

Zona has been considered and described as a species of erysipelas, and there is so little foundation for this error, that it is almost sufficient to notice it: in fact, none of the symptoms of this exantheme are to be found in *zona*, and especially none of the symptoms of *zona* are met with in erysipelas. Yet we shall dwell for an instant on the probable cause of this opinion. It is no doubt based on this circumstance, that certain cases of erysipelas are complicated with bullæ; but there is a great difference between isolated, irregularly-formed, and often times extensive elevations of the epidermis, as is seen in erysipelas, and the small congregated vesicles, seldom exceeding the size of a pea, which constitute *zona*. This reason, joined to the regular course of *herpes zoster*, which is also that of herpes phlyctenodes, is sufficient to combine these two latter affections, and to distinguish *zona* from erysipelas.

Herpes zoster, or *zona*, is characterized by the presence of irregular patches, of variable extent, of a bright red colour, which are covered with congregated vesicles, and which present themselves under the form of a half-cincture or zone, on the trunk or extremities. It usually happens that it is from some point of the median line of the body that *zona* sets out to return at the opposite point, without ever passing this line.

Zona is most frequently met on the trunk, where it most usually forms an oblique demi-zone. Nor is it uncommon to see it commence on the trunk and finish on the extremities. Thus, setting out from the middle of the inferior and posterior lumbar region, it surrounds obliquely the external and anterior iliac region, so as to reach the groin and terminate at the inside of the thigh; or else, commencing at the middle and upper part of the back, it makes for the posterior part of the shoulder, then for the anterior part, and come to terminate on the inner edge of the arm, which it sometimes accompanies as far as the cubital edge of the hand. In some cases we may observe two lines set out from one and the same demi-zone, one of which extends along the lower extremity, and the other ascends along the arm. But the most frequent seat of all is the base of the thorax; it is very seldom seen to occupy merely the

extremities. Nineteen times out of twenty zona occupies the right side of the body, though we cannot account for this extraordinary predilection. It is sometimes seated on the neck, on the face, and in this case it has been observed to extend as far as the mouth, always, however, on only one side. We have seen it two or three times occupy the right side of the hairy scalp; it never exists on both sides at the same time.

In all cases these demi-cinctures are formed, not by a continued series of vesicles, but by isolated patches, which follow one and the same direction, and present intervals where the skin is perfectly healthy. These patches are sometimes very close together, sometimes they are separated by considerable intervals.

The duration of the disease is from one to three or four weeks.

Symptoms.—Zona, at first, makes its appearance by irregular spots of rather a bright red colour, placed at but little distance from each other, which become developed one after another in the inverse ratio of their distance from the first, and thus surround one half of the body. These spots sometimes commence at the two extremities of the zone at the same time, and join by successive eruptions. In general those which commence and terminate this kind of chain are broader, and present an irregularly rounded form, whilst the patches included between them are smaller. In some rare cases the development of these spots is preceded by a painful, and sometimes a burning sensation, which always accompanies their appearance. If they be closely examined there is soon perceived a crowd of small white, silvery projections, which soon increase in size, and present to view distinct transparent vesicles, of the size and form of small pearls. In the space of three or four days they attain their highest degree of development, which rarely exceeds the size of a large pea, but which is sometimes larger. At this period, the surface on which the vesicles are developed, presents a somewhat bright redness, and the red tint passes some lines beyond the edges of each group of vesicles. According as new groups become developed they follow the same course.

Towards the fourth or fifth day of the appearance of each group of vesicles, the redness diminishes, the vesicles fade, become depressed, and their surface becomes shrivelled.

The fluid which they contain, from having been transparent, is now become

opaque, and blackish in some; in several there is formed even real pus; ultimately these form small slight crusts, of a deep brown colour, which fall off in the course of some days. The other groups observe the same course, and towards the tenth or twelfth day of the disease, in the place of the eruption there is found nothing but red spots, which disappear gradually. But it sometimes happens, more especially in the patches situate on the posterior part of the thorax, that excoriations, and even slight ulcerations, succeed to them, which seem to arise from the frictions of the diseased parts against the bed; the duration of the disease is then prolonged, and oftentimes very much so.

Such is the most frequent course of zona, which however may present many varieties; thus, the re-absorption of the fluid may take place towards the fifth or sixth day, and the disease may terminate by desquamation after the seventh or eighth day; at other times, in persons enfeebled by age or hardship, the vesicles acquire considerable size, often very soon, and leave behind them extensive and painful ulcerations, which are followed by cicatrices more or less marked. In some very rare cases, and more especially in old persons, we have seen zona followed by gangrene of the skin in which the vesicles were developed.

We had an opportunity of observing, in the Hospital St. Louis, a great many causes of zona, and we never saw it accompanied by this group of constitutional symptoms, and especially gastric symptoms, with which it has been gratuitously supposed to be always attended. A state of indisposition, in some rare cases a slight elevation of the pulse, always some heat, a feeling of tension sometimes very painful, even in the site of the eruption, a rather acute pain in the zona, terminating in ulceration; lastly, a local pain, more or less intense, continuing for a longer or shorter time after the cure; such are the only phenomena, which, at least in the great majority of cases, accompany the zona. If stronger proofs of this assertion were necessary, we might give M. Biett's opinion, who never saw those alarming symptoms mentioned by another, among upwards of five hundred instances which passed before him in the Hospital St. Louis, as well in the wards as among the extra patients.

Causes.—Herpes zoster attacks young persons in particular, and persons whose skin is fine and delicate; it is more frequently observed in men than in women:

it sometimes attacks old men, and appears more particularly in summer and autumn than in spring or winter. It is sometimes seen after variola; in some persons it has returned several times, almost periodically. Some have asserted that it is hereditary. It may rage epidemically.

Diagnosis.—This affection cannot be confounded with any other; its vesicular nature, and its demi-cinctural form, are two symptoms which will never admit of the least error. Sometimes when the zona begins to become developed, or when its development is incomplete, there is observed but one group near the median line, and it might be mistaken for *herpes phlyctenodes*; but in these cases it is often sufficient to examine the opposite side of the body, to find still further groups of vesicles of more or less extent: lastly, there frequently exists between these groups, thus remote from each other, small red points, indicative of new groups which are in the point of appearing: moreover the mistake is of no bad consequence, since, in fact, the two diseases are similiar.

Prognosis.—Zona is almost invariably a slight affection: but when it terminates in ulceration, it may be more or less troublesome; it would be still more so, if it were followed by gangrene of the skin, as is observed in old persons.

Treatment.—In almost all cases zona disappears under the influence of the most simple treatment; a somewhat strict regimen, rest, and diluent drinks, such as lemonade, etc., without its being necessary to have recourse to blood-letting, either local, or general.

A few simple baths are serviceable in case the inflammation be any way severe, and in irritable subjects.

With respect to local applications they are to say the least useless. Those most extolled are saturnine solutions, or some astringent liquid. If ulcerations supervene, they should be dressed with cerate, with which opium may be combined.

If the disease presented itself in an individual enfeebled either by age, or by some previous disease, we might derive advantage from the employment of some tonic drinks, ferruginous mixtures, for instance, and at the same time support the patient's strength by nourishing diet.

If the zona terminated in gangrene, we should have recourse to tonics, and to local applications of a stimulating kind.

Sometimes it is difficult to remove the pain which zona leaves after it; after frictions and narcotic applications it is some-

times necessary to apply a blister to the part affected.

Of late years M. M. Serres and Velpeau have spoken highly of the application of the ecrotic method to zona; it is, it must be owned, one of the cases, in which it might present most chance of success, in as much as it would be far less our object to remove an inflammation than to modify the sensibility of the parts affected: however, it is for the most part useless in a disease which, in the generality of cases, is very slight and very simple.

HERPES CIRCINNATUS.

Herpes circinnatus is a very frequent variety, which presents itself in the form of rings.

Herpes circinnatus is characterized by globular vesicles, which are in general, extremely small, so disposed as to form complete circles, of which the centre is usually intact, and of which the edges being of a more or less bright red colour, are covered with those small vesicles. This red band is often very broad, relatively to the centre, more especially in the small rings, and the redness goes beyond the vesicles, as well at the great as at the small circumference.

Symptoms.—This eruption announces itself by a redness more or less bright at the part which it is to occupy. The redness, sometimes confined to a surface whose extent does not exceed that of a franc, may present in other cases, a diameter of about two inches. This surface is most frequently round, but sometimes presents an oval form.

In the small spots the redness is much less bright at the centre; in the largest it is altogether absent, and the skin there retains its natural colour. In all cases the circumference of the circle soon becomes covered with vesicles very close to each other, and generally very small, but which when examined carefully, presents a very globular form. The fluid contained in these vesicles being at first transparent soon becomes turbid; the vesicles open, and there are formed small scales which are almost always very thin, and which soon become detached; and it generally happens that the eruption has run through all its stages in eight or ten days; there remains only a greater or less degree of redness, which disappears slowly.

Such is the ordinary course of *herpes circinnatus*: but sometimes the centre of the ring is itself inflamed, and a slight desquamation takes place, without any

vesicles ever being developed. Sometimes the vesicles of herpes do not terminate in the formation of scales; but the fluid which they contain is re-absorbed, the vesicles decay, and fall off by an almost imperceptible exfoliation. This occurs chiefly in rings of a small diameter; and in these cases the vesicles are often so minute, that great attention is required to distinguish them. Lastly, in some cases, the circles are very broad, and the vesicles more developed, seldom however exceeding the size of a grain of millet.

Herpes circinnatus usually lasts from eight to ten days when there is but one ring, or when those which do exist are few in number, of small extent, and are developed together. But in cases where the rings appear successively, the duration of the disease may be prolonged beyond two or three weeks. In persons whose skin is very fine, the redness often continues for some time after the disappearance of the eruption and the scales.

Though it may become developed over all parts of the body, herpes circinnatus generally attacks the arms, shoulders, chest, and above all, the neck and face. It is very common to see in young persons, and particularly in ladies whose skin is white and fine, small herpetic rings of the size of a tea-soup piece, confined to one or both cheeks, and very often to the chin.

Causes.—Herpes circinnatus most frequently attacks children, young persons and females. It is principally observed in persons with fair complexion, whose skin is fine. Its appearance sometimes seems to be occasioned by the impression of cold; on the face it may be produced by lotions or applications of a stimulating character.

A slight smarting or itching are the only symptoms which accompany the development of this slight affection.

Diagnosis.—It would appear that character so well marked and so exclusive should prevent the possibility of mistake. Yet a small herpetic ring, the faded vesicles of which merely present a slight exfoliation, seated on a red and accurately rounded ground, might in many cases impose on one for a patch of *lepra* divested of its scales. But on the one hand the depression of the centre, and the projection of the edges, on the other hand, the unity of the surface, and above all the presence of some remains of vesicles on the edges, are sufficient to prevent all mistake, which, for other reasons, cannot be of long duration;—for a her-

petic ring is on the eve of cure, after the disappearance of the vesicles. Besides it very rarely happens that there is but one patch of *lepra*, and probably other parts of the body might be found, where the characters of this latter disease are more marked.

There might perhaps be more difficulty in distinguishing herpes circinnatus from *porrigo scutulata*, so much the more as the same name, that of ringworm (a worm in the form of a ring), has been applied to these two diseases.

However the one (herpes circinnatus) is a vesicular affection, and gives rise only to scales; its duration is short; it is not contagious, and when it occupies the hairy scalp, its presence does not cause the hair to fall off. The other (*porrigo scutulata*), is a pustular and contagious affection; its duration is long and indefinite; it gives rise to the formation of crusts which increase in thickness; it is scarcely observed except on the hairy scalp, and the hair soon falls in the parts where the rings become developed.

It might probably be more difficult to distinguish it from *lichen circumspectus*, if, in general, the rings of the one were not larger than those of herpes, and more particularly, if it could not be discovered, even by the remains, that the latter affection commenced with vesicles, whilst, on the contrary, it is papulæ which characterize *lichen*.

The treatment of herpes circinnatus is nearly the same as that of the other species, only here we may employ with advantage some lotions rendered alkaline by the addition of some subcarbonate of soda or potash (one or two drachms to the pound of water). We often see the itching occasioned by the small herpetic rings of the face, and the inflammation accompanying them, relieved by repeated application of a little saliva. Astringent lotions with alum or sulphate of zinc may also be used.

If this variety of herpes attacked several parts of the body simultaneously, we should prescribe mild laxatives, and alkaline baths.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

Ulceration.

Before I enter on this subject I shall make a few more general observations on absorption.

Some parts of our solids are more susceptible of being absorbed, especially by ulceration, than others under the same or similar circumstances. This is particularly the case with cellular and adipose membrane, as we often find muscles, tendons, and ligaments deprived of their connecting membrane by ulceration, as may be observed in the opening of large abscesses. The skin itself, if affected by pressure from without, is less easily absorbed than the cellular membrane; hence we may observe, that in continued pressure from without the skin will remain whole, although the parts beneath are wasted by the absorption of the cellular membrane; but sometimes the skin is more susceptible of absorption than the cellular membrane; this may proceed from the skin acting with so much more vigour, either in opposing any injury or in taking on salutary action. Although in abscesses, in tumours, and in the case of extraneous bodies, the parts all round are equally pressed, yet we find that the progressive absorption takes place only on that side nearest the skin, and arrives at the skin only on that side: a very slight degree of pressure from within will produce this effect, so slight as would from without have produced only a thickening of parts.

Bones are susceptible of a similar process. Absorption may be of two kinds,—without suppuration, or with it. The first, I believe, is universally the case with the interstitial absorption of callus, of the alveoli of the teeth, &c.; but the second may precede or produce suppuration where there was none before, as in old sores breaking out anew. To distinguish the second from all other modes of absorption of whole parts, I shall call that absorption ulceration which is either preceded, accompanied, or succeeded by suppuration. Absorption may be a consequence of pressure under two circumstances,—where the pressure is from diseased parts, or from extraneous substances. Of the first is that from tumours, &c.; thus, in a case of aneurism, where the coats of the artery press against the bones, the rib for instance, its coats begin to be absorbed, and, after they are absorbed, that absorption goes on in the bone, the adhesive inflammation takes place at the same time round it, and unites the circumference of the absorbed parts: another instance is where tumours make their way to the skin, without any suppuration taking place. Of this I once saw a very remarkable instance in a soldier in the Dutch service; a tumour had formed be-

tween the pia mater and the dura mater, which gradually increased to a very considerable size, and had shown itself externally some time before the man died. Upon examination after death I discovered that the pia mater was absorbed underneath it; but the chief absorption had taken place on the side next the skin, for on this side the skull was absorbed, and the absorption had begun in the integuments of the scalp, which it would soon have probably ulcerated had not the man died before Nature had finished her operations; and in this case no matter was found either on the brain, skull, or integuments, owing, perhaps, to the pressure being made by a living part. This species of absorption is attended with very little or no pain, and its effects are as trifling on the constitution, although it may be an effect of an alteration in the constitution, as the absorption of calluses in scurvy, &c.

Ulceration.—I shall now take notice of that action of the absorbent system which I call ulceration, and which is the second species of our first division, being connected with the formation of pus, either as a consequence or as a cause; and it is a kind which always constitutes an ulcer.

This process of ulceration or absorption with suppuration, is almost constantly attended with inflammation, which led me to call it ulcerative inflammation. Ulceration is generally attended with considerable pain, which is called soreness; but this does not attend all ulcerations, for there are some which are of the specific kind, which give little or no pain, as scrofula; but even in this disease, where ulceration proceeds very fast, it often gives considerable pain, wherefore the pain may be in some degree in proportion to the quickness of its operation. In those cases where ulceration is set up to separate dead parts, as sloughs, it is seldom attended with pain, and it is not easy to assign the cause of this.

It seldom or never affects the constitution much, although the process is affected by the constitution.

What I have hitherto said of ulceration I shall illustrate by noticing what occurs in an inflammation of the peritoneal coat of an intestine. The first inflammation is the adhesive, which occasions an adhesion between the inflamed part of an intestine and the peritoneum lining the cavity, which remains, although the inflammation should stop here; but if it does not stop here, then the suppurative takes place and an abscess is produced,

the matter of which is collected into a regular cavity in these adhesions, and is prevented from diffusion through the cavity of the abdomen by the effects on the surrounding parts, by the preceding adhesive inflammation, as well as of that which accompanies it. This matter, by its pressure, irritates, and absorption takes place in consequence; but as none of the parts, except those between the matter and the skin, are hardly, if at all, susceptible of this irritation, no parts are absorbed but such as are so situated: hence the abdominal muscles, cellular membrane, fat, and skin are removed in preference to the coat of the intestine. If the suppuration had at first begun in different points, the parts between are absorbed until it becomes one abscess; and when it reaches the skin we have the ulcerative inflammation. It is in the same manner it acts in all abscesses of circumscribed cavities, as in common abscess, inflammation of the lung of the side next the pleura, of the pleura itself, gall-bladder, liver, &c.; also in the case of lumbar abscesses. In the substance of the lungs we sometimes find abscesses go on in a different manner, and open into the cells, and this because the adhesive inflammation finds it difficult to connect the air-cells together; and that the air-cells do not take on the adhesive inflammation is evident from many observations. Whilst a part is under the ulcerative inflammation, irritation will increase the absorption on any part of its surface. Thus, if a large abscess forms on the thigh, opposite the great trochanter, we shall find that, from the pressure of the trochanter on the part opposite to it, ulceration will take place there likewise. An irritation we have of the same kind in milk abscesses, from the irritation of the matter in a depending part of the abscess, which shows how very easily, from the slight pressure of matter, the ulcerative process may be produced. Ulceration is, therefore, no more than a process by which parts are removed out of the way of pressure. The ulcerative process has no effect on the cuticle; but in general this is so thin as not to give any trouble, as it easily bursts. But on the fingers and hands of working people it becomes so thickened as to cause excessive pain and trouble in whitloes; and as from this cause we have so considerable a separation between the cuticle and the skin, these abscesses should be opened early. Poulices in these cases are more useful than in any other, for their moisture is

absorbed by the cuticle as by a sponge, and the cuticle is rendered more dilatable. After these have been opened, or have opened of themselves, by a small orifice, the soft parts lying under are apt to push through the opening, and appear like a fungus, occasioning great pain, which is owing to the cuticle around the granulations underneath. To this escharotics have been applied; but it would appear that there is no necessity for them, as it would disappear of itself when the thickening of the parts in consequence of inflammation has gone off. But besides ulceration, the consequence of previous suppuration, which we have been hitherto describing, we have ulceration taking place where no reason can be assigned for it, except perhaps weakness be the cause, the parts not being able to support themselves. New parts are more susceptible of it than old, as cicatrices, stumps, calluses, &c. This arises from the new parts being less firm than the old original ones, as in Anson's voyage, when there was a general debility from the change of climate, &c. The appearances of ulceration are different at different times, according as the process is going on, at a stand, or the parts healing. The ulceration in the smallpox is attended with death in the parts, hence loss of substance and pitting.

Restoration of Parts.

We are now to trace the operations of Nature to bring parts back as near to their original formation as possible. These operations cannot be looked on as morbid, as they are for a salutary purpose.

Granulations.—These have, I believe, in general been supposed to be a consequence of, or an attendant on, suppuration; but the formation of granulations is not confined to a breach of the solids allowed to suppurate, as from accident, or a breach of the solids, produced in consequence of suppuration, as in abscesses; but it takes place under other circumstances, and when the first and second bond of union have failed, as in simple fractures.

I believe no internal canal can granulate in consequence of suppuration, except there have been a breach of continuity. And here I may observe, that when granulation does take place in such a canal, it is not on the proper coat of the canal, but on the surrounding cellular membrane. Few surfaces of abscesses granulate until opened, either of themselves or by art; therefore in abscesses of

very long standing we seldom or never find granulations.

In most abscesses, if not in all, after they are opened, there is one surface more disposed to granulate than the others, which is the surface next to the centre of the body in which suppuration takes place, the surface next to the skin hardly ever having the disposition to granulate; on the contrary, it is sometimes ulcerating when the bottom of an abscess is granulating. Exposure is so far necessary for granulations, even in cases where there is an opening, that if the opening is only a small one, and the abscess is deeply seated, the latter will not so readily granulate, which often becomes the consequence of deep-seated abscesses not healing.

I have said that granulations are not confined to a breach of the solids attended with suppuration; for parts are capable of making new matter internally in cases where union by the first intention ought to have occurred. A case in St. George's Hospital first gave me this idea.

I was called to a man with a fractured thigh, and made use of the usual means, but without success, for no union of the fractured parts was formed in the usual time; and about the end of four weeks the man died with another complaint. Upon examination of the parts, I found that the upper end of the bone rose considerably over the under, and consequently there was a great cavity in the soft parts, the parietes of which were thickened by the adhesive inflammation, though not so much as if the parts had been better disposed for the adhesive inflammation. There was no extravasated blood, nor matter, nor coagulable lymph to be found, except a few threads, which were probably the remains of extravasated blood. Here the parts had lost two chances of being united, the one by the extravasated blood, the other by the coagulable lymph thrown out by the adhesive inflammation; and Nature had begun a third, which was that of forming granulations of new animal matter on the ends of the bone and the surface of the surrounding cavity; and adhesions, you see, had taken place between the bones and soft parts, by which the bones would have been united by a bony case. Hence we find that granulation may take place without the parts being exposed, and without suppuration.

This mode of union by granulation is, I believe, much more extensive than has been imagined; this third bond of union taking place where the parts have missed

the first and second, as just mentioned. In the exposure of cavities of abscesses we have granulations going hand in hand with and following suppuration. As the suppurative inflammation follows injuries with exposure, it seems that this inflammation is in general necessary to granulation in these cases.

Granulations are an accretion of new animal substance on the surface of a wound, or a newly-formed surface composed of coagulable lymph exuded from the vessels, into which new substance the old vessels probably extend, and entirely new ones are formed, so that the granulations come to be very vascular, more so indeed than any other particular animal substance. The vessels pass from the original parts to the base of the granulations, and from thence to their outer surface. The surface of this new formation continues to have the same disposition for the secretion of pus as the parts on which they are formed had; therefore it is easier to suppose that the nature of these vessels does not alter by forming granulations, but they are completely changed for this purpose before granulations are begun to be formed, and that these granulations are the consequence of the change. They always also are of the same nature with the parts on which they are formed: if a diseased part, they are diseased: if the disease be of any specific kind, they are of the same kind and produce similar matter. The surface of the granulations is convex, being just the reverse of an ulcerating surface, which is thus, as it were, shagreened by a great many points or small eminences: the smaller these points are, the more healthy the granulations. The colour of healthy granulations is a florid red, which would make us suspect that it is principally owing to arterial blood: when they are of a livid red they are most commonly unhealthy, and have a languid circulation in them; however, this appearance frequently is owing to the particular position of the parts. I knew an instance of this in a young man who had a granulating wound on his leg. I was surprised to see it on some days of a healthy scarlet, and on others quite livid; but the cause of this he explained to me, by showing that if he kept it in a recumbent posture for a short time, its surface was then of a bright scarlet, but if he stood for a few minutes it would become quite livid. This appearance must have arisen from the stagnation of blood in the newly-formed vessels, and from their not possessing sufficient strength

to resist the superincumbent column of blood, which sufficiently accounts for the difficulty of healing sore legs when patients are allowed to stand or walk much.

Granulations not only show the state of the part on which they are formed, but also how far the constitution is affected in many cases. The chief of those which affect granulations are the irritable and indolent habits, and, still more, fevers, which must be of such a nature as to produce universal irritation in the constitution.

Granulations have a disposition to unite with one another, which is absolutely necessary to healing; and this is done, I suppose, in the following manner: when two granulations meet, the mouths of the opposing vessels are irritated, which causes them to embrace each other; this junction perhaps being aided by the attraction of cohesion, or they may throw out coagulable lymph, and unite in that way. I have seen granulations from the dura mater and scalp unite so closely in twenty-four hours as to be with difficulty separated, and then to bleed very freely, which shows their great disposition to unite. When the parts, and consequently the granulations, are not sound, there is not this disposition to unite, and a smooth surface is formed, which continues to secrete pus. I conceive the internal surface of a fistulous sore to be of this nature, and somewhat similar to the urethra in gleet. Ulcers of this kind are cured by exciting inflammation in them.

Granulations have less powers and shorter lives than originally-formed parts. Different animals have different periods of life, and so have granulations, and sometimes they seem to be formed with a short period of existence. They often die and slough off without any visible cause, and, coming down to the original parts, a fresh crop of granulations is formed, which in a certain time will again slough off without any apparent change in the constitution.

Many small wounds would perhaps do much better without any dressing. The blood, coagulating and drying, forms itself into a scab, which falls off and shows that Nature has completed her work under it; the same will often happen when small suppurating sores are suffered to dry. This is a circumstance not attended to, perhaps, so much as it ought: even compound fractures with a small opening, if suffered to proceed in this manner, will often give but little trouble. In blisters, where the cuticle is not removed, the process is exactly similar. It would be a

great advantage to us to ascertain what sores require dressing, and what do not. I believe all cutaneous sores do best without dressing; excoriations and little pimples had best be left to themselves, for often when applications are made to any of these, a hundred little pimples will sprout up: when this is the case, I make it a general rule to desist from any application.

A young gentleman had a small pimple on his leg, to which a little ointment was applied, and in a day or two the surrounding parts were covered with similar pimples: these, being treated with similar applications, spread, until the whole leg was covered with them. When I was consulted, and asked what was to be done—"Nothing." "How is that?" "Can anything be easier?" I said; "do nothing to the leg." "Then the stocking will stick to it." "Let no stocking be worn: put the boy on a pair of trousers." The advice was taken, and the leg dried up and healed directly.

Cicatrization.—Immediately on the formation of granulations, cicatrization would seem to be in view: contraction is going on in every part, but principally from the edges to the centre, so that the sore becomes very small, without much new skin. This contraction is easiest effected on loose parts, but with difficulty when over bones, as on the scalp, shin-bone, &c., where the granulations cannot contract much. This observation should direct us, in operations on such parts, to leave as much skin as possible. This contraction continues until the whole is skinned over; but their greatest power, or at least their greatest effect, is at first. This contraction can be assisted by art, which shows there is a resistance; this is done by bandages, but these should be avoided at first, while there is inflammation, and until granulations are formed, otherwise they might prevent the granulations rising. Besides the contractile power of the granulations, there is a similar power in the surrounding edge of the cicatrized skin, which assists the power of the granulations, and is often greater than that of the granulations; this may be seen in sugar-loaf stumps, where the skin grows round and embraces the granulations like a ring, appearing to squeeze them out; but it is only in the new skin, the old being loose all round. This contractile power prevents the necessity for so much new skin, the surrounding old skin being drawn over the parts. The advantage of this is very evident, the original skin being

more fit to live than the new, and less liable to ulceration. As the granulations contract, the old surrounding skin is stretched, and is probably elongated. If it is elongated, it must be so by the interstitial deposition of new matter.

Of skinning.—When a sore begins to heal, the old skin, which had been inflamed, then becomes whitish, and especially near the edge; this is one of the first appearances of healing. The new skin is a very different substance with respect to texture from the granulations on which it is formed: but whether it is an addition of new matter, or a change in the surface of the granulations themselves, is not easily determined. We find new skin generally taking its rise from the surrounding old skin, as if elongated from it; but that is not always the case, for in very large old ulcers, where the edges of the old skin have but little tendency to contract, new skin forms in different parts of the ulcer, standing on the surface of the granulations like little islands. These little specks show that the ulcer is healing slowly, and it seldom or never takes places the first time a part is ulcerated; but the old surrounding skin assists by shooting towards the new. The granulations may perhaps acquire a disposition to skin from their being in the neighbourhood of the old skin, but it is plain they can take on this disposition without that assistance.

Skinning is a process in which Nature is always a great economist. We never find that new-formed skin is so large as the sore was on which it was formed. This is brought about by the contraction of the granulations, which in some measure is in proportion to the quantity of the surrounding old skin. If a sore be in a part where the surrounding skin is loose, as the scrotum, the contractile power of the granulations being not at all prevented, very little new skin is formed; whereas if the sore is on a part where the skin is tight, as the scalp, the new skin is nearly as large as the sore.

Nature of the newly-formed Cutis.—When granulations are formed near a bone, the skin is at first fixed; but it gradually becomes loose, from elongation, by continued attempts at motion. Motion given to the part so affected must be mechanical, but it becomes a stimulus by which the parts become conscious of their not being able to exist as they are, therefore the lymphatics set to work to absorb all the adventitious substances which prevent their motion. Medicine has not as

much power as we could wish in assisting this process; however, mercury seems to have nearly the same effect as motion, especially when combined with camphor, and should be used. When everything else fails, electricity may be tried, for it has restored the motion of parts after they have been fixed from inflammation after strains.

The newly-formed skin has no indentations, or lozenge-shaped marks, on it, like the old, nor has it the living principle so strong. The new cutis is at first very vascular, but afterwards becomes less so, the vessels perhaps being obliterated, or converted into absorbents, and so becoming white.

Cuticle.—That formed on the new cutis is at first horny, but afterwards shining. It is sooner restored than the cutis, and is formed at once from every part of the cutis.

Rete Mucosum.—This is much longer in forming than the cuticle, and sometimes is never recovered, as we see in wound, blisters, &c., in blacks, their skin in that part remaining white for ever.

THE MEDICAL JURIST.

No. 4.

INSANITY.

When insanity occurs after the death of a friend, it is not from actual sorrow for his loss, but from the anxieties which were previously entertained respecting him, and which death has deprived of their object, and thus left to prey on the mind. A similar case is that of soldiers, in whom insanity, when it takes place, comes on after the campaign; and not while the excitement lasts. It is the same with mental suspense, arising from mercantile speculation, and various other causes. Gluttony and drunkenness bring the brain into a state, very likely, to be affected by any exciting cause of insanity. The functions of the brain may be disordered by these various circumstances; just as the functions of other parts are disordered by appropriate causes. Disorganization is not necessary to insanity; and therefore, if we find disorganization in the brains of the insane, we are not always to conclude that it must have been the cause of the insanity. Love that fertile source of insanity, more frequently produces it in females than males; for they are kept lon-

ger in suspense,—waiting till the lover declares his intentions.

It is very questionable whether private mad-houses ought to be allowed; for it is wrong to place any man in a situation in which his interest and his duty are opposed to each other. The friends should be admitted to see a patient at all times. Before the parliamentary inquiry into lunatic asylums, much iniquity prevailed in the treatment of the insane. Even George the Third was horse-whipped by his keeper. A mild treatment is to be pursued; for the least harshness may throw a patient back. You must be very firm, and, at the same time, candid; for the insane are very suspicious, and generally very acute. Far from being wholly bereft of sense, they are perhaps deficient only on one subject. You must treat such patient according to the particular direction his disease takes. Keep him at home, at first, if the disease will allow it; putting knives, and all other dangerous instruments out of reach, and fastening the windows. If he do not recover, and is wealthy, let a house be taken for him in the country, and let him be attended there by keepers; taking care that a relation is constantly in the house with him. If he cannot afford this, send him to a public asylum. In order to get him there, be very cautious in your proceedings; for if he be only slightly affected, the knowledge of your design may make him furious. I was taking a gentleman, in a carriage, to a lunatic asylum, says Dr. Mackintosh; and he thanked me for my kind behaviour; while on previous occasions, he had been taken by others, laid in the bottom of a carriage, with his hands tied together. I lodged him in my house the night before; and in the morning told him I was going to visit a patient in the country; but that he should not go with me because he was so violent. He promised to be very quiet, if I would allow him to accompany me; and he was so. A clergyman gave the first symptom of being insane, by asking a gentleman to dine with him, at the time he was reading prayers in church. He then told his wife he had been sleeping with two women; and though he had previously been a moral and excellent clergyman, he used to parade the streets in the company of prostitutes, kissing all who passed. He used to wear a tartan dress; for it is curious how fond they are of outré dresses. Dr. Mackintosh got him to accompany him quietly to an asylum in the country, by a pretended invitation from Lord Melville

to fish. He was locked up all night; and in the morning knocked for the steward, when a patient told him he was in a mad-house. He immediately put a restraint on himself; was let out, well, in a few months; went to England; and was there again placed in confinement.

The details of Mr. Combe's visit to many establishments in Dublin, are given in the *Phrenological Journal* for August, 1829. One was the case of Bridget Smith, in Mercer's Hospital. The organ of hope was small; and the organs of cautiousness and destructiveness were large. This combination gives a tendency to suicide; which this patient had twice attempted; on account of her husband, of whom she was very fond, not living with her. Phrenologists have been accused of irreligion, in having connected the mind with the organization of the brain; but it would be as fair to blame them for connecting the secretion of urine with the organization of the kidneys. A clergyman who had been opposed to phrenology, was convinced of its truth by hearing two lectures from Mr. Combe. There are many things they say which it is difficult to follow; and it is not easy to distinguish the numerous organs into which some parts of the brain are divided. A brain was taken to Mr. Combe, as having belonged to a girl of notoriously immoral habits. On examining its development, he declared his conviction that the person to whom it had belonged was of a very different disposition; and if it did not prove so, he would give up phrenology. It turned out, on investigation, that the brain of a particularly modest person had been sent by mistake. It is asserted by some, that if a flat thermometer be applied over any organ of the brain in increased action, it will indicate an increased temperature. The division of the brain, adopted by phrenologists, is no doubt correct to a certain extent. What they say is that the mind displays itself through the organs of the brain; and that disease of these organs constitutes insanity. The great variety of character among men, is proved by history, as well as by observation of different persons in our own day. What a mixed character was David, King of Israel! Phrenologists consider that his head would have shown the organs of conscientiousness, adhesiveness, and veneration large; and that his one raging propensity would have been indicated by a large cerebellum. They also consider that if Dr. Dodd had been pardoned, he would, most likely, have repeated his

crime; for though he was very devout, the cast of his head indicates want of conscientiousness and firmness. The first observation of Dr. Gall was, that boys having a peculiar formation of the head, got their lessons more easily than others.

Mr. Combe examined, at Dublin, the head of Mr. Oldham, without knowing him and pronounced an opinion that he would excel in mechanics. His wonderful machines for printing notes at the Bank of Ireland, are well known. Mr. Combe was also taken to the Richmond Lunatic Asylum there; and gave his opinion on persons, whose cases had been previously written down, but concealed from him. The first patient was Patrick Lynch; whose insanity he pronounced to be connected with religion. This patient used to write sheets of splend, but confused imagery, about heaven and hell. He was mad only in this one particular. The next patient had the worst development Mr. Combe had ever seen; and the latter wondered he had never been hanged. It turned out that he was an incorrigible villain; who had attempted to murder his fellow soldier, and even to poison his father. In the next patient, self-esteem was large; and he thought himself an emperor. Another had the organs of wit and wonder large; and he wished that the office of hangman should be procured for the villain just mentioned. Another thought himself to be God; and said he was without beginning or end, and threatened those he did not like with hell. Mr. Combe accordingly pronounced on the kind of hallucination these patients were subject to, without any previous knowledge of them. He was afterwards taken to the Dublin Penitentiary, where previous notes had likewise been taken of the cases, and Mr. Combe's opinion agreed admirably with them. Dr. Mackintosh saw most of the patients we have mentioned, about a year afterwards, and he confirmed the accuracy of Mr. Combe's opinions. It is difficult to imagine a more decisive test to which the science could have been subjected, than the foregoing.

Before sending a man to an asylum, be sure you have sufficient evidence of his insanity to produce to a jury. I have in my possession, says Dr. Mackintosh, a letter which would make a thousand juries believe that the writer must be perfectly sane; but if you spoke to him on certain subjects he became furious. He deceived a number of London physicians, at the very time he had bought a hearse

and six horses, to bury a Highland chief, whom he intended to kill. He had it driving up and down before his house; put his name on his door as a baronet; bought all kinds of things; and entered into fifty law suits, without having any money to carry them on. After all the London physicians said he was of sound mind. I got him confined in the Perth Asylum; which is the best in Scotland. If the patient be troublesome, it is best to call in the assistance of the police, and he will most likely commit himself at their office, and then you will have the evidence of their books to justify your confining him.

Be cautious of bleeding heroically in mania, unless there are decided marks of plethora as well as of increased action of the brain. Insanity sometimes arises from a deficiency of blood in the brain. If you are in doubt of bleeding, use leeches and cupping, and apply cold;—administering laxatives at the same time. Much may be done by diet and exercise, which are of the greatest importance, especially in melancholia, which is the most inveterate kind of insanity. Patients afflicted with it have generally great cautiousness, and little hope. It is of great consequence to keep the feet warm. Dr. Mackintosh once heard, while outside the door, a maniac say, that if his feet were warm he should get well. He found they were cold as marble; had them warmed; and the patient began to recover immediately. Asylums are too often without efficient means of being warmed. The directors who are appointed, too frequently neglect their duty; and the complaints of the patients are not attended to, when they tell the truth about bad treatment. As to diet, it is wrong to feed them on salt meat, two or three times a week, when they have been used to better things.

If blisters are ordered, they must be carefully watched. In one instance the patient scraped off the cantharides, and put them into his eyes, one of which was lost, from the violent ophthalmia which ensued. It is often difficult to get them to take medicine, for they think it poison. They may be sometimes be tricked into taking it. Thus, tartar emetic may be administered by putting it into the teakettle; but they will often make the doctor taste it first. If they say they are poisoned, you can tell them the medicine you wish them to take is an antidote; or, if they boast of having an emperor or some other great man, for a friend, you

can tell them he has sent them something to take. For instance, a gentleman who boasted of his intimacy with George the Third, was induced to take medicine by having a pretended proclamation from the latter read to him. When he got well he laughed at all these subterfuges. He said he was annoyed at the window having been fastened down; for he had intended to jump out of it, and swim across the Frith of Forth. The fall from the window must have killed him.

As to the moral treatment, it is wrong to keep a patient among those who are worse than himself. Dr. Mackintosh knows a clergyman in confinement, who thinks himself chaplain to the asylum, and would not leave it if permitted. He reads prayers and performs divine service every Sunday. It is important to obtain a complete mental command over the insane, for this restrains their violence. For want of it, the distinguished physician just mentioned had once his arm dislocated by a maniac. He finds he can always control them if he can fix his eyes on theirs. The effect of moral treatment is seen in the following case: A lady became insane after delivery, and thought she was to be executed for the murder of her child. She was put into an asylum, where, after some months, she was visited by her husband, and told him she was to be executed. He walked up and down with her, talking calmly about her children; but she then took into her head that he was a ghost. When he was taking leave, however, she said she thought she had been under a delusion, and she soon got well.

We have already given instances of the extravagant notions and language of patients. A man in the Chatham Asylum, thought himself our Saviour; that he had a thousand brothers and sisters, who lived in the eye of a needle; but that he never met them, except when a lady (probably his sweetheart), was mending the frill of his shirt. He said that his feeling was so acute, that if his friends were on the other side of a wall twenty thousand miles thick, he could feel their noses through it!

It must never be forgotten, says Dr. Traill, that in asylums no more restraint should be employed, than is necessary to restrain the unfortunate being from hurting himself or others; while the order and economy of the house are to be maintained by a mild, but firm administration,—rather like the authority of a parent over children, than the rigid sever-

ity of a task-master towards a dependent.

DISQUALIFYING DISEASES.

Many bodily diseases disqualify for various social relations. The marriage relation, for instance, has given rise to many curious questions connected with the function of generation; but suits of this nature have been quite unheard of in Scotland, for many years, and but seldom in England. The questions relating to the disabilities of soldiers and sailors (whose disease may be either feigned or concealed) are very important to those engaged in the medical department of public service. Marshall's work on this subject is a very good one.

There are either civil or military duties which the law requires of all; and it is the business of the medical man to decide on maladies which are alleged as exempting from them. He may be required to determine whether a man is capable, without imminent danger to his health, or risk of life, of performing the duties of a jurymen, for instance; or of an officer of justice; or of serving in the army. In all such cases, the certificate should be carefully drawn up, on an honest consideration of the case, and a fearless determination to do justice. There are some diseases, which are easily and evidently seen to disqualify; but in chronic cases, it is often a nice point to determine whether they disqualify or not. Here the medical man must act from principle; and not from a desire to oblige any person. Certificates exempting from serving on a jury, have been given to those subject to asthma, gout, or rheumatism, as it might be dangerous for them to sit long; and it would be impossible for those subject to incontinence of urine. Persons threatened with consumption, have also been excused. Certificates have been given to persons subject to epilepsy, stating that fact; and the judge has always allowed them. If an epileptic fit occurs, it is often succeeded by stupor, which might stop a trial for a whole day.

In France, a military substitute cannot be provided by purchase. If a surgeon in that country were known to sign a false certificate, or to take a bribe, or to accept a fee, he would be imprisoned, fined, and dismissed from his situation. Under Napoleon, every man above the age of fifteen, and below that of fifty, could be called out. The ages are now twenty and forty. Before the former period, puberty is not complete, and after

the latter, the limbs are not pliable enough to perform military evolutions. The best surgeons are of opinion, that no man will make an effective soldier, if under twenty-one years of age, or if he have not been drilled till after twenty-five. The waste of life under Napoleon, from the tender age of many of his recruits, was greater than from the sword. It was very common for diseases of the hip-joint to be produced by drilling. Mr. Marshall gives very excellent directions for examining recruits. His remarks on the cruelty of filling up the ranks of regiments going abroad with raw recruits, are very excellent.

In England, any mental imbecility excuses from civil service. Great cruelty is committed by magistrates, in ordering the tread-mill as a punishment indiscriminately. It is light work for an agricultural labourer, for instance, but not for a tailor, or for persons of a similar occupation. It is a savage treatment for women, especially for prostitutes, who are very liable to prolapsus uteri, and other diseases of the generative system.

THE STUDENT'S MANUAL.—No. I.

ORGANIC DISEASES.

Disease is the irregular performance of a function. If the stomach, for instance, be diseased, we have irregularity in the performance of its functions; producing flatulence, dyspepsia, vomiting, &c. Every disease has its particular seat, but other parts may be affected by sympathy with it. Thus the stomach and brain have a strong sympathy with each other. Hence inflammation of the brain is accompanied by disorder of the stomach; and attention to the latter would not relieve the former. Such attention to the one might even be injurious to the other; for stimulants and narcotics would allay the vomiting, while they would aggravate the disease of the brain. We must, therefore, always inquire whether any symptoms which an organ presents are primary or secondary; for if they are the latter, we must direct our attention to the primary affection. Should this primary affection be confined to a particular part it is called a local disease; but if other parts are disturbed it is called general. Thus, if the lungs are but slightly inflamed, the mischief may be confined to them; but if they are violently inflamed, the whole system is disturbed.

298.

This general disturbance is called a febrile affection, or symptomatic fever. Here we must attend to the primary disease, for it will not be enough to attend to the increased arterial action. The latter may be reduced by cold and purging; but this would not cure the primary affection, which requires copious bleeding; and if that should overcome the primary affection, the secondary symptoms will give way. Every disease is local at first, and may remain so. Pneumonia, for instance, as we have already observed, is not necessarily attended by any general disturbance. All general diseases are dependent on some local primary disease, with which the general system sympathises. There is probably no exception to this general rule,—that all general affections have some local disease at the bottom: though it may have escaped the attention of the patient. Consumption produces hectic fever; which may also be the result of disease in a large joint; and we cannot cure the hectic without removing its cause. This we cannot do in the case of consumption; but a diseased joint may be removed by amputation, and then a cure will be effected.

In treating any disease we should first consider its signs or symptoms. These comprehend the feelings of the patient, disordered functions, &c. If there be any pain in any part we infer that the part in question must be in a morbid state. But there are some parts endowed with a very small share of sensibility; and these may be diseased without pain. This rule applies to very important organs; such as the brain, which is the source of feeling to other parts, but is itself very defective in feeling. The lungs have but a slight degree of sensibility; and in the worst diseases of the brain and lungs there is the least pain; so that in this case we cannot judge of the violence of the disease by the degree of the pain; we must judge by the state of their functions, and this is a better criterion than the former.

Some diseases are known at once by some prominent symptoms; such as jaundice by the yellow tint of the skin and eye-ball; or consumption by the dyspnoea, the emaciation, and the hectic flush; or dropsy by the swelling, fluctuations, and pitting. But a more minute inquiry is necessary for practice. Jaundice, for instance, may depend on different causes; such as the presence of gall-stones in the ducts of the liver, or inflammation of the liver or its ducts, or the pressure of neigh-

E

bouring parts on the ducts, or perhaps spasm of the ducts. It will, therefore, require different modes of treatment, according to which of all these causes may be in action. Thus, if inflammation be present, we must resort to blood-letting; but if the jaundice be the result of spasm, we must not bleed, or use any active remedy. Here we must attend to the primary symptoms, and not to the secondary. Dyspepsia attends jaundice, from the want of bile in the intestines; but here it is only a secondary affection; and if it were alone attended to, we should employ stimulants and tonics; which would aggravate the primary disease. Remove the latter, and the former will disappear.

From the symptoms we form the diagnosis. This is very important, for a disease once known, is half cured. We must first notice what we can discover for ourselves; such as the state of the pulse, countenance, and tongue; and then inquire the patient's feelings. He will generally point to the part affected; but we must not trust to that; as he may only notice the secondary affection. For instance, he may not think his stomach alone affected; whereas, it may be affected secondarily, from sympathy with disease of some other part. In the case of infants, and idiots, who cannot explain their feelings, we may discover the disease by examining the functions.

After ascertaining the symptoms, inquire into their cause; for often when this is removed, the disease cannot cease. If ophthalmia be produced by an inverted eye-lash, or by a foreign body within the lids, no remedies can cure the inflammation, without removing the offending body. A disease, however, when once set up, may go on independantly of the cause which originally excited it. Thus, although inflammation may be produced by cold, will not cease on the removal of the cold. The same may be said of contagious fever, and various other diseases; and here it is not necessary to enquire the cause of the affection; for the latter is independant of it. A disease, on the other hand, may cease, although the cause of it may still be present; otherwise, contagious fever could never be cured.

The causes of disease have been divided into immediate, and pre-disposing; and into recent and remote. Cold, for instance, is often applied to the body without injury; but sometimes it excites the most violent diseases. To account for this different effect, there must be something different in the state of different in-

dividuals, or of different individuals at the same time; and this difference of state is called a pre-disposing cause. Thus, persons who have been weakened by any cause, are more liable to disease; and here debility is a predisposing cause. Again, certain diseases prevail in some countries, and not in others; as liver complaints, which are most frequent in hot countries; and pulmonary diseases, and scrofula, which occur most frequently in cold. Here, climate is a pre-disposing cause. When a disease does not immediately follow the application of its cause, the latter is called remote. When various matter is applied, the disease does not follow for eight days. When on the other hand, the effect immediately follows the cause, as in the case of a burn, the latter can hardly be called remote, though it has been so denominated. The proximate cause has been applied to mean the disease itself; as in the case of cholera, where the spasmodic contraction of the intestines, is styled the proximate cause; but this spasmodic contraction is the disease itself. In like manner, the proximate cause of pleurisy is said to be inflammation of the pleura; but this inflammation can only be styled proximate with respect to the symptoms.

In the production of disease, there are many intermediate steps which we do not understand. Thus, when cold produces inflammation of the lungs, we do not know the intermediate changes which take place. The same may be observed of exposure to variolous contagion. The eruption produced by the latter, was formerly said to be the result of fermentation of the humours; but this was all imagery; and we are now satisfied with knowing the facts, that an eruption of a certain kind is produced, at a certain time after the application of a certain cause.

A disease may differ in degree, and hence it is called either acute or chronic. There is no radical difference between the two, which are only different degrees of the same thing; and every kind of intermediate state may occur between these two extremes. The term *chronic* has reference to time or duration, while *acute* refers to the degree of violence. But we may have a disease which is neither acute nor chronic, being too mild for the first, and too short for the last; so that *chronic* is not always a correct designation. A disease may also occupy different parts of the body, and this will modify the treatment. If the seat of the disease be an organ essential to life, our remedies must

be active and powerful; the kind of treatment, likewise, must be altered. Inflammation of the lungs must not be trusted to itself; but inflammation of the mucous membranes often terminate spontaneously. In the first case, blood-letting is essential to the cure; in the second it is beneficial, but not so necessary; and in inflammation of ligaments it is often not curative.

Diseases may differ in their intrinsic nature. Inflammation affects the vascular system; while spasm affects the muscular. The first is much more serious in its nature than the last; and the remedies suited to spasm (such as stimulants and narcotics) would be injurious to the inflammation. A patient, for instance, may have pain in a particular part, but we must not administer opium until we have ascertained whether the pain is inflammatory or spasmodic. Diseases also differ as to whether causes are specific or common; and they require different treatment accordingly. Variolous and venereal inflammations are specific; and bleeding will not cure them, though it does common inflammations. For variola there is no cure, but it terminates of itself: for venereal inflammation we have mercury.

Diseases are affected by age. Inflammation of the lungs in a young subject will, perhaps, prove fatal in forty-eight hours; but in an adult its progress is less rapid, and in old age very slow. Infants are more liable to convulsions than persons in after-life; and also to hydrocephalus and scrofula. The latter never makes its appearance for the first time after the period of puberty has passed. Climate also has a great influence on disease; for instance, we have now a cure for scrofula, and climate will often effect one. Children who come to this country from India, are often attacked by scrofula, but they get well on returning to their native climate. Pulmonary consumption, which is so fatal here, is but little known in hot countries; and therefore we should remove the patient to one of the latter, till the age of exposure to consumption is past. It is not likely to occur after thirty. Individual constitution affects disease. Some families are subject to consumption, rheumatism, gout, affections of the brain, &c. All these circumstances are to be considered in the treatment. The terminations differ. These may be either fatal or favourable; or one disease may run into another. When a disease terminates in health, it may be either spontaneous or with the assistance of art. If we can trust to the first it is better for the patient.

The term, *effort of nature*, is figurative language; and when it is said to cure, it means that the disease subsides when left alone; catarrh is an instance of this. Diarrhœa is often best left to itself, though the discharge might be stopped by opiates, which would be wrong when inflammation is present. The patient should be kept on diet that does not stimulate; and the disease will often disappear. Fever, when it has become fully established, will run a certain course, and had then best, in general, be left to itself; but if taken early active treatment may be employed. If important organs are affected it is not safe to trust them to themselves; and the disease may often be brought to a favourable termination by art; and this is called the practice of physic.

Diseases may terminate fatally in different ways. Sometimes it is by interrupting the function of the part; as in inflammation of the lungs, or heart, or brain. If the disease be not violent, it may not interrupt the function of the affected organ. Sometimes it is by producing general weakness; as in those diseases which affect the stomach, and destroy its function. Extensive burns or scalds, prove fatal by the general disturbance which they cause, and not from the loss of skin; which is a part not essential to life. The same may be observed with respect to gangrene of an extremity; where the mortification of a part, not larger perhaps, than the hand, will cause general disturbance, delirium, prostration of strength, and death. The change of one disease into another, is sometimes beneficial, but at others is not. Rheumatism may terminate in inflammation of the brain, lungs, or heart; which is a much more serious affair than the original disease. Fever sometimes causes inflammation of the skin; and so terminates. Here the change is to be encouraged. Disease very often proves fatal, by a change in the structure of parts. Pneumonia often terminates in this way.

Diseases have been classed in different ways. Sometimes they have been arranged in alphabetical order; but this is a very unscientific mode, as it separates diseases which are very nearly allied. The general division into acute and chronic is also very vague; uniting opposite diseases, and dividing similar ones; as in the case of remittent and intermittent fevers. Diseases have also been divided into local and general; but it is not likely that there are any strictly general diseases. Fevers, for instance, were long considered

to be general diseases; but they are now considered to be symptomatic of inflammation of the brain, or the intestines, by a great number of English and French physicians. A favourite mode of classification, is that in which the diseases are arranged, according to the peculiarities they present; like plants in a botanical system. Cullen's nosological system is of this nature; and as it is still recognized at Edinburgh, we shall put the student in possession, as we go along, of such information respecting it, as may be necessary for any one preparing for examination there.

Cullen then divides all diseases into five classes; 1, Pyrexixæ, inflammatory diseases; 2, Neuroses, nervous diseases; 3, Cachexiæ, diseases of debility; 4, Locales, local diseases. The first class, Pyrexixæ, is divided into five orders; 1, Febres, fevers; 2, Phlegmasiæ internal inflammations; 3, Exanthemata, eruptive fevers; 4, Hæmorrhagiæ, bleedings; 5, Profluvia, discharges. The second class, neuroses, is divided into four orders; 1, Comata, lethargic diseases; 2, Adynamixæ, weaknesses; 3, Spasmi, spasms; 4, Vesaniæ, mental diseases. The third class, Cachexiæ, has three orders; 1, Marcores, diseases of emaciation; 2, Intumescentiæ, diseases of enlargement; 3, Impetigines, spots. The fourth class, Locales, contains eight orders; 1, Dysæsthesiæ, impaired sensations; 2, Dysorexiæ, impaired appetites; 3, Dyscinesiæ, impaired motions; 4, Apocenosæ, increased evacuations; 5, Epischesæ, diminished evacuations; 6, Tumores, swellings; 7, Ectopiæ, dislocations; 8, Dialyses, solutions of continuity.

These orders are subdivided into genera, each of which is appropriated to a single disease; and of this various species are given, and sometimes varieties. We need not enter into these; which will be found in a very portable shape, in Dr. Milligan's edition of Cullen's "Synopsis of Methodical Nosology." Those who wish to pursue the subject further, will find it discussed with great learning and ability by Dr. Mason Good, in his Physiological system of nosology. Every part of the tract on which we are now entering, abounds with treatises. That which contains the greatest amount of information, condensed into the smallest compass is, Dr. Ryan's new edition of "Hooper's Physician's Vademecum" which has just been published. Of large works, of sound sense, and enlightened views of practice, the best is, Dr. Mackintosh's

on "Pathology, and the Practice of Physic." For surgical diseases, the most pleasing and popular work is, Sir Astley Cooper's "Lectures." The student would do well to consult likewise the treatises of Liston and Syme. The dictionaries of Dr. Hooper, and Mr. Samuel Cooper, are libraries in themselves. The fullest account of the diseases of children, is to be found in the course of lectures on the diseases of children, from birth to puberty, published in this journal.

The London Medical AND Surgical Journal.

Saturday, October 14th, 1837.

THE METROPOLITAN UNIVERSITY.

SINCE the period when this new and important national establishment received from the government a locality in Somerset-house, and the sum of one thousand pounds was placed at its disposal, to meet with the exigencies incidental to its organization, it has been progressively advancing and making such arrangements as will enable it, before long, to fulfil the intentions of the founders. It can readily be conceived that there must have been numerous difficulties in arranging the details of an institution of so comprehensive a character, and more particularly from the discordant materials of which the senate was composed. It will be recollected that much contention arose in the first essential measure which came before its consideration—the appointment of a REGISTRAR, on which occasion there was a gross attempt at jobbing, which was first exposed in this journal. One division of the medical senate proposed that no less a sum than eight hundred a year should be given as a salary to the said Registrar, and Dr. Forbes, of Chi-

chester, with the approbation of his "friend in arms," Dr. James Clark, was proposed to fill this office, whilst Dr. James Somerville was brought forward by Mr. Warburton as a highly qualified candidate for the situation. It was, however ultimately decided, as we repeatedly urged, that the proper business of a registrar would be more efficiently performed by an active intelligent clerk than by the most accomplished member of the medical profession; and we have every reason to believe that the decision on this point has given universal satisfaction. Another circumstance which created a good deal of discussion, was, the attempt made by the Roget Dilly to form *secret committees* for carrying on the business of the University, and the ejection of that most illiberal measure was of essential importance in the future government of the institution; and there could be no more convincing proof of the real objects of Dr. Roget and his *select* friends, than the mode and means which they adopted to exclude Mr. Warburton from the medical senate. The Chancellor of the Exchequer was well aware when he selected the members of the senate, that they were of a heterogeneous character—that unions and reunions, compositions and decompositions would take place before a harmonious assemblage would be formed, and had he even acquiesced in the express wishes of the honourable member for Finsbury, and have elected either him or his Brightonian prototype, it is not at all improbable that in the senate a better arrangement could have been made.

Besides other important points which may now be considered certain, one will, we venture to say, meet with general approbation, the University having determined to grant their medical degrees, not only to the students of all the *recognized schools* of the United Kingdom, but also

to admit general practitioners, whether members of the College of Surgeons or of Apothecaries Hall, to examination, without any reference to their previous education. It may be also considered as certain that they will grant diplomas in midwifery, by doing which they will perform an important duty to society, the value of which may be fairly appreciated from the well known horror which such a measure has been looked upon by the corruptionists of Lincoln's Inn, and Ipecacuanha Hall, as well as the old Ladies of Pall Mall East.

We have stated that pupils from all the recognized schools in the Kingdom will be received as candidates for medical degrees, and whilst we announce this just and liberal regulation, we are glad to take the opportunity of calling public attention to the low and contemptible means which the Gower Street and Strand Joint Stock Companies have resorted to, with a view to delude especially young men, green, raw, and fresh from the country, into the belief they and they alone, were the only schools whose certificates would entitle students to come forward as candidates for diplomas. However culpable the "Strand Union" may have been, the renegades of Gower Street have, according to their liberal system, gone much further. Surreptitiously calling themselves the London University, they were compelled to abandon that title, and in their new charter they are christened University College, a name which, though palpably absurd in the literal acceptance of words, was yet artfully calculated for promoting their fraudulent purposes, leading the unsuspecting and unguarded portion of the community to confound them with the New London University.

DEATH OF THE ANNALS OF MEDICINE.

At the time when we noticed the debt of gratitude which many of our professional brethren owed to Mr. Sherwood, for the encouragement which he had given to medical literature, it had been whispered in the "Row" that the *Annals of Medicine* would not long survive its projector and patron. These forebodings have been realized, and though it be too much the custom for journalists to trample on the ashes of their contemporaries, we are sincere in expressing our regret, that the publication of the *Annals of Medicine* is discontinued. The present corrupt state of the medical press, whether we regard that journal, the avowed hireling of abuse, or the still more dangerous foe to all substantial reform and good government, the "Independent Journal," led us to anticipate that the principles of the *Annals* would have, at no very distant period, assumed a more steadfast and *unbending* aspect, and would have materially assisted us in remedying many of the more serious abuses which now exist in the profession. During the early part of their career, the Editors of the *Annals* were unavoidably surrounded by many difficulties, by none of which they were more seriously clogged than being under the necessity of appropriating the superabundant supply of another periodical to fill up their pages; and to this mistaken view may, in a great measure, be attributed the decease of the hebdomadary.

We understand that the editors of a certain Quarterly have it in contemplation to bring a second son into the market, whose success in life will, we hope, be more prosperous than that of his precursor.

R E V I E W S.

Evils of the Factory System Demonstrated by Parliamentary Evidence.
By CHARLES WING, Surgeon to the Royal Metropolitan Hospital for Children, &c.

We have been tardy in noticing this work from various causes, which it is now necessary to mention. The importance of the volume before us has undoubtedly called for an earlier review of its contents; but as the question on which it treats is still open, and the work is not one of the mere ephemera of the hour, we shall be rendering the children, whose cause it so ably advocates, some service, even though we are rather late in the field. The work is too voluminous for us to enter into an abstract of its entire contents, embracing as they do, a most excellent abridgment of all the parliamentary evidence given on the Factory System. The talented and benevolent author has prefixed to this abridgment a series of valuable observations on the present system. We extract the following as forming some of the "reasons for publication:"—

"The object of the present publication is to prevent, as far as bringing evidence within the reach of the public can do so, a partial return to the factory system, as it existed previously to the year 1833, since a partial return to that system is in itself an evil, and may be the prelude to a total return. An act was passed in that year, of which the operation was to be gradual, but its ultimate aim was to prevent, from the 1st of March, 1836, any child who had not completed his thirteenth year from working more than eight hours a day. This act contained many provisions which the manufacturers found exceedingly troublesome and vexatious, and which were consequently observed by the conscientious and defied or evaded by the less scrupulous. Memorials were sent to the Board of Trade, not seeking the total repeal of the act, but of that part of it which afforded protection to children under thirteen years of age. At the suggestion of the memorialists, the president of the Board of Trade brought in a bill to repeal so much of the act as prohibits the working of children under thirteen years of age beyond eight hours a day, and leaving it in the power of children, from twelve and upwards, to work twelve hours a day. The sole object of bringing

forward the bill is said to be to prevent 35,000 children being thrown out of employment, and this object is effected by withdrawing the protection of the act from all those children who are in the thirteenth year of their age, and suffering them to be worked twelve hours a day, exclusive of meal-times. The inconsistency of ministers, in bringing forward this bill, is obvious. They threw out Lord Ashley's ten-hour bill at the recommendation of their own commissioners, who gave it as the result of the evidence they had collected, that the labour of children ought to be restricted to eight hours, and that, therefore, a ten-hour bill would not afford them sufficient protection. And now these same ministers would drive back a large portion of these children to twelve hours, that is to say, to the labour of adults, for twelve hours is the usual period of adult labour, though, upon emergencies, it is protracted to thirteen or fourteen hours.

*Quicquid delirant reges, plectuntur
Achivi.*

Ministers bring in an inefficient bill, and 35,000 children are to suffer for it. Two thirds, or perhaps three fourths, of the hands employed in mills, are children or young persons, and their labour is strictly connected with the labour of adults. Ministers, anxious to afford protection to the children, but reluctant that the benefit of this protection should extend to adults, attempted to legislate for the children only. Their own inspectors tell them that the main provisions of the bill, framed upon this principle, are impracticable. That, in many situations, relays of children, which this bill renders necessary, cannot be procured. Now, as there is a mutual dependence of the hands upon each other, if the children, who are employed principally by the spinner, are dismissed, his work ceases, and the mill is at a stand, so that if children are restricted to eight hours' labour, and relays cannot be procured, the labour of the adult will, in fact, be restricted to eight hours. If, on the other hand, relays can be procured, either the labour of the children must be less than eight hours, or the labour of the adult must be extended to sixteen hours. Though the inspectors call the main provisions of the act impracticable, they must be understood as limiting this assertion to peculiar localities, for they admit that they have found benevolent men who adhere to the very letter of the law. Men act from mixed

motives; and though the epithet conscientious seems more applicable to men who observe a law that is easily evaded, and that many do evade, yet we can easily conceive that one great incentive to this conscientious conduct is a repugnance to overwork the children, whatever they themselves may suffer by the law, and therefore they are well entitled to the epithet benevolent. Ministers found themselves in a dilemma; either they must overwork the children, or underwork adults—and they have got out of the dilemma by determining to overwork the children. In their alarm, they have thrown consistency overboard; and the very same men who declared even ten hours' labour too long for a child in his thirteenth year, would now expose him to be worked twelve hours. The case of the factory children is not a party question; for though conservatives have been among their most active champions, yet both whigs and radicals have fought in the same ranks; and perhaps the present ministry would not be found so lukewarm in their cause, if it were not for the formidable front presented by the manufacturers, some of whom have seats in parliament, and most of whom can make their influence felt at elections. To the credit of this country, I repeat, this has not been made a party question; and I can well conceive that there are many noble minds in the present administration who would gladly have their humane intentions strengthened by the force of public opinion from without, and the main object of this work is to effect that purpose, by affording the public that well-attested information which has not yet been laid before them, and which, without a publication of a similar kind to the present, would obviously not be within their reach."

The author in his preliminary observations gives a historical sketch of the factory system—preliminary objections with regard to the freedom of labour and foreign competition. He then discusses in a masterly manner the physical evils of the present system; in which he embraces inquiries into:—the regular hours of labour—the time allowed for meals—the extra hours of labour—the age at which children begin to work, the nature of their employment—the state of the buildings in which their employment is carried on—the treatment to which the children are subjected—and the ultimate effects of their employment on their physical condition. The author shows that the pre-

sent system with regard to these is exceedingly injurious to the factory children. The regular hours of labour are, however, very various, but generally, are undoubtedly too long for the little work-people. The hasty manner in which the meals are swallowed, from no stoppage from labour being allowed, in some factories, either for breakfast or tea; and only, in general, half an hour for dinner, must bring on a train of disorders and diseases of the nutritive system, which no doubt are felt through the whole period of their lives. He shews respecting the "extra-hours" the great abuses which exist. The children do their own work, the time requisite for which is either stolen from the regular times allowed for meals, the poor workers "eating how they can," or made up in some other way; by which the intentions and objects of the present act are grossly and wickedly frustrated, the children not in any way receiving benefit from its provisions. With regard to the age at which children begin to work Mr. Wing exposes, very clearly, the great objections to the plan proposed by Mr. Horner, that of taking the heights and appearance of the child as the only evidence of its having attained a certain age; so that, in many instances, the protection is afforded to the child of fourteen years of age which is denied to the one of ten, because the latter, forsooth, happens to be less in stature, and not so robust as the former! As the author well observes, "Mr. Horner's plan is very unjust to all children, who are often weaker than they appear to be, from the rapidity of their growth; and such is the degree of injustice done to them, as entirely to withdraw the protection of the act from them, unless they happen to be sickly in appearance." Mr. Wing shews, by extensive tables taken from the Marylebone workhouse, Christ's chapel national school, Maida hill, and other places, and he proves very satisfactorily that the tables constructed by Mr. Horner, and acted upon in the factories, do a great injustice to the children employed, and that his average height is considerably under that, which Mr. Wing, and other authors of celebrity are justified by experience in deciding on. Mr. Horner had considered that "the stress laid by some surgeons on the development of the teeth as a safe guide, might tell the actual age of the child, but would not indicate its bodily strength." In order to ascertain how far the teeth could be relied on as a guide,

Mr. Wing obtained the opinions of several of the most eminent dentists on the subject; among others, of Mr. Bell of Broad-street, Mr. Waite, Mr. Henderson, Mr. J. P. Clark, and Mr. Saunders; the whole of the author's interesting correspondence with these gentlemen is published in the work before us; the result of these opinions is, to use the words of the author, "I have examined several hundreds of children with reference to this enquiry, and if I may be allowed to offer an opinion, I must express my concurrence in the views of these professional gentlemen, who judge favourably of the teeth as a practical and very valuable *auxiliary* in determining the ages of children." We perceive that the interesting enquiry of Mr. Wing has given rise to a pamphlet on the subject, by Mr. Saunders.* With regard to the nature of factory employment, it appears generally not to be inconsistent with health, provided the hours are sufficiently limited. To obtain this proper limitation will be a work of some difficulty, and as is well observed:—

"A very great and recurring difficulty will, in the long run, operate as an impossibility. The vigilance of inspectors is not a match for the money-getting spirit of the masters, and the stimulating effect of higher wages upon the workmen. The apparatus for carrying the present act into effect is palpably inadequate; the few inspectors and superintendents that are appointed would need the eyes of Argus, the hands of Briareus, and the seven-leagued boots of Jack the giant-killer, with his coat of invisibility, to discharge their duties effectually; and wherever the various clauses of the act have been rigidly observed, it has been owing either to the benevolence, or to the conscientiousness of the masters. An act, to be effectual, should resemble the machinery, and be in some measure automatic. The present act enlists so many interests against itself, that it has been, and will continue to be, defied or evaded. A ten-hour bill would enlist nearly all the operatives in its favour, for those of the operatives, who at present oppose it, do so, in most instances, from no other motive than that of keeping in favour with their masters, and full employment. As the masters derive very great advantages from employing children instead of adults

* See an excellent little work displaying much research, "The teeth a test of Age," by Ed. Saunders.

and the labour of both classes is linked together, the adult ought surely to derive some advantage from a circumstance which has deprived so many of his class of bread, or made them dependent upon their children. It is stated, by witness after witness, that, from the nature of the employment, the factory workmen, at a period when others are in full capacity for labour, are incapable of any very gainful employment, from impaired eyesight and general debility. The system of relays acts against the adult, and aggravates the evils of which he has, year after year, been complaining. He dares not quit his occupation, not only from the dread of losing work altogether, but from the consciousness how little he is fitted for any other employment which will support either himself or his family. It is a spurious kind of humanity which would protect the child and leave the adult unprotected, upon the futile plea that he is able to protect himself. How have those fared who have sought to protect themselves? A candid answer to this question would abundantly show the fallacy of the pretext, that they are able to protect themselves."

The following sketch of the nature of the buildings in which their employment is carried on needs no comment. :-

"With regard to the state of the buildings in which factory labour is carried on it appears generally from the reports of the commissioners, that the large factories and those recently built, have a decided advantage over the old and small mills. Of the old and small mills the report is almost uniformly—'dirty, low-roofed, ill-ventilated, ill-drained, no conveniences for washing or dressing; no contrivance for carrying off dust and other effluvia; machinery not boxed in; passages so narrow that they can hardly be defined; some of the flats so low that it is scarcely possible to stand upright in the centre of the rooms;' while the account of the recent structures and the large establishments in general is—'infinitely better managed in respect to ventilation; height of roofs; a freedom from danger to the workers near the machinery, by the greater width of the passages in the working-rooms, and by the more effectual boxing in of the machinery, than those on a small scale." The commissioners have given several examples of mills in which every advantage of this kind is combined in an almost perfect degree; but they admit that there are too many instances in which an utter disregard is shewn, not

only to the convenience and comfort, but even to circumstances, which must influence, in no inconsiderable degree, the moral feelings and habits of the operatives. 'But one water-closet for both sexes, which children, and men and women, use indiscriminately.' 'Privies situated in view; common to males and females; this, in his (witness's) opinion, has a tendency to destroy shame, and conduces to immorality.' 'Workers complain of smells from the water-closet.' 'Picking-rooms pretty well freed from dust by effective fanners; but there is considerable annoyance to the workers from the effects of the water-closets; the effluvia must be unpleasant in warm weather; it made the walking through the apartments to-day very disagreeable in several places.' This is the account given by one of the commissioners of a factory stated to be remarkable as that at which the finest cotton is spun in Scotland, and as having the greatest number of spindles in Glasgow, about 43,000." There is one district in England in which the privies are in a condition no less disgusting and disgraceful."

The catalogue of miseries to which the poor children are subjected we scarcely dare trust ourselves to descant upon. Look at the evidence of some of the unfortunates who were examined on the subject:—

"The physical effects of factory labour on children, as stated by the commissioners, are immediate and remote: the immediate effects are, fatigue, sleepiness, and pain; the remote effects, such at least as are usually conceived to result from it, are, deterioration of the constitution, deformity, and disease. The Central Board have been much struck with the perfect uniformity of the answers returned to the district commissioners by the young workers in this country, in the largest and best regulated factories as well as in the smaller and less advantageously conducted. In fact, whether the factory be in the pure air of the country, or in the large town; under the best or the worst management; and whatever be the nature of the work, whether light or laborious; or the kind of treatment, whether considerate and gentle, or strict and harsh; the account of the child, when questioned as to its feelings of fatigue, is the same. Young persons of more advanced age, speaking of their own feelings when younger, give to the commissioners such representations as the following:—"Many a time has been so fatigued

that she could hardly take off her clothes at night, or put them on in the morning; her mother would be raging at her, because when she sat down, she could not get up again through the house.' 'Looks on the long hours as a great bondage.' 'Thinks they are no much better than the Israelites in Egypt, and their life is no pleasure to them.' 'When a child, was so tired she could seldom eat her supper, and never awoke of herself.'

The ultimate effect of their employment on their physical condition is told best in the words of the author:—

"Pains in the limbs, back, loins, and side, are frequent as fatigue and drowsiness. Pain is seldom complained of when the labour did not commence until the age of nine, and was not immoderate. Girls suffer from pain more commonly than boys, and up to a more advanced age; though occasionally men, and not unfrequently young women, and women beyond the meridian of life, complain of pain, yet there is evidence that the youngest children are so distressed by pain of their feet, in consequence of the long standing, that they sometimes throw off their shoes, and so take cold. 'Feet feel so sair that they make him greet.' 'Was quite well when she went to the mill, but the confinement brought on a complaint in the head, and her left side is now pained.' 'Many nights I do not get a wink of sleep for the pain.' 'At first suffered so much from the pain that he could hardly sleep, but it went off. 'Knee failed from excessive labour; severe pains and aches would come on, particularly in the morning: it was better in the evening; felt no pains in any other parts. There were two or three complaining at the same time of their knees aching.' 'I have seen children under eighteen years of age before six at night, their legs have hurt them to that degree that they have many a time been crying.' 'Swelling of the feet is a still more frequent source of suffering.' 'Obliged to bathe the feet to subdue the swelling.' 'The long standing gives her swelled ankles, and fatigues her so much that sometimes she does not know how to get to her bed.' 'Night and morning her legs swell, and are often very painful.' That this affection is common, is confirmed by the concurrent statements of parents, operatives, overlookers, and managers.

"With regard to the ultimate effects of their employment on their physical condition, it appears that this excessive fati-

gue, privation of sleep, pain in various parts of the body, and swelling of the feet, experienced by the young workers, coupled with the constant standing, the peculiar attitudes of the body, and the peculiar motions of the limbs, required in the labour of the factory, together with the elevated temperature, and the impure atmosphere in which that labour is often carried on, do sometimes ultimately terminate in the production of serious, permanent, and incurable disease. From cases detailed in the evidence and the accuracy of which has been strictly investigated, the commissioners do not conceive it to be possible to arrive at any other conclusion."

The medical evidence which has been given on the present factory system on two occasions, first in 1816, and last in 1832, with the exception of some *remarkable opinions* from medical men, residing in or near large manufacturing towns, discloses a system of physical evils which no slavery in the colonies has yet equalled. All the men of eminence who were examined on the subject, agree in condemning the present system as most cruel, and most injurious, as well to the body, as to the mind. We agree with Mr. Wing that a ten hours bill is the proper and only remedy. In the next parliament we trust that Lord Ashley's endeavours to obtain this desirable reformation will be crowned with success. We trust that no narrow-minded policy will stifle the voice of suffering humanity. We are conscious we have not done justice to Mr. Wing's valuable work, but in calling attention to it in the way we have done, we trust we shall be the means of inducing many to refer to the work itself, it will long remain an honour to the intellect, heart and industry of its benevolent author. We finish with Mr. Wing's summing up at the conclusion of his observations:—

"From all I have read, seen, and heard upon the subject, I am confident that there can be no effectual remedy for the evils of the factory system which does not make a ten-hour bill its basis. The present act aims at the exclusive protection of the children, and on that very account it has failed to protect them. But even if it had succeeded, as it offers no relief to the adult operative, but rather aggravates his case, it can never restore tranquillity to the manufacturing districts. That the adult operative requires protection, and that it would be for the advantage of the children that he should be

protected, I have given satisfactory proof; satisfactory, not indeed to those who think indifferent persons more unexceptionable witnesses to the existence of grievances than those who actually suffer them, nor to those who would suspend their judgment upon the subject till there should be no conflicting evidence, but to those who are content with such evidence as the nature of the case admits.

"It is surely enough that medical men, eminent in their profession, and practising in the manufacturing districts, together with master manufacturers, whose interests are involved in the system, have forcibly denounced its evils. It is highly improbable that such persons should either have been deceived themselves or should have attempted to deceive others; and as probability is the guide of human affairs, we must consider the evils of the system as proved. That they should so long have been suffered to continue without a comprehensive and effectual remedy is a matter of deep regret. It cannot be defended upon any principle of policy; since it cannot contribute to the stability of a state that so large a portion of the population should remain in a state of discontent, and the infraction of the law should become a habit. It cannot be defended on any principle of justice; for justice requires that a speedy and effectual protection from wrong should be extended to all classes of the community. It cannot be defended upon any principle of religion; for religion teaches us to consider every man as a brother, and the concerns of all mankind as our own. Religion enlarges our views much beyond the narrow sphere of self into universal sympathy. Let not, then, our legislators be deceived by the the flattering accounts of the system so industriously circulated by interested individuals—let them not be deterred by the clamour of political economists, nor by the sneers of men who, judging, perhaps, from their own hearts, are incredulous as to the existence of philanthropy in the hearts of others, from doing, speedily and effectually, what policy dictates—what justice demands—and what religion enforces by the strongest obligations."

An explanatory Treatise on Diseases of the Skin, with the Symptoms and Treatment of each, adapted for the use of pupils, families, &c. By

GEORGE RIGDEN, Surgeon, &c., Canterbury, Ward.

An interesting little volume on the subject of skin diseases. To junior pupils and the heads of families it will be found of great service.

PUNCTURED WOUND OF THE HEART.

MADRAS NATIVE INFIRMARY.

Communicated by W. Rose, Esq., Assistant Surgeon to the Madras Army.

Wound of the left Ventricle of the Heart—Death after the lapse of Fifteen hours.

Lutching, a Malabar woman, twenty-eight years of age, and mother of five children, was admitted into the Madras Native Infirmary, under the care of Mr. Lawder, with a punctured wound by the left side; on admission she was extremely low, and appeared to have been severely beaten, her face and body were very much bruised, pulse not perceptible at the wrist, countenance pale, skin cold and clammy, breathing difficult, on examining the left side I detected an horizontal incision, about an inch and half long, between the eighth and ninth ribs, and which appeared to have been inflicted by some flat cutting instrument. I could not pass a probe through the wound into the thorax. Although extremely feeble she was quite sensible, and stated, that while going to a native feast a few miles from Madras, about ten o'clock, P.M., on the 25th January, she was attacked by robbers, who threw her down and abused her, while on the ground she received a wound of a stiletto or some other sharp instrument in the left side, below the breast, and inclining towards the back, and that afterwards the fellows robbed her of all the jewels she wore on her person. The people who brought her to the hospital said that she lost a great quantity of blood at the time, but that when they came up to her no blood appeared to flow from the wound, they at first supposed her dead, but after a little while she revived somewhat, they then placed her in a palankeen, and brought her to the hospital. She was placed in bed on her left side, a reddish fluid issued from the wound, evidently coming from the thorax. She continued very low, pretty much in

the same state as when admitted until ten o'clock, P.M., next day, when she expired.

Autopsy.

The body was examined three hours after death, and the weapon was found to have penetrated into the cavity of the thorax, between the eighth and ninth ribs, six inches from the centre of the spine, and to have passed obliquely upwards and forwards through the thin margin of that lung into the left ventricle of the heart.

The lung was collapsed, and about ten ounces of coagulated blood was effused into the thorax. Some coagulated blood was also found in the pericardium, and the surface of the heart itself was covered over with a thick layer of coagulating lymph. The eighth rib was partially cut through by the weapon in entering. The external opening of the wound was removed about two inches from the internal, the integuments thus forming a kind of valve, which rendered it impossible to introduce the probe into the thorax on her admission into the hospital.

This I conceive to have occurred from the position of the arm at the moment the wound was inflicted, which, no doubt, was thrown upwards and forwards in order to protect the ornaments she wore.

To this valve we possibly may impute her not having bled to death at the time, which from the size of the wound formed in the ventricle (nearly an inch long) might be expected.

I am not aware of any case on record where the patient survived a punctured wound of the heart so long as in the present instance, an interval of fifteen hours having elapsed from the time of receiving it to her death; and on this account, with all due deference, I submit the case to the board, and shall feel great pleasure in forwarding any preparation also, if required.

(Signed) J. LAWDER.

HOPITAL DE LA CHARITE, PARIS.

Gun-shot Wound of the Dorsal Vertebra—Piece of Ramrod imbedded in the Fourth Dorsal Vertebra, and traversing the right side of the Chest—Death—Autopsy.

A. B., one of the national guard, was admitted under the care of Monsieur Velpeau, on the evening of the 9th September, 1836, with a gun-shot wound of

the back. On examination, there was observed a wound of about two inches in length, running obliquely downwards from left to right, opposite the fourth dorsal vertebra, inclining a little to the left side, and discharging a thin frothy sanious matter; about ten inches of a common-sized musket ramrod projected from the wound, and appeared firmly fixed in the body of the vertebra; the projecting extremity was rough, the broad end being broken off.

10th.—On being examined by M. Velpeau at the morning visit, he did not complain of much uneasiness, had no cough, *no difficulty of respiration*, could make a full inspiration, without particular pains, and on percussion all parts of the chest emitted the natural sound; no palsy, had the full and free use of all his limbs, and there appeared to be no disturbance of the general functions of the system, skin cool, pulse regular, tongue clean, appetite as usual; he appeared a healthy stout young man, of rather a full habit of body and about twenty-five years of age.

One or two of his officers who were present, stated that on the previous day they were going through the manoeuvres of a sham-fight, *petit guerre*, when one of his comrades in the act of ramming down his cartridge, slipped, the gun went off, and lodged the ramrod in the poor fellow's back, who happened to be his front rank man, he complained of a good deal of pain at the moment, but did not fall, nor feel any particular weakness. From some unexplained cause the ramrod broke short at about ten inches from the wound, and left the anterior small end firmly adherent in the body of the vertebra.

Two or three of his comrades with all their force essayed, one after the other, to extract the portion of ramrod from the wound, but unsuccessfully. He was then brought to the hospital, the butt-end of the ramrod was produced, and on comparing it with another belonging to a similar musket, there appeared to be from six to seven inches lodged in the cavity of the thorax, and about ten inches projecting from it posteriorly.

There did not appear any symptoms present of internal or external hæmorrhage, except the slight bleeding before alluded to.

He was bled to two palleys, put upon a strict antiphlogistic regimen, ordered to be kept in the sitting position, his back supported by pillows, and his bowels to be opened by enemata.

Monsieur Velpeau remarked, that there was considerable difficulty in forming a correct diagnosis in this case; he was of opinion that the ramrod must have passed close to or through some of the important organs in immediate connection with the spine, in this direction, but from the symptoms present he was not justified in saying if any of them were injured, and if so, what one in particular.

The *œsophagus* did not appear to be wounded, for there was no impediment to the act of deglutition. The *medulla spinalis* did not appear to have suffered any lesion, for there was no paralysis, nor any particular disturbance of the nervous system. The *thoracic aorta* or *descending cava*, did not seem to have sustained any injury, as there was no symptom present indicating internal hemorrhage. Yet after all these favourable indications, M. Velpeau hesitated to extract the foreign body. From the direction it took, he was apprehensive that it had passed through one of the large blood vessels, and by acting as a *bouchon* or cork, effectually prevented hemorrhage, if this diagnosis were correct, instantaneous death must be the consequence of extraction; inclining then to this opinion, all ideas of extraction were precluded, at least for the present. He said that in the course of a few days the inflammatory process might form a trajet for the ramrod, thereby repairing, as far as possible, the injury done to the vessel, and effectually prevent hemorrhage, that then the extraction might be attempted with safety.

In the meantime, Charrière, the Surgeons' Instrument Maker, of the Rue de l'Ecole de Medecine, was ordered to devise some instrument by means of which the extraction might be effected with the least possible violence.

11th.—Symptoms nearly the same as on yesterday, slight degree of febrile heat, bowels opened once by the enema, he was again bled this morning to the same quantity.

Con. Cætera.

Charrière produced his instrument this morning, which appeared well calculated to answer all the indications, but it was not applied.

12th.—Died suddenly in the night; without any particular symptom of distress. Every one present at the morning visit of course agreed with M. Velpeau that death must have been caused by hemorrhage from one of the large vessels before alluded to.

Autopsy twenty-four hours after death.

The ramrod had passed obliquely through the body of the fourth dorsal vertebræ, within about a line of the anterior aspect of the spinal canal, passing *behind the large vessels*, without injuring them in the slightest degree, came out at the right side of the body of the vertebræ, passed through the middle lobe of the right lung, through the anterior bony extremity of the fourth rib, nearly at the junction with its cartilage, and was embedded in the pectoral muscle, without reaching the integuments.

There was considerable sanguineous *epanchement* of the muscle, but no other appearance of hemorrhage.

The immediate cause of death remains, therefore, adhuc sub judice.

The injured vertebræ was removed from the spine, still containing the portion of ramrod, Charrière's instrument was applied, and the foreign body extracted apparently with the greatest ease.

From the great interest the case excited, Corvisart's Theatre, where the examination was conducted for the sake of affording more room, was crowded to excess.

Had Charrière's instrument been applied on the second morning after admission, and the foreign body extracted, might not the man's life have been saved?

A SKETCH OF THE LIFE AND WRITINGS OF TREVIRANUS.

For the London Medical and Surgical Journal.

Gottfried Reinhold Treviranus was born at Bremen on the fourth day of February, 1776, where he was a merchant. He received the first elements of education at the *Gymnasium*, or academy of that city. He early displayed a taste for the mathematics; a science in which he attained great proficiency. His attention was next occupied with physics and natural history, and these became his favourite pursuits.

In the year 1793, the young Treviranus repaired to the university of Gottingen, and prosecuted with remarkable diligence, the study of medicine. While yet a student, he wrote a paper on "Nervous Energy," which appeared, without the author's name, in the first volume of Reil's "Archiv für Physiologie."

After defending his inaugural Thesis *De emendenda physiologia*, and receiving

the degree of Doctor of Medicine, in 1796, he returned home to practice his profession. Not long after which, he was appointed Professor of Mathematics and Medicine, in the Academy of Bremen. Hereupon he married Elizabeth Foeke, whom he outlived three years. His extensive knowledge, his kind and amiable deportment in the sick-chamber, did not fail to gain for him the confidence and esteem of his townsmen; and although most assiduous in the discharge of his professional duties, he yet found leisure to investigate the organization of plants and animals. For being naturally fond of retirement, he generally spent the summer months at a country seat in upper Neuland. Here, he used to enjoy his hours unmolested, and prosecute his studies without interruption. He had little inclination for travelling. Nevertheless, he visited Paris in 1812; and ten years later was present at the meeting of German philosophers, assembled at Heidelberg.

By such a mode of life, and by indefatigable application, we may understand how a man like Treviranus, engaged in active practise, was enabled to enrich the literature of physiology and comparative anatomy, with so many, and so valuable contributions. As early as the year 1797, not long after his removal from the University, he gave to the world the first, and in 1799, the second part, of a collection of different memoirs of subjects connected with physiology, under the title of "Physiological Fragments." In the year 1809, his interesting observations and experiments on the influence of voltaic electricity, and certain chemical agents on vegetable life; as also, his experiments relative to the action of opium, and belladonna on the lungs of Amphibia, together with observations on galvanic stimuli; appeared in the *Archiv* of Plaff and Scheel. During his sojourn at Göttingen, he conceived the plan of his great work, a continuation of physiology from the period of Haller, up to the present time. Of this stupendous undertaking, the first volume came out in 1802, entitled *Biologie*, or the philosophy of animated nature. In the year 1810, he produced his interesting researches into the physiology of insects and fishes, followed by those on the internal structure of the arachnidæ. In 1816, in conjunction with his brother, Ludolph Christian, he commenced a kind of repertory of anatomical and physiological essays; illustrated by numerous engravings, mostly executed by himself. This work extended to four volumes.

Contemporary with the above, he published a paper in the transactions of the Royal Society of Göttingen, *de Protei encephalo*.

In the year 1824, Treviranus, his brother, and Tiedemann, to whom we are indebted for the particulars of this biographical sketch,* became joint-editors of a journal, appropriated to researches into the nature of man, plants, and animals.

Of this, five volumes were completed; these contain numerous articles from his own pen. Four years later, the first part of his "contributions to the anatomy and physiology of the apparatus of the senses" came forth, but was not continued, owing to the expence of bringing it out. In the years 1831 and 1833, appeared, in two volumes his work on the "Laws and phenomena of Organic life," detailing the most important discoveries in physiology, subsequent to his *Biologie*, the first volume of which then dated thirty years.

About the above period his bodily health began to decline. He was attacked with violent, protracted cough, and oppressed breathing; and in the Spring of 1832, expectorated blood. Last Autumn he suffered, in addition to his other ailments, from sleepless nights, his pulse became intermittent; and he had well marked symptoms of pulmonary congestion.

Indisposition, if it interrupted, did not suspend his scientific inquiries. He was just congratulating himself on having finished something which had engaged his attention; when the influenza, then prevalent over Europe, seized, and confined him to bed. Ere long, an imposthume in his lungs, which must have been forming previously, burst, and he expired without a struggle, on the 16th. day of February, 1837.

Treviranus was an admirable example of temperance, humility, and simplicity of life. The diligence with which he pursued his studies is sufficiently evident from his success. Statesmen and generals may grow great by unexpected accidents, and a fortunate concurrence of circumstances, neither procured nor foreseen by themselves. But reputation in the learned world must be the effect of industry and capacity.

* See preface to Treviranus, *uber die Theorie des Sehens*. Bremen, 1837.

RECENT ATTACKS ON THE APOTHECARIES' COMPANY.

To the Editors of the London Medical and Surgical Journal.

Gentlemen,—The lecture lately given by Dr. Elliotson, attacking the Apothecaries' Company, has produced, I may venture to say, but one feeling throughout the profession, as it is quite obvious that the Cantabrian Professor had a very unworthy motive in that address. There was, indeed, no individual from whom an attack on the Company of Apothecaries came with a worse grace, as in gratitude to the memory of his father, he ought to have been one of the last in coming forward on such an occasion. I am more particularly urged to address you now, as some of my associates have expressed a desire that you should, in your truly liberal journal, take notice of another attack which has just been made by a conceited coxcomb in an introductory lecture, at King's College, wherein this juvenile professor, in the most indelicate and inappropriate manner, introduced the subject, and made a most unwarrantable attack on the Apothecaries' Company, which appears the more inconsistent as the patrons of King's College absolutely solicited and entrapped the Company as large shareholders. But they are now prompted by pecuniary motives, the shares of the Gower Street Company having fallen from £100 to £35, and those of King's College even £10 less. Both these speculators feel no longer any hesitation in throwing overboard the Apothecaries' Company, and worshipping the rising sun of the New University at Somerset House, the operations of which they suppose will extinguish our existence.

A LICENTIATE OF THE
APOTHECARIES' COMPANY.

CANCER OF THE PYLORUS.

Causes of vomiting in this affection.

Two patients who presented all the signs of cancerous cachexy, placed themselves simultaneously under the care of M. Denonvilliers. The disease was nearly of two years standing. In both cases the onset of the affection was marked by vomiting; but in the first case, though frequent at first, afterwards became rare and

very copious; obstinate constipation till death. In the other case, the vomiting though rare at first, afterwards became frequent, and then entirely ceased. Now on the one hand there existed an enormous distension of the stomach, coinciding with an almost total obliteration of the pylorus; on the other hand, there existed a process of ulceration, which almost entirely destroyed the pyloric valve. The pylorus being compressed in the first patient, he must necessarily be constipated and have vomited from the onset of the disease. The stomach being but little dilated, and little accustomed to any prolonged contact of food, must necessarily at first frequently reject it. Gradually enlarging so as to be able to retain in its cavity the substance of several meals, and becoming less sensible to its presence, vomiting then became profuse and infrequent. In the other patient the disease had probably commenced by the development of the scirrhus tissue in the vicinity of the pylorus, which, interfering with the circulation of the food, brought on vomiting from time to time. By little and little this vomiting became frequent in consequence of the increased size of the scirrhus, which had progressively closed the pylorus. At length the scirrhus tissue having been destroyed by ulcerative softening, the communication was re-established between the stomach and duodenum; the obstacle being removed, the vomiting ceased.

The obstacle to the passage of the food is then a determining, or at least, an assisting cause of the vomiting. When the stomach, solicited by any cause whatever, contracts and draws in by sympathy the action of the diaphragm, and of the abdominal muscles, the substances contained in it escapes by that opening which presents the least resistance. When scirrhus induration occupies one of the curvatures of the stomach vomiting is then possible, but not necessary; it is, on the contrary, an inevitable and necessary consequence when the pylorus is obstructed.—*Archives Generales de Medicine, August, 1837.*

ON DESTROYING SLUGS, WORMS, &c., &c.

Every amateur conversant with the management of a garden, however small, has experienced more or less annoyance from the marauding depredations of slugs. My own crops, such as lettuce and salad,

as well as young plantations of vegetables have not unfrequently been destroyed. Their intrusions being generally committed in the night or in moist rainy weather, they are the more difficult to detect; and even were they attempted to be gathered by hand, they could never be wholly cleared. I have tried several caustics, such as hot lime and coarse snuff, and with this have generally succeeded in greatly lessening their numbers; but as they are seldom on the surface of the ground, except in dull moist weather, the above application soon loses its destructive powers, and therefore to be effectual requires frequent renewal, it therefore becomes both tedious and expensive. Traps, such as cabbage leaves, are sometimes strewed over the ground, under which the slugs are decoyed, so that when the leaves are removed they may be readily destroyed, so far this answers the purpose tolerably well; but the following is the plan which, after many trials, I find attended with the least trouble and expense. Take a handful or two of decayed vegetable tops of any kind, pea or bean halm I generally prefer, this is laid down at short intervals throughout my beds or quarters, especially in the kitchen garden, amongst recently planted crops of greens, saladings, &c. The decaying weeds, or pea halm, are shifted about a yard or so every morning, and the place where it lay watered with lime water, a very small portion of which will quite destroy both slugs and worms. It may be well to observe that any kind of vegetable substance in a decaying state, will answer quite as well as pea or bean halm. In the flower-garden I frequently cut down some of the herbaceous or annual plants that require it and are nearest at hand, or a flat branch of a tree when very full of leaves, and this will generally last a week or ten days.

Lime water I find to be a most essential thing, not only for slugs and worms, for the destruction of which it is, however, of incalculable value; I frequently apply it on my grass sward, among the flower beds, and for plants in pots, also to box edging in the kitchen garden; and since I applied this freely, I have suffered but little from insects of any kind.—*Floricul- tural Magazine*.

**LECTURES ON DISEASES OF THE
SKIN,**

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

—
HERPES IRIS.

Herpes Iris is an extremely rare variety which presents itself under the form of small vesicular groups, accurately encompassed by four erythematous rings of different shades. Patients themselves often compare this eruption to small cockades. Bateman was the first who described it with care, and who placed in it the genus herpes.

It manifests itself by small spots, which are soon succeeded by zones of different colours. From the second day there forms in the centre a vesicle, which is soon encompassed by smaller vesicles. In the space of from two to three days the central vesicle has become flattened, the contained liquid turbid, and has assumed a yellowish tint; the erythematous zones are more developed; they form four distinct rings, which surround successively the vesicular group placed in the centre, so as to form a disc of about the breadth of a franc, on which there is observed, setting out from the central point to the circumference, a brown red tint, then a yellowish white one, then a deep red, and lastly a rose-coloured tint, which becomes imperceptibly lost in the colouring of the skin. The number of these discs is in general rather considerable. This variety of colours is not always observed so well marked.

Of these rings the third is usually the narrowest; all of them, but more particularly the first, may become covered with vesicles.

No. 299.

The termination takes place from the tenth to the twelfth day by the re-absorption of the liquid, and a slight desquamation. Sometimes the vesicles open, and slight scales form, which soon fall off.

Herpes iris may become developed over all the parts of the body; it is most frequently observed on the face, hands, insteps, fingers, neck, &c. In some cases it appears to affect projecting parts, such as the ankles.

Causes.—Herpes iris is most frequently observed in children, females, and individuals with a fair complexion, without our being able to assign to it any special cause. It may become developed simultaneously with other varieties of the genus herpes.

The only disease which could be confounded with herpes iris, is roseola with multiple rings. This roseola differs from it in the greater extent of the discs which sometimes exceed that of a five franc piece, and by the absence of vesicles. It is probably this eruption which Willan has placed among the exanthemes. Herpes might be confounded with roseola, especially when the vesicles have opened and disappeared; but in these cases it is in general sufficient to examine with attention, in order to find some remains of vesicles.

This slight affection scarcely ever requires any treatment. In all cases the treatment of herpes circinnatus might be employed for it.

Herpes iris is extremely uncommon and amidst the immense crowd of diseases of the skin which have fallen under M. Biett's observation for several years, among the external patients of the hospital Saint Louis, he has met it but three or four times. We have very recently seen a very fine specimen of it in his wards.

ITCH. (Gale.)

The itch is an eruption essentially con-

tagious, characterized by vesicles which are in general discrete, somewhat pointed, transparent at the summit, somewhat broader at the base, accompanied by greater or less itching.

Some authors consider and have described it as a particular affection: others have admitted one variety of it to be of this kind; this is an error. The pustule which besides is only met with in the smaller number of cases, is merely accidental, and M. Biett has long considered the itch as essentially vesicular. There are however, some rare cases where the vesicles evidently become pustular.

The itch may appear over all parts of the body, except the face, which is always exempt from it. But there are certain parts for which it manifests a decided preference; thus it frequently attacks the fingers, the wrist, and in general, it is developed in parts destined for flexion.

The itch is a very common disease, it attacks all ages, both sexes, appears at all seasons of the year, in all climates, and in all ranks of society; but it principally attacks the lower classes, where every thing seems to invite it; wretchedness, want of clean linen, and insufficient food. When it appears in the higher classes, it generally owes its introduction to servants, nurses, &c.

It never becomes developed spontaneously: it is not epidemic: this is proved by numerous facts observed at the hospital St. Louis. The epidemic cases of itch which have been published were, to all appearance vesicular affections of another kind (eczema) the epidemic nature of which is moreover far from being established. It is never endemic, it is essentially contagious.

The time which elapses between the contagion and the invasion, presents important varieties which are worthy of notice.

It usually appears in cases of children, after the lapse of four or five days; but this again varies. Thus, if they are feeble and delicate, the incubation is longer; it is more sudden, being often but two days, if they happen to be strong and plethoric.

In cases of adults from eight to twelve days are required in Spring and Summer, and from fifteen to twenty in Winter.

It is more slow again in *aged persons* where dry and hard skin presents less facility both to its transmission and development.

The incubation is still more difficult in those who are under the influence of inflammation of any internal viscus.

The vesicles first appear where the skin is fine and delicate, where the number of the lymphatic vessels is increased; thus in the spaces between the fingers, in the axillæ, etc., etc.

The different trades and professions, however, occasion some varieties: in black-smiths, lock-smiths and dyers it is not either in the fingers, nor at the wrists, that the eruption first appears, and for this reason, that in these parts the skin is with such persons coarse and impervious. It is on the contrary more particularly on the hands, that it comes out in tailors and mantua-makers. It often commences on the right hand in fencing-masters. Again cases have been cited where it had been transmitted to the face by the collar of a cloak. We doubt however whether this could be the itch; for we have seen thousands of persons affected with it, without ever having met it even once on the face.

Symptoms.—When the itch has been transmitted, the individual so affected feels an itching on the parts where the contact took place. This itching is increased at night by the heat of the bed, under the influence of alcoholic drinks and spiced food. It appears in the form of vesicles which are slightly raised and increase in number. They are pointed, and transparent at the summit; they present a slightly rose-coloured tint in young persons, and contain a serous and viscid fluid. If the individual is weak, the eruption makes but little progress; in the contrary case it extends rapidly. It appears at the joints, in the spaces between the fingers, then at the wrists, at the folds of the arms, in the axillæ, in the hands subsequently on the abdomen. It may be general, excepting however the face; but it is mostly confined to a surface of small extent, to the abdomen, and to the arms. In some cases it consists merely, in a very small number of vesicles, scattered here and there between the fingers and on the wrist.

If the vesicles are few in number, they occasion but little itching; they retain their original form for a longer time. But if they increase rapidly, if they occur in persons whose skin is fine and delicate, the itching becomes insupportable. The patients scratch themselves, tear the vesicles, the fluid which they contain, escapes, and they are succeeded by a number of small red points, which are often considerably inflamed. Lastly, in some cases, the action of the nails, occasioned by the itching, increases the inflammation still

more, so that the itch becomes complicated with pustules of *impetigo*, and frequently even of *ecthyma*: this however is only observed in young and vigorous subjects, and after excesses in diet, etc.

However extensive the eruption may be, it never occasions those formidable effects which some persons have attributed to it. The eruptions and internal inflammations which might accompany it, are but complications.

Youth, the sanguineous temperament, male sex, handling lanuginous clothes, spring, summer, southern climates appear to be so many causes which predispose to the itch.

It attacks more particularly infancy and youth, and M. Biett has clearly pointed out that the reason is to be found in the great proportion of individuals of this class.

From the examination of the patients who present themselves at the hospital St. Louis, it would appear that males are more subject to it. This however probably arises from the circumstances of their being more exposed to it.

The sanguineous and lymphatic temperaments are those which present most examples of this affection. It is much more infrequent in bilious temperaments. But this may be accounted for in this way, that the proportion of persons presenting this temperament is so much less considerable.

It is very frequently observed in tailors, mantua-makers, &c., &c.

With respect to the proximate cause. it is still entirely unknown: it has been attributed to an acid principle, to a peculiar fermentation, and lastly, to an insect.

The acarus, at first admitted by Avenzoar, by Ingrassias and Joubert, was described from a more remote period by Moufet, and designed from nature by Hauptmann; and finally, it was presented to the 17th century with many details by Francis Redi, in its development, and in the mode of its occasioning vesicles. The acarus was assigned a place with respect to its natural history by Linnæus, Degur, Fabricius and Latreille.

Its existence was still questioned, when in 1812, the experiments of M. Gales, apothecary to the St. Louis were so successful, that they appeared calculated to remove every doubt.

The first experiments were not successful; but others instituted by him subsequently, were crowned with such success, that upwards of three hundred of them were collected: he was able even to describe their generation, &c.

However these experiments have been frequently repeated since, and never brought the same results.

In 1818, 1819, &c., and probably twenty times since, M. Biett repeated them himself: he furnished himself with excellent lenses and with the best microscopes; he even made use of the horizontal microscope of Amiei. These experiments were made on a great number of individuals and under the most favourable conditions to discover the insect, if it really existed. The result was that he never met it!

These researches were made in other places besides France, and with the same want of success.

Notwithstanding all the descriptions, and the different drawings which have been given by authors who have seen the acarus of itch, and thinking that the passage even in Morgagni himself refers rather to the pedicular disease we feel ourselves warranted in concluding that the acarus does not exist.*

Diagnosis.—If the itch is in most cases very easily recognized, there are also cases where it is very difficult to distinguish it from some eruptions of an entirely different character, and which are not at all contagious; however it is one of those diseases of the skin, the diagnosis of which is of the utmost importance; for the least error may not only compromise the character of the practitioner, but may also, on the one hand, give rise to unjust suspicions, or even deprive a person of his place, &c.; or on the other hand, it may leave an entire family in a treacherous security with respect to a disease, the rapid contagion of which has in a short time affected all the individuals of the house.

One of the eruptions most frequently confounded with the itch is *prurigo*.

But independently of the primary characters which may be always found, and which are for the one affection *papular*, and for the other *vesicular*; the ordinary seat of *prurigo* is the back, the shoulders, and the extremities in the site of the extensors; we have already seen that the itch attacked the flexors in preference. In *prurigo* the *papulae*, which are almost always torn, present on their apex a small dried clot of blood, of a black, or at least blackish appearance. The vesicles of the itch, when torn, are surmounted by a

* The insect was detected at the hospital of St. Louis two or three years since, and exhibited to the pupils of Baron Alibert, and was frequently seen by the late Mr. Plumbe.—*Ed.*

small, thin, yellowish scale.

The itching is more acrid, and of a more burning character in prurigo. Lastly, prurigo is not contagious.

Lichen simplex might sometimes impose on one for the itch; but with a little attention one may readily satisfy himself that it is formed by papulæ, that these papulæ are usually very close to one another, a thing scarcely ever observed in the itch; that they retain the colour of the skin, while the vesicles of the itch are of a light rose colour; that when it exists on the hands (where it is most likely to be confounded) it occupies the back of the hand, and not the spaces between the fingers, as the vesicles of the itch; that it generally covers the external surface of the extremities; that the itching is not very sensible: and that it is not contagious.

It is still more readily distinguished from *lichen urticatus*, in which the itching is more acute to be sure, but the papulæ of which, more inflamed, larger, and more prominent, are more easily appreciable.

Lastly, the itch might be confounded with *eczema*, more especially with *eczema simplex*; but the vesicles are flattened, whilst they are pointed in the itch. They are crowded in greater or less number in *eczema*; in the itch they are generally discrete. The itching of *eczema* is a kind of general smarting, very different from those exacerbations which characterize the itch. *Eczema* is not contagious in the generality of cases.

The itch may be complicated with several eruptions of an entirely different order.

One of these which most frequently complicate it is *eczema*, generally occasioned by irritating lotions and frictions. This is the eruption which is occasioned by the remedies of certain quacks who persuade the public that they drive out the itch.

The irritation of the skin may be so severe that the itch becomes complicated with pustules of *impetigo*, most frequently of *ecthyma*, which appear chiefly on those parts occupied by a great number of vesicles; it is those which have been taken for cases of pustular itch, but this is incorrect: they are but complications chiefly met with in young persons of a sanguineous temperament.

The inflammation still further increased by the action of the nails, may extend to the cellular tissue, and it is not uncommon to see a considerable number of fur-

uncles supervene. Vesicles of itch; pustules of *impetigo* and of *ecthyma*, and furuncles are sometimes observed simultaneously in the same patient.

Again, in some still more uncommon cases, small papulæ of lichen make their appearance simultaneously with the itch, or a little time after its eruption,

With respect to inflammations of internal organs, they are very uncommon in patients with itch, and when they do exist; they are but concomitant diseases. If some cases of inflammation of the gastric or intestinal mucous membrane have coincided with the disappearance of the itch, is it to this disappearance that we are to attribute such results, or is it not rather to the internal inflammation itself, under the influence of which the itch disappears.

Lastly, the itch may exist with *syphilis* and *scrofula*, without these diseases being at all influenced by each other. *Scorbutus*, in some very rare cases, imparts a livid tint to the psoric vesicles.

Prognosis.—the itch, in itself, is a slight disease: its complications alone can render its prognosis more or less unfavourable, according as they themselves may be more or less severe; it never occasions those consequences which have been noticed by some writers.

The itch never terminates spontaneously: it is never critical, and the cases represented as such, were evidently eruptions of an entirely different nature; it never terminates in death, never in any other malady: it sometimes happens that there co-exists with it, or that there becomes developed during its treatment, some other eruption, which continues after it; but the converse does not hold good. If left to itself it may continue for years, and even for life. When subjected to proper treatment, its duration varies from ten days to one, or even several months, according to the complications which often interfere with the therapeutic means employed, and which may, more or less, retard the cure.

Treatment.—The itch is a purely local disease; so that it requires merely local means of treatment, and bleeding and purgatives which formerly constituted a very essential part of the treatment are now but rarely employed, and only in particular cases. Thus we shall often considerably assist the local treatment by bleeding from the arm in the case of a young and robust patient who is in the vigour of health, in whom the eruption is general, and accompanied with violent

itching; or by administering a purgative, either at the onset, or in the course of the treatment, to a person of a soft, lymphatic temperament, who may labour at the same time under habitual constipation.

With respect to the local means proposed for the treatment of the itch, they are too numerous to be detailed here; we shall confine ourselves to the enumeration of those which are dangerous, and those which are applicable in the generality of cases.

Generally speaking, *mercurial preparations*, and especially the *citrine pomade*, and the *antiporic quintessence*, of which the base seems to be corrosive sublimate, may be replaced, with considerable advantage, by milder means; they often occasion very serious and mischievous results. Thus independently of the accidental eruptions which they almost invariably occasion, and which retard the cure, they almost always induce engorgements of the salivary glands, salivation, and sometimes even glossitis, &c. Such means should be excluded from the treatment of the itch.

Among the means which experience has shewn to be most serviceable, we shall first mention the *powder of Pyrol*, that is sulphuret of lime pulverized. Half a drachm is to be rubbed in twice a day, on the palms of the hands, diluting it with a very minute quantity of olive oil. The mean duration of the treatment is about 15 days.

This mode of treatment is only applicable where the affection is recent and not extensive.

M. Jadelot's liniment is often useful, and yet it is one of the means after which accidental eruptions are most frequently observed. The mean duration is 15 days.

Dupuytren's lotions consist in four ounces of sulphate of potass into a pound and half of water, with the addition of half an ounce of sulphuric acid. The patients wash the parts affected with vesicles twice a day with this solution; this treatment is very beneficial, and above all particularly convenient in patients who do not like pomades; but it is scarcely applicable in irritable subjects, for it often occasions very painful smarting; the mean duration of the treatment is 16 days.

Hellebore pomade incorporated with axunge in the proportion of one eighth, has given in many cases observed by M. Biett, a mean duration of thirteen days and a half, without ever occasioning any unpleasant results.

But of all the methods of treatment, that which succeeds most invariably, most promptly, and which often gives rise to accidental eruptions, is that of *Helmerich*, modified and adopted for several years by M. Biett.

It consists in making the patient rub in, morning and night, over all the parts affected with vesicles, half an ounce each time of the following sulphuro-alkaline pomade: *sublimed sulphur*, two parts; *subcarbonate of potass*, one part; *axunge*, eight parts.

The patient is to take a simple bath every day, or even every second day.

The mean duration of the treatment is 12 days.

In children, lotions with a solution of soap, and artificial sulphurous baths are the only means to be employed.

M. Delpech has proposed frictions with oil (*huile douce*). This method has been tried at the St. Louis by M. Biett with variable results.

Baths and fumigations are useful auxiliaries in the treatment of the itch; but they are only auxiliaries. Sulphurous baths are those which effect the most prompt cure; they never occasion any unpleasant results; the mean duration of the treatment is 25 days.

With respect to sulphurous fumigations they are far from producing the extraordinary effects sometimes attributed to them; they are often useful as auxiliaries, particularly in aged persons; when employed alone, they constitute a treatment the mean duration of which is 33 days, at a single fumigation per day; but this treatment is often very fatiguing, and cannot be supported by patients.

In most cases it is plain baths which are added to the local means, in the treatment of itch. Yet there are cases where new vesicles are incessantly forming, where they do not fade always, and where they are slow in disappearing. It is then often serviceable to alternate them with sulphurous fumigations, or, what is still better, with sulphurous baths. Alkaline baths are particularly indicated when the patient is annoyed with very severe itching.

Whatever be the method adopted, if the malady comes to be complicated eruption, with *eczema* for instance, we must interrupt the ordinary treatment, and give the patient diluent, or acidulated drinks. Sometimes the itch presents at its onset, or is complicated, during the treatment, with pustules of impetigo or eethyma, &c. We should not then have recourse to irri-

tating lotions, or frictions, or, if we have commenced them, we must suspend their employment. On the contrary, we should persevere in the use of simple baths, and give drinks of a gently laxative character; and it is often of use to dip the hands and fore arms, which are most frequently the seat of these pustules, in emollient local baths, of bran-water, or marsh-mallows water.

To insure a cure and prevent a relapse the clothes should be disinfected, and particularly woollen garments, by a current of sulphurous acid gas. The use of simple baths should be continued for some days, and the patient should change his linen as often as possible.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

Effects on the Constitution.

I have divided diseases into local and constitutional; and when on local, I observed that they, and especially inflammation, had secondary or sympathetic affections, which were immediate or remote. The immediate were considered when on inflammation, namely, the sympathetic fever. The remote are now to be treated of.

One would suppose that the suppurative would only so far affect the constitution as by the preceding inflammation which produces it; but the contrary is sometimes the case, and the suppurative will produce worse symptoms than the inflammation itself. The condition which the constitution takes on after suppuration is sometimes productive of those diseases termed nervous, as locked-jaw, hysteria, spasm, &c., all of which seem to arise from the suppurative action, and are not salutary effects, but harass the constitution and even produce death. The locked-jaw I shall defer for the present, and consider hectic or sympathetic fever.

Hectic fever is a remote constitutional sympathetic affection, and appears to have a very different origin from the other remote sympathizing effects, though in general the consequence of a local disease. It is the constitution affected by a local disease, or irritation, which it is conscious it cannot cure: for while the inflammation lasts, which is only preparatory to and an immediate effect of most injuries, in those parts at least which can most

affect the constitution and call up her powers, there can be no hectic.

It takes its rise from a variety of causes, which I shall divide into two: 1st, From an affection of vital parts; 2nd, From an affection of parts not vital. The only differences between these is in the time of the hectic's coming on, and its rapidity and violence when it does come on. In vital parts, hectic will be produced by many complaints which will not produce it in other parts, as scirrhus of the stomach or mesenteric glands, also diseases of the lungs or liver. These only produce other symptoms, according to the nature of the part injured and of the injury; as coughs, when in the lungs; sickness and vomitings, when in the stomach; dropsies and jaundice, when in the liver.

When hectic arises from disease in a part not vital, it is generally in parts where such a quantity of mischief can take place as to make the constitution sensible of it, as the large joints. In small joints, although the same local effect takes place as in large ones, yet the constitution is not made sensible of it, so that we find scrofulous joints of the toes, &c., not affecting the constitution with hectic, and the ankle, elbow, and shoulder are much longer in affecting the constitution than the knee or hip.

Although hectic commonly arises from some incurable local disease of a vital part, or of a common part of some magnitude, yet it may be an original disease of the constitution; the constitution may fall into the same action without any local disease whatever.

Hectic may be said to be a slow mode of dissolution; the general symptoms are those of a low or slow fever, attended with weakness; but more the action of weakness than real weakness, for on the removal of the part causing the hectic there is immediately the action of strength produced. The particular symptoms are, debility; small quick sharp pulse; the blood forsakes the skin; there is loss of appetite; often vomiting; wasting; tendency to sweating, especially when in bed; constitutional purging; urine clear at one time, and at another depositing a branny brick-dust sediment; dissolution. This disease has been supposed to arise from absorption of pus; but I have long thought that the blame has been improperly laid to the absorption of pus, and the following facts will make this evident. First, hectic takes place where there is disease, and no suppuration in vital parts;

also in many inflammations before actual suppuration has taken place, as in many of the large joints, called white swellings, while the same kind and quantity of inflammation and suppuration in any of the fleshy parts, and especially one of them very near the source of the circulation, have in general no such effect. Therefore in such cases it is only an effect on the constitution, produced by a local complaint having a particular property.

I have said that with all diseases of vital parts the constitution sympathizes more readily than with many other parts; and also all diseases of vital parts are more difficult of cure than those not vital; as also diseases of bones, ligaments, tendons, affect the constitution more readily than of muscles, skin, cellular membrane, &c.; and we find these general principles hold good in universal remote sympathy with local disease of those parts and structures.

When a disease is in the vital parts, and is such as does not kill from the first constitutional effects, then the constitution becomes teased with the complaint, which is destroying the necessary actions of health which are vital. In diseased joints there is not a proper power, or rather, perhaps, disposition to produce salutary inflammation and suppuration for their recovery; therefore the constitution is irritated with an incurable disease.

If absorption of pus always produced such symptoms, I do not see how any patient who has a large sore could escape this disease, because we have as yet no reason to suppose that any one sore has more power of absorption than another. If in those cases where there is hectic the absorption of pus is really greater than when the habit is healthy, it would be difficult to determine whether the increase of absorption is a cause or effect. If it is a cause, it must arise from a particular disposition of the sore to absorb more at one time than at another, even while in a healthy state. What reason have we to suppose that a sore in a healthy constitution has power to absorb more at one time than at another, I do not see. If this increase of absorption does not depend on the nature of the sore, it must take its rise from the constitution; if so, there is a peculiarity of the constitution; therefore the whole of the symptoms cannot arise from the absorption of pus, and the cause must be a peculiar constitution and absorption combined.

If the absorption of matter produced such violent effects as are ascribed, which

are never of the inflammatory kind, but of the hectic, why does not venereal matter produce the same effects; We often know that absorption is going on by buboes taking place, yet no symptoms appear until the matter appears to produce its specific effects, and these symptoms are not very similar to those called hectic, though from reasoning we should expect that venereal matter would act with more violence than common matter from a healthy sore.

Again, as matter is often formed on the inside of veins in inflammation of those cavities, and this matter enters directly into the circulation, why have we not the hectic symptoms in these cases; we have the inflammatory, and sometimes death. We also find the matter of large abscesses which have been produced without visible inflammation, such as many of the scrofulous kind, wholly absorbed, and that in a very short time, yet no bad symptoms follow.

From all these facts and reasonings we may conclude that the absorption of pus from a sore cannot be the cause of so much mischief as has been generally supposed. If it was owing to matter in the system, I do not see how the symptoms could ever stop until suppuration ceased; yet we often do find that they get well before suppuration ceases, even when no medicine was given; and in the case of inflammation of the veins, there is reason to believe that after all the bad symptoms are gone suppuration is still going on, so that though matter is still passing into the constitution from the vein, hectic is not produced, which it must be if it was caused by matter getting into circulation.

But I much doubt the fact of absorption going on more in one sore than another. In large abscesses hectic seldom comes on till they are opened, though they have been forming matter for months. In such cases the disposition often comes on soon after opening the abscess; in others very late; but still if the stimulus for restoring parts is given no such effect can take place. If the parts were disposed to heal, no such hectic disposition would come on. In diseased joints also, if the parts are capable of taking on salutary inflammation we shall have only the first sympathetic inflammatory fever; but as they seldom do this, the constitution is teased by the complaint not taking on immediate and salutary steps towards a cure. Hectic, therefore, would appear in some measure to depend on the parts being stimulated to produce an effect be-

yond their powers, and this stimulus is sooner or later in taking place.

Treatment of Hectic.—We have as yet, I am afraid, no cure for this. I believe the cure consists in the removal of the cause, viz., the local disease. Strengtheners and antiseptics are recommended. Strengtheners are proposed on account of the debility,

which has evidently taken place; and antiseptics, from the idea of absorbed pus giving the blood a tendency to putrefaction. To prevent both these effects taking place the same medicines are recommended, namely, bark and wine. Bark will in most cases only assist in supporting the constitution; I should suppose it could not cure the constitution of the disease; however it may render it less susceptible of it. When hectic comes on from some specific disease, as from venereal irritation, the bark will enable it to support it better than it otherwise would have done. Wine, I am afraid, rather does harm, as it increases the action of the machine without giving strength a thing to be carefully avoided. However, I have not yet made up my mind about wine.

When hectic arises from the disease of such a part as the system can bear the loss of, the part should be removed. On removing the cause (as by amputation of an extremity), the pulse, from being very quick, returns to its usual state; I have likewise known the patient sleep the first night without an opiate, after having had little or no sleep for a week before, and the sweats called colliquative have been stopped; and I have known purging immediately stop. Perhaps the pain and newly excited action of the constitution may assist in the abatement of the symptoms.

Of dissolution.—To the hectic I have joined another disease, arising from suppuration, which I have called dissolution, because few recover from it.

It may arise in long continued suppurations, which may not be incurable in themselves, and in this it differs from hectic. Dissolution seems more the effect of the past than of the present, which is the reverse of hectic. We never find this take place in consequence of small wounds, or such as affect the constitution but little, but rather after bad compound fractures, amputations, &c. It appears more in hospitals than in private practice; more in large towns than in the country. In cases of compound fractures and amputations, we find the constitution often capable of going through the inflamma-

tory sympathetic fever, producing suppuration, and granulation, and continuing this for some time, yet sinking under them at last, and often without any apparent cause, the effect taking place more readily if the patient was in full health before the operation, than if he had been for some time accustomed to hectic symptoms.

The first symptoms are generally those of the stomach, shivering; vomiting immediately follows, if it does not accompany it; a small quick pulse: perhaps bleeding from the whole surface of the sore; often mortification and speedy dissolution. Here is a very fatal disease taking place in some almost immediately, and when every thing appears to be within the powers of the animal. It therefore cannot immediately arise from the sore itself; yet the sore certainly assists, because we never see the disease take place where the sore is healed.

The removal of the local disease will not prove effectual for the cure of this as it does that of hectic, nor do I find any thing that has any effect.

PRACTICAL ILLUSTRATIONS OF THE PRECEDING SUBJECTS.

Union of a broken Tendon.—The treatment of a broken tendon is very similar to the treatment of a fractured patella, because their uses, and in some degree their situations, are similar, namely, the giving way of an intermediate substance between the power (that is the muscles), and the resistance. All come under one general principle of cure, though the mode of treatment is somewhat different.

These intermediate parts are principally tendons, probably some ligaments and bones. The fracture of a tendon is probably always produced by the power being in action, and the resistance counteracting at the same time and with great velocity. We might suppose that every tendon in the body would be liable to such accident, but I believe there is only one that stands any chance of such effect by the natural exertions of the body; there is also, probably, but one bone in the human body which can be broken in the same way, that is the patella; though there may be instances of processes of bone being torn off near their insertion, which would be somewhat similar.

The tendo Achillis seems liable to be broken by the natural actions of the body, from having at the same time to sustain the action of the power and of the resistance also. When it has only the action

of the muscles to contend with, there is no danger of its rupture, because the tendon is capable of supporting a much stronger power than that of the muscles. Though the tendon is continually in this state, yet there is little danger, because when the action is voluntary all the actions tend to support one another; but in a careless unguarded action the motion is more violent and quick, and the part less prepared against it. I believe fracture of this tendon often happens when a person is fatigued and off his guard, as after dancing, &c., and after the muscles have acted spontaneously, as in the cramp; at least it happened to me after dancing, and after a violent fit of the cramp. The general principle of cure in parts displaced is the replacing them in their natural situations, which is the whole cure in some, as dislocations, and the first step to be taken in every case where the continuity of parts is broken.

When the tendon is broken it is seldom attended with pain in the parts. It commonly gives a pain, which instantly seizes the calf of the leg. The noise or snap which it produces gives no idea of the mischief done; but being at the same time attended with pain in the calf of the leg, and the patient not being able to walk as usual, he conceives that some one has struck him with a hard body on the calf, and if he is so situated as not to have been liable to a blow, he becomes puzzled to conceive what can have happened. We generally find that the muscle is thrown into a state of cramp when the tendon gives way, losing the power of relaxation by the will, or of itself. As a surgeon is seldom present when such an accident happens, it is often allowed to remain some time in that state; but the pain often leads to the right mode of cure, the patient squeezing the muscle down with his hands, which a surgeon should do if at hand. The broken ends will always at first be at some distance from each other, because they are pulled apart by opposite forces.

The parts should be allowed to remain nearly in their natural position: no inconvenience will attend a small separation of the broken ends of the tendon, namely, half an inch or so; whereas considerable disadvantage would arise if we were to push the two broken ends together by throwing back the heel (which has been the general practice). The only circumstance that would seem to forbid such practice, namely, letting the broken tendon remain without a

bandage, is, that the muscle will lose half an inch of its power of contraction, which the motion of the ankle may or may not lose; but though this may be lost at first, we know muscles will acquire it again afterwards, and therefore no attention need be paid to this objection. The advantage of not throwing the heel up, and of allowing the tendon to heal nearly in its natural position is, that the patient may be enabled to walk from the very beginning of the cure, a very desirable circumstance.

However, it is not necessary to adhere rigidly to either of these modes of treatment, but to adopt a medium between the two, which will be best. The heel may, therefore, be a little raised during the time of walking only, by raising the heel of the shoe. A roller should be passed several times round the calf of the leg, and kept constantly applied, as we cannot guard against the involuntary actions of the muscles; and at night we may apply an apparatus consisting of a leather apron or sock, with a strap from the heel to be fixed to a belt, in order to steady the muscles.

When the tendo Achillis is broken, there is but little inflammation attendant; but some general fulness comes on about the small of the leg and ankle, the skin looks dark from the effusion of blood, and the parts have a firm feel, from the coagulable lymph being thrown out. This firmness of the cellular membrane increases near to the fracture laterally, and this assists in keeping the tendon in its place. The inflammation hardly requires any particular treatment when the foot is in a proper position.

As I would not restrain the patient from walking almost from the very beginning, (the inflammation may prevent it for the first day or two,) it is necessary to give him some direction how he is to manage the muscles under the cure, as walking cannot be performed in the usual way. I have recommended to keep the position of the foot nearly at a right angle with the leg, as in standing, but not quite so, the heel being a little raised, by some pieces of leather put into the shoe, which may be removed one by one. When he walks he must turn his toes out, and carry the inside of his foot forwards, without attempting to bend the joint of the knee; indeed, the latter precaution is unnecessary, for this motion is only necessary when the heel can be raised from the ground, which he cannot do. This foot will be for some

time the leading foot in walking, for it will be an easy motion to set it forwards before the other, especially if the heel is not much raised; but it will be impossible to set the other foot forwards and leave this behind. The patient will be hardly able to mend his pace for two months, except it be by getting familiar with his present mode of walking. The ankle and foot will swell occasionally, especially in the evening; and this may continue more or less after the tendon is united, but is of no importance. Three or four weeks after the accident he may remove the roller from under the calf of the leg, and about the same time leave off the slipper at night. We cannot say when he may use the muscle of this tendon; that will depend on the fitness of the tendon to be used, which can only be known by the power the patient has of putting it to use. About two months after the accident we find him gradually bringing his toes more and more forwards, until he at last walks as usual.

It is impossible for a patient with a fracture of the tendo Achillis to act with the gastrocnemius and soleus muscles, if he were to try to do so. When the Duke of Queensberry broke his tendo Achillis he was immediately aware of what had happened, and pointed out to me the broken ends. He readily submitted to my reasoning: walked about the room as well as he could, and found it impracticable to contract the gastrocnemius muscle. Some surgeons thought the tendon could not be broken, because he was walking about his room; but in such a case the patient has no more power to contract his gastrocnemius and soleus muscles than to jump over St. Pauls.

THE MEDICAL JURIST.

No. 5.

INSANITY.

Feigned Diseases.—The feigned madness of David, Ulysses, Solon, and the elder Brutus, is well known. Zacchia lays down admirably the mode of proceeding in such cases. The first thing is to inquire of the friends, the character, and habits of the patient; and the probable motive of the suspected dissimulation. Thus Galen found, that a slave, to prevent separation from a female to whom he was attached, had produced tumefaction of the knees, by rubbing them with an

irritating herb. The second thing to be done is to compare the alleged cause of the disease, with the age, and other circumstances of the person in question; so as to determine whether it is likely that such a cause would produce such a disease in his case. The next is to see whether the patient exhibits an aversion to the usual remedies. In a large school, near Liverpool, many of the pupils were troubled with a short cough, which was treated with tea, liquorice, and a remission of tasks. Dr. Traill, on hearing it, found that it was evidently made up; and ordered Epsom salts in infusion of quassia. The epidemic quickly subsided; and there was not another case for six months. A poor man pretended that although blind from his birth, he had been suddenly restored to sight, while he was worshipping at a shrine at the time Duke Humphrey passed by. The latter, however, proved he was an impostor, by his being able to tell all the colours shewn to him; which he would not have been able to do, if he had been blind from his birth. He was put into the stocks.

Monomania is not easily feigned as mania. In general, they cannot imitate the stately grandeur of melancholy. In feigned dementia there is generally some hesitation in speaking, in order that they may gain time to select their words; and they generally find it convenient to repeat the same idea over and over again, which is not the case in real dementia. It is very difficult to detect feigned idiotism. Real madness seldom comes on suddenly, except when it is produced by narcotics; and then it is transient. Insanity, when real, is generally preceded by gloom, tears, and a tone of solitude. There is great increase of strength, and their sudden and violent motions, render such patients truly formidable. The hallucination is generally confined to a particular range of subjects; while pretenders generally overaul their part. Zacchia says one of these persons was restored by a sound drubbing. Nostalgia is sometimes counterfeited. It is a disease to which the Swiss, Highlanders, Negroes, and others are subject, when removed from their country. Real sufferers are quiet; the eye has a settled glare of melancholy; and they are sometimes insensible to the promise of returning home. Epilepsy is often counterfeited, from the ease of simulating a short fit, with a long interval. Sometimes there are pretensions to demoniacal possessions. In a bad case of this kind, Fagere applied

the actual cautery; upon which the pretender got up, and ran away. In the year 1811, a deserter from the militia had pins thrust under the finger nails, without removing a counterfeited stupor. The scalp was then raised, to look for a fracture; the patient was discharged; went home; and in two days, was assisting to thatch a house. Another man was long fed on eggs, because he could not be made to open his mouth. In an old tract, by the Rev. Mr. Jolly, on "the casting out of a demon," there are the oaths of many persons to physical impossibilities. In 1689, a young man had fits, accompanied by vomiting of stones; and, in one instance, of gold, silver, and brass buttons. Sometimes his body was so heavy, it is said, that it could not be lifted by four men; and at others, as light as a bag of feathers. Some of the persons who examined him declared there was something moving under the skin, like a mole burrowing. He threw stones at his father and mother, who declared they did not know where he got them. He was brought before the magistrate, and threatened; when he said he was affected by the devil. The delusion was at last put an end to by the fear of punishment. This man was said to speak languages he had never learned; and in a strange voice. An impostor was brought to Vienna, where De Haen ordered her at whipping; when she confessed that her pretended profession had been very profitable. The feeling of veneration when anything supernatural is pretended, assists imposture. Dr. Traill knew a patient in feigned catalepsy, who was cured by having spirit of hartshorn rubbed on the cheek. The smart made her run away. A girl, who pretended to be in hysterics, was ordered by a medical man to have red hot tongs applied to each sole. She rose immediately, and asked if he really meant to be so cruel; and on being answered in the affirmative, ran out of the room. The application to the nostrils of snuff, or of the volatile alkali, will detect simulated epilepsy, or syncope. The latter will also be known by the beating of those arteries to which the impostor cannot apply pressure; as the carotids, for instance. Chronic pains are often simulated; and especially chronic rheumatism. You must examine into the nature of the pain, whether it is pricking, burning, or aching; and see whether the account agrees with the pains which would be felt in a real case. Very often the symptoms which should be present are wanting. Severe

pain of the head, if real, is generally accompanied by want of sleep; and pain of the stomach by anorexia, flatulence, or vomiting. If an acute pain be of long continuance, it is generally a symptom of extensive disease; and this would be easily recognized. If you suspect fraud, bleed, or blister, or cup, or apply a moxa, for if the pain be real, the patient will thank you for any means you employ.

Pretended amaurosis may generally be detected by the pupil answering to the light: which it would not do if the retina were paralyzed. Margaret Macavoy, at Liverpool, says Dr. Traill, pretended that she could see with the points of her fingers. She was often blindfolded; but I never could satisfy myself that it was completely. I found, by experiment on myself, that if the eyes were firmly closed at the time of the handkerchief being put on, and the lids were then raised forcibly, and the occipito-frontalis muscle exerted, sufficient light would be admitted by the sides of the nose, to enable a person to distinguish colours held at the point of the latter; which Miss Macavoy did. I proved this at a large party one night. I proposed to be allowed to blindfold her; but she then said she could not distinguish colours, unless the breath from her nose and mouth was allowed to reach her fingers, at the time of contact, in order to assist the delicacy of her touch. I then got a box made, with open sides to admit her hands, and a tube at the top to admit her breath, but bent so as to exclude the light. My doubting, however, gave so much offence, that I was abused in the newspapers; and was not permitted to see her, or to have my apparatus employed. She died a few years afterwards; and no disease could be detected in the brain, or in any part of the apparatus of vision. That might have been the case, however, if she had really been afflicted with amaurosis. The affair is now forgotten in Liverpool; but similar pretensions have lately been revived in France.

Purulent ophthalmia has been much counterfeited by soldiers. In such cases it is observed to be confined to the privates, and always to the right eye; the right hand being most easily applied, and the right eye the most important to a soldier. It is observed not to attack the women and children, as a real epidemic would. Dr. Traill saw a man who feigned deafness so well, that he stood the sudden firing of a cannon near him, without starting; and was unmoved by the

mention, in his presence. of the most terrible operations. Such imposters may be detected by dropping a little money, or by some slight sound. A man who pretended to be deaf and dumb, deceived a hundred prisoners by whom he was watched; and even the Abbé Paré, who invented a system of tuition for the deaf and dumb. He was detected by the Abbé Sicard; from the circumstance of his orthography being formed by hearing, and not by sight. Instead of using the hard *c*, for instance, he wrote *k*. At last, on finding he was fairly detected, he took up a book, and read aloud. The hue of the skin in jaundice, may be imitated by the use of walnut juice, or coffee, or an infusion of tobacco, or a solution of nitrate of iron, or dilute nitric acid. But these fail to colour the eye, or the urine, or to cause the clay-coloured stools of jaundice. The latter may be procured by the use of dilute muriatic acid; and the urine may be coloured by using madder; so that the colour of the eye is the only decisive test.

Bloody urine (*hæmaturia*) is sometimes procured by the tincture of cantharides; but it is rarely used, on account of the pain which it causes. *Hæmatemesis*, and *hæmoptysis*, are sometimes simulated by eating the prickly pear (*cactus opuntia*). In one case, a small bag of brick-dust was laid under the tongue, and a little coloured saliva was occasionally spit out, accompanied by a cough, so as to imitate hæmoptysis. A young lady, procured her discharge from a convent, by contriving to drink blood, and to vomit it before the physician. Pretended catamenia may be discovered by washing the genital organs; which will become discoloured again, if the menstrual discharge be really present. Foderé mentions a woman, who produced simulated dropsy, by blowing up the cellulæ tissue of the abdomen. There is a well-known instance in record of imitating hydrocephalus by similar means. Dr Traill remembers a man coming to his grandfather, with an abdomen apparently much distended. This appearance was produced by a bag beneath his vest, inflated by means of a small pair of bellows placed under his arm; which worked up and down, as if affected by a convulsion.

One of Zacchia's rules for detecting imposture, is to observe whether the progress of the symptoms corresponds with that of the real disease. Thus, if the person alleges that the rheumatism under which he declares himself to labour, got

worse, the part affected should become swelled, reddened, and painful on pressure. If the patient be really mad, he loses fear in the force of his hallucination. Fear is often an effectual means of detecting pretenders to epilepsy. There was a man in Liverpool, says Dr. Traill, who was always counterfeiting fits, observed that he uniformly chose to fall in a convenient place; and when a good many people were passing by. One day, when he fell down before my door, I told the servant aloud to heat the poker red hot; as if he did not recover shortly, it would be necessary to apply a hot iron to the back of the neck, to prevent apoplexy. On hearing this, he ran off. I gave information to the police, he was taken a few days afterwards; and confessed that he had gained considerably by practising this imposition. A woman had deceived many people by feigning insanity; and had thus escaped punishment for a robbery, which she had committed in connection with a gang of thieves. Foderé told the nurse, in her hearing, that if she were not dressed in the morning, and the room in order, he would apply a hot iron between her shoulders. Next morning she was dressed, and her room put to right.

A woman in a Catholic country on the continent, used to start up and stand for an hour with her arms extended in the form of a cross, and her eyes fixed upwards. Sometimes she would raise herself on her toes, as if to get nearer heaven; and her countenance assumed a variety of hues, being sometimes red, and at other times pale. At last she used to come to herself, like a person awaking from sleep; and the multitude crowding around, would honour her as a person inspired; at which, says the narrator, I smiled with pity, and she no doubt, with contempt.

Factitious ulcers are generally less excavated, with their edges less callous, than real ones; and they are usually less painful. They are very common in the army, where it is sometimes necessary to lock up the affected leg in a box of suitable construction, that the healing of the ulcers may not be interfered with. In the hulks, these ulcers used to be produced by rubbing sand into the leg, at those spots where it was wished to form them. Some surgeons have recommended flogging in order to put a stop to these tricks, and sometimes that plan has been adopted. A woman imitated a cancer of the breast, by applying to the latter the

spleen of some animal. Her healthy looks excited the suspicion of the surgeon, who detected the cheat. Cachexia is sometimes imitated by dyeing the skin; and sometimes pustules by paint; but soap and water will wash off the whole. The pallid countenance of fever, may be imitated by tartar emetic; and the pulse may be quickened by a blow on the inner condyle of the humerus. Ague is often imitated well; but if watched closely, the hot fit will be found not to follow the rigors naturally.

Diseases of Privation.

"The rights of the deaf and dumb," says Dr. Traill, in his admirable Outline of Medical Jurisprudence, "are secured by law; and if the intellect be perfectly sound, there is now no question of their competency to enjoy all the civil rights of other subjects of the state. They can intimate legal consent by signs, or by writing, and should be considered as responsible agents." They are allowed to marry,—their consent being given by signs; but it must be proved that their other faculties are perfect. The Abbé Sicard, and Mr. Braidwood, have shewn that they may be instructed. One gentleman educated by the latter, afterwards filled an important situation. He could read English, French, and Latin, pronouncing them all alike. He managed to dance in excellent tune, by watching the motions of his partner. A gentleman who visited Mr. Braidwood's establishment, gives an account of a young lady, thirteen years of age, who could read well, and give the sense in different words. A deaf and dumb person was once brought forward as a witness, with his sister to interpret; and from his evidence the prisoner was transported for seven years. At Edinburgh, a deaf and dumb girl, on whom a rape had been committed, was allowed to give evidence. Another deaf and dumb girl was brought to trial for infanticide, it being alleged that she threw a child from a bridge, into the river. She was indignant at the charge, declaring that the child had fallen accidentally. It was proved that she knew right from wrong; and that punishment followed crime. She was dismissed from the bar, as her counsel would not allow her to plead, till it was explained to her that she might plead guilty, or not guilty; and this could not be done. This would have been easily accomplished if she had been educated on Sicard's principles.

The deaf and dumb can hold property. Dr. Traill knew two cases in which, after trial of their causes, persons so afflicted obtained their inheritance. If they should be blind, as well as deaf and dumb, the law regards them as idiots. Blackstone says that such persons are without any means of acquiring ideas; but touch, taste, and internal sensations will impart some. This was proved by the boy Mitchell, as described by Playfair. Dr. Hebbert describes another, who, in 1818, was eighteen years of age, and in whom, among other passions, the venereal appetite had appeared.

Insurances.

When a number of lives are taken together, it is easy to calculate what premium should be given to provide against contingencies. Dr. Price's tables were found to be favourable to the insurance offices. It seems that, of late years, a considerable improvement has been going on "the expectation of life," that is, the average period which a certain number of persons may expect to live. Indeed, it seems to have been improving gradually for several centuries, for the expectation of life was formerly eighteen years, but it is now twenty-five. This, as is well observed by Dr. Christison, is contrary to the opinion of the "laudatores temporis acti," who think that men lived the longer, the longer age they lived.

Great improvement has taken place in the lives of children. Various reasons have been assigned for this; the principal of which are improved habits of living and management; better medical advice, and less concentration of people in cities; though the population of London has increased enormously, the number of those living within the bounds of the city has actually diminished. It is pretty certain, although sometimes doubted, that the average of life is longer in the middle ranks, than among the poor. The difference in Paris between the two classes, in this respect, is stated by two different authors to be nearly two to one. One of these authors compared a number of poor people, with sixteen hundred of the richest in Europe. It was found that, after forty years of age, the annual mortality among the poor was double that of the rich. Among females, the expectation of life is at all times longer, by about four years, than that of males. In the beginning of the last century, the advantage in this respect of women,

during the period of child-bearing, overmen, was almost nothing; but it is now nearly four years. This is no doubt attributable to improved medical practice.

An insurance office, when applied to for an insurance on the life of any person, generally employs a medical man, to report whether the person in question has any disease or pre-disposition tending to shorten life. Many diseases have not this tendency; or, at any rate, not such a degree as to render it worth while to notice it. The printed tables of the insurance companies are very defective. They should first ascertain the general diseases which influence the mortality; then the diseases to which the bodily confirmation of the person applying to be insured, most exposes him to; then his hereditary tendency to disease, founded on the diseases by which his ancestors have been most affected; then those diseases of which he may have had previous warnings; and lastly, those which tend to shorten life, and those which do not. The bills of mortality at Berlin, are now kept with great accuracy; and will soon afford important information. Morgan's tables of the Equitable Insurance Company, also give interesting information. According to these tables, diseases of the head account for twenty-one per cent of the deaths; those of the lungs for twenty-one per cent; old age for thirteen and a quarter per cent; and general fever for thirteen per cent. Where these causes exist, or a great disposition to them; the life is hardly insurable. Dropsy, accounts for seven per cent of the deaths; diseases of heart and blood-vessels, for six; diseases of liver, for five; urinary diseases, for three; and diseases of the intestines for five. During the last century the last mentioned class of diseases, monopolized one quarter of the whole number of deaths.

The subject of all these statistical observations, is to shew the necessity of detecting these diseases, or a predisposition to them. Diseases of the head, and particularly apoplexy are very important; for of those who perish by these diseases, nearly a fifth die before the age of forty. Whenever apoplexy or epilepsy has once appeared, life is very precarious. No case is more hazardous, than where epilepsy succeeds an attack of apoplexy; but Dr. Christison has known such persons insured at a nominal premium. Diseases of the lungs are very important; and proper medical skill would, in a great measure, secure insu-

rance offices from loss on this head. Consumption accounts for more than eight per cent of the whole number of deaths; and a quarter of these die before the age of forty. The premonitory circumstances are hereditary tendency, and defective respiration, as known by the number of seconds during which the person can speak during one expiration. A person should be able to speak from twenty-two to thirty-six seconds, without drawing breath. If the number of seconds fall below eighteen, the case is equivocal. As to old age, it is the object of the office to get as many of this class as possible. Hereditary longevity, a full and not easily excited pulse, slow respiration, regular habits, and a good temper, are said to give a fair promise of old age. With respect to fever, we have no data on which to found an opinion of a predisposing tendency; nor can we detect a constitutional tendency to diseases of the heart, or great vessels; for the only sign with which we are acquainted, is great muscular development. After the age of forty, these diseases are often present in a latent state; and we must take means to discover them. The only predisposing circumstances to diseases of the liver, which are known at present, are hot climates, drinking freely, and excessive eating. Persons afflicted with urinary diseases, should be rated higher when they for fatal dropsy is quite as often dependent on disease of the kidneys, as on that of the liver. The disease of the kidney which has taken Dr. Bright's name, may be detected by the coagulability of the urine, and the low specific gravity. Suicide comprehends one per cent of the deaths; and the only predisposing cause which is known, is ancestral tendency.

MEMOIR ON HYPERTEOPHY OF MAMMARY GLAND,

BY DOCTOR FINGERHUTH OF ESCH.

The tumefaction of the mammae which forms the subject of this paper, is not occasioned either by the formation of new products, or any modification in the texture of the gland. It merely consists in an increase in the size of the lobules whose combination constitutes the mammary gland, and in the anormal accumulation of fat in the surrounding cellular tissue. It is characterized by the uniformity of the tumour, progressive increase

of the tumified mass, and by the absence of all pain. It presents itself under two forms: in the first its course is more rapid, and the affection is always connected with the phenomenon of puberty, with which it coincides. In the second the development is more tedious; the increase of size is nearly imperceptible, and the disease is chiefly connected with some disturbance in the functions of the generative organs. The following is a description of the former of these varieties, to which alone the author confines himself.

The course of the disease and the symptoms which mark it as the following: increased size of the mammary gland, generally of the right, seldom of both at once. This increase is preceded by a sense of prickling, and is accompanied with irritability of the mamma. This affection always appears at the period of puberty, and co-exists with the natural development of the mamma. It generally happens that those affected with it have not menstruated regularly; or, if menstruation is established, the discharge is very scanty, lasts but for a short time, and soon ceases not to reappear. The abnormal development produces more rapidly even at the period when the menstrual period terminates, and very often at the time of the menses, the patient feels a more marked sensation of local tension which diminishes after this time; then the progress of the hypertrophy becomes more slow and more continued. The voice sometimes undergoes a peculiar change: it becomes rough, hoarse, and as one might say, double. This state of the voice may continue for several days, disappear and then return, without our being able to recognise any distinct lesion. In one patient it was observed that this hoarseness of the voice returned at the menstrual periods, though the menses had ceased to appear; whilst in another no alteration of the voice was observed. If the affected breast be examined, the nipple is found to have become flatter and broader, and the areola to have become larger. At first the tumour gives a sensation of resistance, without its colour having undergone the least change. Subsequently when the size of the mamma has become more remarkable, if we confine ourselves to a superficial examination, the tumour appears softer, and it is only by pressing the finger deeply that we can recognize the indurated and hypertrophied lobes of the mammary gland.

At this period, the veins which traverse the integuments are more manifest, and the mamma assumes a bluish tint, without there being however any very remarkable change of colour. Thus the disease goes on permanently, and under certain circumstances, with considerable rapidity. The mamma acquires an enormous size; it may become from 18 to 20 inches in length, and more, with a circumference of from 20 to 23 inches, may acquire a weight of from 10 to 12 pounds, and cause the patient annoyance in moving. The transpiration as well as blood recently drawn from a vein have a peculiar odour; the latter contains much free carbonic acid. According as the tumour is developed by reason of the excessive hypertrophy of the mammary gland, the rest of the body wastes away gradually, a circumstance which causes the affected mamma to appear to increase much more rapidly than it really does. At a more advanced period the thoracic organs sympathise. Then there comes a difficulty in the breathing, a sensation of constriction in the chest, a cough at first dry, and then followed by the expectoration of frothy sputa, sometimes streaked with blood. The strength diminishes, hectic fever is lighted up, and death sometimes preceded by symptoms of hydrothorax, is occasioned through exhaustion.

However the course of the disease is not always what has been now described, and, in reference to the termination, that also may be different. Accordingly, the swelling having attained a certain development, may remain stationary without the intervention of any treatment for a great number of years, and even during the patient's entire life, and that without any inconvenience save the annoyance occasioned by the enormous size of the mamma.

The disease may terminate in three different ways:—1, in cure—The swelling ceases to make any progress; but the part, once swollen, never returns to its natural size. For this reason the cure cannot be considered as complete, except as far as the increase of the mass is limited to a certain degree of development, and that is no longer any grounds for apprehension with respect to the general health.

2. In another disease—Effusions and cysts may form in the interstices of the hypertrophied glandular tissue.

3. In death—This disease never terminates favourably, that is, never remains stationary at a certain stage of its in-

crease, without the interference of art: when left to itself it never ceases to progress. Death takes place when emaciation commences, and when the organs of the chest sympathise either by abscesses forming in the air passages, or by hydrothorax, or by phthisis with hectic fever.

Pathological Anatomy.—The internal tissue of the mammary gland is seldom altered. Notwithstanding the enormous development of the entire mass, and the increase in the size of the lobules in particular, the latter present this natural structure. The cellular tissue is looser, its cells are larger, and it contains much fat. The arteries present no change either in their texture, or in their size. On the other hand the internal laciferous vessels are dilated, and present a larger size than natural; the veins are considerably enlarged, and some times present an alteration in their tissue. The nerves are neither diminished in size nor attenuated; but compared with the great size of the hypertrophied gland, they appear diminished though in reality they have retained their original dimensions. However, in certain points where the nerves appear more resisting and harder, the nervous mass is found to have lost a portion of its medullary tissue.

In an hypertrophied mammæ there is found an increase in the mass, an augmentation in size and in the absolute weight. The latter increases in the same proportion as the mass; but it is not so with the specific weight, as we know takes place in inflammation. To this we must add a remarkable development in the venous vessels and dilatation of the the veins, whilst the arteries retain their natural size. A fact which we which we cannot explain, but which is not the less true is this that that the organs richest in venous blood are most disposed to hypertrophy; and that in the parts subjected to this morbid development the mass of the venous vessels arising from the dilatation of the veins increases in the same ratio as the tumour increases and *vice versa*.

Etiology.—The hypertrophy of the mammæ which presents itself as a morbid complication of puberty, seems to be entirely owing to the internal predisposition peculiar to this period. For the mammæ are intimately connected with the development of the generative function. A sensation of constriction accompanied with difficulty of breathing, perceptible swelling, increased activity of the gland, such are the symptoms indicat-

ing the increased vitality mammæ; and the great change going on in them at the period of puberty. To this predominant disposition there are added other influences which cannot be always appreciated in particular cases:—1st, the too common use at this time of irritating and heating food: this food without a powerful predisposition could only cause a more rapid development of the mammæ; but in persons predisposed, and when combined with other causes it very much favours the morbid development. 2nd. —Frequent touching of the mammæ, which acts in two ways, by direct irritation, and by exciting the venereal appetite. The excitation of the genital organs reacts sympathetically on the mammæ. 3d.—Ablutions and washing of the mammæ with perfumed waters, and waters holding in solution divers irritating substances. 4th.—There are facts which go to prove that compression or a blow on the mammæ may occasion its hypertrophy, more especially when improper treatment has been resorted to; a marked scrofulous disposition may also favour their enlargement.

Treatment.—The treatment of this disease is either radical or palliative, according as the disease is more or less advanced, and according to circumstances. The treatment for a radical cure may be effected in two ways: 1st, by derivatives; the object of these is to stop the excessive activity of the gland: 2nd, by removal of the mammæ.

In order that the first mode of treatment may be effectual, it must be employed at the onset of the disease, when the subject of it feels a prickling and sometimes stinging, with a sensation of fulness in one breast. Even when these symptoms do not shew themselves, there appears, at this period, in the affected, a more rapid increase of size, which indicates the critical moment, at which, *ceteris paribus*, we may hope to obtain a cure. But if the menses have not yet appeared, the commencing increase of the gland is the only phenomenon which this period marks, which so often passes unperceived, when the disease may be prevented by active treatment.

In subjects of a sanguineous temperament, robust, and well fed, and more especially in those whose breasts evince a disposition to congestion, the antiphlogistic treatment is indicated. To fulfil this indication, bleeding from the foot is to be employed, as a derivative; inter-

nally we should give nitre, and apply camphor externally over the tumour, which exercises a very favourable action; besides this we should recommend a vegetable diet, and care should be taken to avoid all these influences which may tend to stimulate the anormal activity which is developed in the breast.

It generally happens that the aid of medicine is not called for till the swelling has already become very remarkable. We must then apply our therapeutic means over the affected part in order to diminish the tumour and effect a cure, if not a perfect, at least a partial one. Under these circumstances the more plethoric the patient is, the more applicable is the antiphlogistic treatment. Internally iodine and sponge should be employed; externally we should advise frictions with ointments consisting of hydropotassate of potass and of mercury, and compresses impregnated with camphor should be applied to the mammary occasionally. From time to time from six to ten leeches should be applied to promote the absorption of the iodine. This treatment to be persevered in for three or four weeks; then to stop for about 15 days, nourishing food, but such as is easy of digestion to be allowed the patient during this progress. The effects of the iodine must be carefully watched.

When the symptoms have diminished in violence, recourse should be had to antiphlogistic measures. When they have entirely disappeared, camphor emulsion may be given with advantage. The effects of this will be particularly serviceable, if the inflammatory phenomena came on under the influence of cold. In several individuals the symptoms occasioned by iodine are more striking and more rapidly developed after the internal use of this medicine than after its external application.

If the hypertrophy is either closely approaching or has already attained its full development, we may still expect to save the patient and to effect a radical cure by removing the breast.

The means of treatment here pointed out should only be employed when the general health is good. If the disease be too far advanced, and if amputation of the breast be contra-indicated, we must confine ourselves to a palliative treatment, which is chiefly to consist in an apparatus for supporting the mammary.—*Zeitschrift für die gesammte Medicin*, 1837.

IRISH MEDICAL CHARITIES BILL—COUNTY INFIRMARIES.

OBSERVATIONS BY DENIS PHELAN, Esq.
M.R.C.S.

I cannot here avoid observing that the course pursued on this occasion by the infirmary surgeons was unusual, and, as regards the other practitioners of Ireland, not quite a fair one. A member of the government brought in a bill which the public prints had long announced it to be his intention to propose. The memorialists disapprove of certain parts of it, those chiefly which would affect themselves. They had two courses open to them, if they felt aggrieved—the one, resolutions and a petition; the second, a memorial. The petition would be a public document, accessible to every member of the legislature, as well as to the whole profession, through the printed votes of the house. Men who rely fully on the justice of their cause usually adopt the first course. There is no secrecy about it, nor any effort to influence a particular party to get up an opposition. The second was that pursued; it was attended with no publicity; there was no public—or, as far as we know private—meeting of the memorialists, who appear to have authorized Dr. John Jacob to affix their signatures to a document perhaps entirely prepared by himself. I can scarcely believe that some of them knew its contents, for reasons I shall state hereafter. At all events, the business was done in the most private way, and it was by mere chance that a document which, for the time, decided the fate of the bill, became known to me or the profession.

This memorial, however, deals only in assertions; there is no proof attempted to be given. Let us, then, inquire to what credit are these assertions entitled; and if it be found that they are opposed by such authorities as have not yet been and are not likely to be disputed, it is clear that the case of the memorialists falls to the ground, and that no similar step will be much attended to.

The documents which I shall draw on to disprove the assertions of the memorialists are but few; one, a work published by myself in 1835, entitled 'An Inquiry into the Defects and Abuses of the Medical Charities of Ireland, with Suggestions for a Medical Poor Law;' the other, the reports of, and the evidence and information obtained by, the four medical gen-

men appointed by the Irish Poor Inquiry Commissioners to inspect and report on the public medical institutions of Ireland. Three of these were Englishmen; for such I may call the late much lamented and talented Sir D. Barry, who never practised in this country, though he was a native of it, and was partly educated in Dublin. The fourth was Mr. Cusack Roney. The result of their labours was published in 1836. It is appendix B of the Inquiry Commission. Both these works give numerous facts and circumstances diametrically opposed to the statement of memorialists. Mine was noticed in several of the most respectable English medical periodicals—works which every infirmary surgeon reads. A considerable portion of it is occupied in pointing out the defects and abuses of the infirmary system in this country. The sources from whence I drew my information are given, and are perfectly authentic. They are the returns obtained by Dr. Barker, the excellent and talented Secretary of the Board of Health, in answer to the circulars sent to each infirmary by the direction of Lord Melbourne. They are for 1828 and 1829. In addition I have given much valuable information which I obtained from the governors and medical officers of these institutions. The reports of Doctors Barry, and Corrie, and that of Dr. Borrets, have been published in full in the *Medical Gazette*, and in Dr. Ryan's *Medical and Surgical Journal*, with comments by these journals no way favourable to the Irish infirmaries. It is stated by the latter, [Dr. Ryan's], that these reports are in a great measure 'an abbreviation' of my work—a sure proof that these defects and abuses exist, and are apparent to all who will permit themselves to see them.

Now, if the memorialists really believe that these institutions have been thus grossly misrepresented, how does it happen that they took no notice of either work? Mine they might perhaps pass over, as the author was of no note: though the sources from which the information was obtained appeared to others to entitle it to full credit—at least, until shown to be erroneous. But the official document published by parliament, under the sanction of the poor inquiry commissioners—that surely could not be overlooked; for whether the facts and opinions it contains be well or ill founded, they are given on such authority that, until satisfactorily disproved, they must remain as a lasting memorial against the infirmaries. And

what makes the case still stronger is this—the very parties aggrieved have at their command the only medical periodical in Ireland; edited too, by persons not likely to refuse insertion to any statement that can be made out favourable to the infirmaries—I mean Dr. Arthur Jacob, and Dr. Graves. And here I cannot help observing that these editors have not performed their duty to their *own part* of the profession, or to the public, by omitting to notice the works to which I allude.—Either the statement they contained in reference to the infirmaries were well founded or they were not. If they were well founded, would it not be the duty of an Irish medical journalist to call the attention of the infirmary surgeons and governors to the subject—intimating the expediency of putting their house in good order, and of coming forward themselves, praying the legislature to amend any defects that existed, when the abuses would naturally cease.—But if not well founded, how does it happen that they have not exposed such erroneous statements, and allowed all connected with these institutions to be misrepresented?

One thing will, I think, at least be admitted—that could Dr. Arthur Jacob controvert the statements respecting county infirmaries which these works contain, he would not be slow in doing so. His silence is, therefore, a strong though a negative proof that these defects and abuses have existed, and do exist. It may be said the *Dublin Medical Journal* is not intended for such discussions. There have been, however, articles in it, which show the *animus* of the editors had they but safe grounds to tread on.

Such, at all events, are the documents from which I expect to bring evidence, to prove the statements of the memorialists are not entitled to much attention.

The memorialists state "that these establishments have been generally well administered, and have afforded most valuable aid to the sick poor—that the subscribers continue to aid in support of such institutions, and closely watch over their interests. Yet without cause assigned reference being made, or an opportunity of defence or explanation afforded, these corporate bodies (mark the expression corporate bodies), established by law, and in existence before the union, are to be nearly extinguished, and the powers heretofore exercised by the respectable gentry, traders, &c., transferred to four medical inspectors."

Let us now enquire what degree of

credit is due to this statement, which is indeed very ingeniously worded.

The *corporation* of each infirmary is composed of the Protestant archbishop, bishop, rector or vicar, Lord Chancellor and subscribers. It will, I am sure, be admitted that all these, particularly the clerical governors, may be fairly expected to make such moderate exertions as may not inconvenience them in exercising the powers with which they are vested to obtain the necessary fund for supplying the legitimate objects with medical aid; for, surely, it will not be contended that, even a paying governor, if he reside sufficiently contiguous to the institution, is justified in merely contributing his subscription, but that he ought to interest himself in taking care that, as far as possible, sufficient funds be procured. Trying the question by this test, it is to be feared that but few infirmaries have been well administered; for instance, there has been usually a good attendance at the King's County Infirmary, which is, perhaps, one of the best conducted in Ireland; but it would appear that no exertions are made to obtain any funds except the public grants—about £30 a year, being the average subscriptions. The governors state that “they keep as many beds occupied as they can afford, and “had they funds, the demands on the institution are great, they could occupy double the number of beds.” The same is stated to be the case in many other counties. At Maryborough—Dr John Jacob's own infirmary, which is also well managed in the above limited sense—nearly as many [fit objects] are refused as are admitted—and like as in the former, the “governors proportion the number of patients admitted to the hospital to its probable income.” Here, however, they really do make an exertion to obtain subscriptions, and are to some degree successful; but even so, not one half the sick poor are relieved.

But there are other institutions differently conducted, or the medical commissioners have done them great injustice.

The county of Kerry has a population of 263,000, and its infirmary, at Tralee, at the time of Dr. Borret's and Mr. C. Roney's visit, contained 23 beds and 25 patients, just accommodation enough for about a tenth of the county, and a clear proof that, as far as the nine-tenths of the county is concerned, this infirmary is a mere farce. And so it is in most others. But what say Dr. Borret and Mr. Roney as to this hospital? “The general ma-

nagement of the affairs of the charity is vested in nine governors. In point of fact, however, however, the direction of the institution has been left very much in the hands of the surgeon, as there has not been a meeting of the governors since the year 1823, nor is there any fixed period for their assembling. There is neither managing committee nor any visiting governors.” “No rules or regulations whatever exist for the conduct of the establishment.” “There is but one life governor, whose subscription was received since last assizes. There is no annual subscriber.”—(Appendix B., pages 313 to 374.) Almost all the governors are stated to be *absentees*!!

And yet, notwithstanding all this, the memorialists will contend that the Tralee infirmary is ‘generally well administered,’ for I find the surgeon's name to the document; but whether he authorized Dr. Jacob to affix his signature to it remains to be seen. I have now before me the fiscal concerns of this hospital for four years, during which time not a shilling was received in subscriptions or donations, the entire expenditure being paid by the county treasury, viz.—£500 per year the former, and £90 the latter. Now, a word more to show that a very small population is chiefly benefitted. In one year 281 patients were admitted, of which 231 were residents of Tralee and of a circle not beyond five miles, containing a population of about 33,000, whilst the remaining population of the country, 30,000, obtained accommodation for 57.

Dr. Borret says of Mallow, that ‘although possessed of a county infirmary, and favoured, it would naturally be presumed, over other places on this account, instead of gaining by this circumstance, it seemed upon the whole, to be worse off for it. In no town that I visited did the sick indigent inhabitants stand more in need of medical aid.’ ‘Not only febrile affections, but all internal complaints—in fact the bulk of disease with which humanity is afflicted, are inadmissible into the infirmary, which is appropriated to cases purely surgical, sometimes of a mild and simple character, which might be treated for the most part quite as well if they only attended once or twice a week at the dispensary.’

“This anomaly is not chargeable on the medical officers. It is incumbent on them to admit such cases in turn when provided with a subscriber's order, and there was no lack of attention on their

part to a proper discharge of their duties. It is not to them that I impute the blame—it is to the principle that I object, which obtains in the management of all these establishments; for of a truth *that system must be bad* which goes to provide internal accommodation in cases where without any injury it might be dispensed with, and leave others at the same time to perish for the very want of it."

Here let me observe, that it is my decided opinion that the intern duties are well performed by all the medical officers of infirmaries—and that much of the good management of these institutions, where such is the case, will be found to arise from the sole exertions and attention of these gentlemen, rather than from those of the governors. But they cannot cure a bad system.

The only two other county hospitals visited by these two medical commissioners were the Roscommon and Kildare; and here again, we find the surgeons do their duty in the most exemplary manner, but "the same bad system" prevails. Neither hospital is large enough for one third of the county, yet "excellent accommodation is afforded the surgeon" in each. In Roscommon he occupies, besides stable, coach-house, &c., two rooms of 163 by 15, and another of 12 by 9;—and yet, "it is the custom here, when, from want of room, they cannot be admitted, to take lodgings for the patient in the town, where they are kept at the expense of the institution till there may be a vacancy. This procedure is said to be very inconvenient, as well as a source of additional expense. The Kildare infirmary "contains ten rooms, of which five are appropriated to the use of the surgeon and attendants."

So far for the inspection of Dr. Borret and Mr. Cusack Roney; whether the result be favourable to the statement of the memorialists, "that these establishments have been generally well administered," it will be for the public to judge.

But what say Doctors Sir David Barry and Corrie, who inspected sixteen county infirmaries—some in each province?

"The following, amongst others are some of the abuses which we had occasion to observe in the management of this class"—(infirmaries).

"1. The chief medical officer becomes the contractor to his own hospital for a particular article of diet, the consumption of which he can encrease himself ad libitum."

"The dietary is constructed so as to favour this consumption."

"2. He becomes possessed of and turns to his own private profit, all the land, sometimes of considerable extent, attached to the charity,"

"3. He occupies the best part of the hospital, and its out-building, with his family, to the manifest prejudice of the sick poor."

"4. He establishes a dispensary within the hospital, and receives under that pretext, an additional salary for seeing patients in the hospital surgery."

"5. He charges for additional medicines for his dispensary, but does not keep that medicine apart from the hospital medicine."

"6. He keeps no diet table, nor accounts of the provisions issued."

"7. He is himself the purchaser of all provisions."

"8. He builds for his own accommodation on the hospital premises."

"9. He takes in such cases as are least entitled to hospital relief, and are likely to be a burthen to the institution."

"10. He knows little or nothing of the rate or quality of diet, or of the provisions bought or issued at his own hospital; leaves this department chiefly to the care of his purveyor or matron."

Reference is made under each head to the infirmary, or infirmaries, in which the abuse was found to prevail. But the commissioners add, that "they are happy in being able to refer to a large proportion of examples in which the zeal, high integrity, and attention of all concerned, are entitled to the highest praise," particularly specifying Antrim, Londonderry, Cavan, Clare, Limerick, Limerick city, and Queen's County, as instances.

On this I shall make no comment—I believe it scarcely requires any; but I will conclude this letter by stating what the defects are stated to be, under which such abuses are committed and permitted not by medical men so much as by the governors.

In the 4th chapter of my work on provincial infirmaries, pages 38 to 118, I have stated these defects to be—

1. The inconvenient sites of many.
2. Vesting the power of establishing a second hospital in each county in the governors of that first erected.
3. Monopoly of the physicians and surgeons of the Dublin Colleges.
4. Providing public funds, these being insufficient.
5. The want of a proper controul and

inspection.

6. The annual subscriptions being too high.

7. The non-appointment of a second medical officer.

8. The non-appointment of a house surgeon and apothecary.

9. The want of efficient medical aid for the sick poor of the districts immediately contiguous to the infirmaries.

10. Want of exertion on the part of the governors to obtain funds.

11 and 12. Insufficiency of funds and of beds.

Each defect is pretty fully explained, and instances are given where they occur, and how they operate.

Drs. Barry, and Corrie, observe that, "The leading defects, in our opinion, in the original construction and present state of the public medical relief system to the sick poor may be traced to—

"1st. The total omission, on the part of the legislature, of all provision for an efficient superintendence, or controul being exercised by proper qualified persons, whether over the working of the whole system, or over that of its subordinate machinery, as county hospitals, dispensaries, fever hospitals, &c., in the different districts.

The 2d and 3d relate to fever hospitals and dispensaries.

"4th. The exclusiveness of the county infirmaries act relatively to the qualifications, as well as to the number of physicians and surgeons to be employed in the hospitals, &c."

"Under such an easy system," they observe, "of legislation, and a still more *lax administration of its enactments*, it is not to be wondered at that abuses arose, not that these abuses all tended, directly or indirectly, to divert to *selfish* purposes a greater or less portion of the means originally destined for the relief of the sick poor."

Did Dr. Jacob, and those who signed the memorial, read these before they sent it to Lord Morpeth and the Irish members?

But, it may be insinuated that Mr. Phelan, Drs. Barry, Corrie, and Borret, are prejudiced witnesses; and that Mr. Cusack Roney, in his report, has only in one instance alluded to any infirmary abuse, and has nowhere touched on their defects; and, beside, that all these reports refer to a very recent period, from 1828, to 1834. Is Dr. Rennie a prejudiced witness, or has he not rather been one of the greatest supporters of the College of

Surgeons? Well, what said he in 1800? "We *know* and *lament* that some of these establishments—the county hospitals of Ireland—are far from being on the best footing." "The radical difficulty is to find a local controul, which shall be steady, upright, and energetic."

In my next I will endeavour to show that the remainder of the memorial is as weak and unfounded as that which asserts that "these establishments have been generally well administered."

The London Medical

AND

Surgical Journal.

Saturday, October 21th, 1837.

THE IRISH MEDICAL CHARITIES BILL.

Our readers will perceive, by reference to an article in another part of our pages, that the public charities in Ireland loudly demand a radical change in the supply of medical aid and medicine; and no rational individual who reads Mr. Phelan's letter can doubt the fact. The hospitals, dispensaries, and other charitable institutions whose management he describes, are entirely monopolized by the members of the Dublin College of Surgeons, to the exclusion of all those of the British Colleges, who are actually nine-tenths of the profession in the Sister Country. It is manifest that such an unjust monopoly as this is highly injurious both to the interests of science and suffering humanity. The defence of the Dublin College is, that their members are better educated than those of the London and Edinburgh Colleges, and therefore ought to be preferred. But the real reason is, that some half dozen members of the College have hitherto amassed great wealth by apprentices, some of them having had as many as *forty* at one time, each of whom paid

£500 as an in-door, and an £150 as an out-door pupil, for which the public charities were secured to them by their masters, who form the Dublin College. This gross job is about to be destroyed by the legislature, and hence the ravings of the interested few, who have thriven upon it for the last thirty years. They well know that any change will destroy the apprentice-fee system, and hence the clamour raised against the intended Medical Charities Bill. But surely the wants of the most wretched sick poor are to be supplied at the expense of a few fat monopolists, and common justice done to the whole medical profession in a large portion of this kingdom. The Irish government has at length seen the necessity of remedying this monstrous evil, and would have corrected it, had it not been for the sudden dissolution of the last parliament.

The monopolists, however, strained every nerve, and had the folly to declare, that English surgeons were inferior to Irish, and that it would be injurious to the Irish poor, to be attended by them. According to this logic, the Irish poor in England must be sadly treated by such surgeons as the Coopers, the Brodies, &c., &c. Moreover we should very much like to know, what have the superior surgeons of Dublin contributed to the advancement of science? We answer much less than the provincial surgeons in England, and if this be any criterion, in our humble opinions, the less said by these self-constituted superiors the better. We are ready to admit that there are some members of the Dublin College very enlightened and distinguished individuals, but it by no means follows, according to our notions of reasoning, that their apprentices are to be equally eminent, and surpass their fellow students, who are not apprentices and who hear the same lectures, but receive a

diploma either in London or Edinburgh, for the purpose of evading the apprentice fee already mentioned. It is certainly a remarkable fact, that the London surgeons are considered best qualified for the army, navy, and all departments of the public service, save and except, according to the Dublin College monopolists, attending the public charities in Ireland. Really this is the *argumentum absurdum*. The rest of the world is foolish enough to consider, the approbation and diploma of such surgeons as Sir Astley Cooper, Sir B. Brodie, Mr. Guthrie, Professor S. Cooper, &c., are sufficient proofs of a surgeon's competency, while none but the traders of a self-interested Dublin junta maintain the contrary.

If we look to our army we find the majority of the surgeons members of the London College, and after having had the care of regiments for twenty years in the most opposite climates, should the Irish portion of them return to their native towns, they, forsooth, cannot be county hospital surgeons, nay, not even dispensary surgeons, though they have seen more operative surgery in one year, than any ten members of the Irish College during their whole lives. Nevertheless, they are ineligible, unless they submit to examination at the College, where they will be assuredly rejected, unless they have been apprentices to some of the examiners. This scandalous monopoly is carried so far, that it is openly avowed by the examiners, that they never will admit the students of the Richmond Hospital school as members of College, because Mr. Carmichael had the manliness to oppose this fraudulent apprentice-fee system. Yet these are the worthies for whom the sick poor of Ireland are to be neglected, and nine-tenths of the profession degraded and insulted. The letter of Mr. Phelan is, at

this moment, particularly apposite, as it contains internal evidence of the system which has given rise to our strictures, and we feel perfectly convinced that the present government will fully redeem the pledge which they have given in their bill to the great portion of the profession in Ireland.

ON THE INDUCTION OF PREMATURE LABOUR IN CASES OF DEFORMITY OF THE PELVIS.

To the Editor of the Medical and Surgical Journal.

Sir,—If the following case possess sufficient interest to be worthy of introduction into your useful and scientific Journal, you will, by its insertion, oblige
Your obedient servant.

EDWARD AUGUSTUS CORY,
Surgeon to E. L. Lying-in Institution, &c.
Cannon-street Road, St. Georges-
in-the-East, Oct. 16, 1837.

Mrs. H., of short stature, and aged about 30, had twice undergone the operation of embryotomy. I attended her, for the first time, about three years since, when the same operation was again deemed necessary, and was performed in the presence of a most respectable practitioner. The pelvic deformity was of the reniform character, the space between the sacro-vertebral angle and symphysis pubis (conjugate diameter), being about two inches and three-fourths. It was consequently determined, should the recurrence of pregnancy render it necessary, that the premature induction of parturition at the seventh month of utero-gestation should be had recourse to, as affording the only means of saving the infant from the murderous application of the perforator. She had again become pregnant, and it was calculated that she had arrived at the seventh month of her pregnancy about Thursday the 14th of September last. From some remarks and cases which have been recently published by Dr. F. Ramsbotham, it appears that he has succeeded in effecting the induction of premature labour, (solum ope secalis cornuti). I was therefore led to employ this substance according to the formula he has suggested viz., R. Secal. cornuti ʒiij Aq. Bullientis

ʒviij infunde per semihoram et adde Acid. sulph. dis ʒij Sy. Simpl. ʒij tr. card. co. ʒiij ut ft. mist cujus cap. cochl. ij magna. tert. horâ. The first dose of this mixture was ordered at 2 P.M. on the 14th Sept. At 6 P.M. soon after the administration of the second dose, the uterine energy became slightly excited, and it was interesting as well as satisfactory to observe its gradual increase soon after the repetition of each dose of the medicine. On the next day (Friday) at one P.M. the parturient pains were tolerably active, but at considerable intervals. A vaginal examination was instituted, and the membranes were distinctly felt pressing against the undilated os uteri. Saturday, at 11 A.M., the pains had gradually diminished in force and frequency since my last visit, and she had experienced no pain from yesterday at four P.M. to the present time, and was, to use her own expression, quite well again. The institution of another vaginal examination demonstrated that the os uteri had not in the least degree increased in dilatation, and that the pressure of the membranes which had been previously experienced even during the interval of pain, had now entirely subsided. She expressed great anxiety and apprehension as to the result. On the same day, about six P.M., I again visited her, and found her precisely in the same situation. I was fearful of repeating the secalæ cornutum lest it might destroy the infant. I therefore thought it most prudent to rupture the membranes, the distention of which had now completely subsided; and this, having converted the nail of the index finger into a saw, I accomplished with some little trouble. She was again visited on Sunday at a little after one P.M., she remained in a similar condition, and there had been no accession of the pains of parturition. On Monday she had not yet experienced any pain, and the bowels being in a constipated state, I thought it prudent to prescribe an aloetic purgative, with a carminative addition, which had the effect of thoroughly evacuating the bowels, and exciting the uterus to action, so that early on Tuesday morning the pains of labour commenced with considerable activity, and continued with but slight intermission until six o'clock in the evening, when she was delivered of a living infant of healthy appearance. The fœtal head, notwithstanding the severity of the parturient paroxysms, occupied several hours in its passage through the contracted pelvis, and after expulsion presented, on its lateral

portion, an evident indentation, and was also considerably flattened. The whole process terminated as in a common accouchement. The placenta was expelled with but little assistance, about half an hour after the birth of the infant, which was restored in ten minutes by immersion in the warm bath, and by artificial respiration. The child remains at the present time (Oct. 16.) healthy and vigorous, takes the breast freely, and there is every probability that it will continue to live. The patient has not suffered the least pain or inconvenience since her delivery, in short, I never witnessed a more rapid recovery even in an ordinary case.

Remarks.—The necessity for the induction of premature labour in the present instance, must, I think, be evident to every well-informed obstetrician, and I am of opinion that the means so carefully adopted for the production of so desirable an object were based upon the soundest principles of obstetrical science. I am induced to believe that had I continued the administration of the secale cornutum for a longer period that the expulsion of the infant might most probably have been effected, without the necessity of the least manual interference, but I was deterred from persevering in its use from the apprehension that it might exert a deleterious effect upon the infant, and also injure the mother. I was fully aware of the great importance of maintaining the membranes entire as long as possible in order to be able with greater certainty to ensure the safety of the infant, but as the secale failed to produce the anticipated result, I was reduced to the alternative of rupturing the membranes, even with some risk to the infant, rather than hazard perhaps irretrievable injury both to the mother and child by persevering in the administration of the ergot. The induction of premature labour appears to have been practised by the ancient physicians more particularly by *Ælius* and *Palus Egineta* who recommended it in cases of extreme contraction of the pelvis; but it was not until about the middle of the last century that the most eminent practitioners in London decided on its propriety and morality. It may be laid down as an incontrovertible obstetrical axiom, that if there be less than the space of three inches and more than two and a half inches between the sacral promontory and the pubis, that the induction of parturition at the seventh month of utero-gestation becomes indispensably necessary, and its utility will be

rendered more evident when we consider the disproportion between a structure thus constituted, and the fatal head at the full period of intrauterine maturity. From accurate and multiplied observations, *Madame Lachapelle* has arrived at the conclusion that the bi-parietal diameter of the fœtal head at the seventh month of pregnancy, does not measure more than three inches, and sometimes even less; and therefore allowing for its compressibility in consequence of incomplete ossification, it may be easily imagined that no very considerable difficulty will be experienced in its passage through such a pelvis as I have mentioned. The records of the science prove most satisfactorily that the woman is not subjected to a greater risk by premature labour induced artificially, when carefully performed, than by spontaneous parturition at the full period of gestation. The existence of some morbid affection, rupture of the uterus, or some accident entirely independent of premature delivery has been invariably discovered in those cases which have had a fatal termination. *Denman* operated eight times with complete success, (*Introduction to Midwifery*, vol. 2, p. 224). *M. Salomon* mentions sixty-seven; *Kluge*, twelve; and *Ferrario*, six, which also terminated successfully, (*Journal Compl. des sc. Med. &c.* June, 1834, p. 339). In the practice of *Reisenger*, (*Dict. de Med.* 2d edit. tome 1, p. 429), one died in fourteen; but *Merriman*, (*Synopsis of Difficult, &c.* p. 161), has not lost one in forty-six, upon whom he appears to have operated. Artificial premature delivery does not however terminate so happily with regard to the infant. In forty-seven cases which occurred in the practice of *Merriman*, (*Synopsis, &c.* p. 180), twenty-six were dead, five were born living, but not possessed of viability, and sixteen lived. *Hamilton* has been more fortunate, and in twenty-seven cases has succeeded in preserving the lives of twenty-three (*Ryan's Manual*); *Ferrario* five in six, *Kluge* nine in twelve, *Salomon* thirty-four in sixty-seven, and *Burckhard* (Thesis, Strasburg, July 20, 1830) thirty-five in fifty-two. Premature delivery has also been recommended in cases entirely unconnected with pelvic distortion. Its performance has been proposed by *Mai*, *Ritgen*, and *Carus* in those instances where the fœtus habitually dies some time before the expiration of the full period of gestation, as well as in some diseases induced by pregnancy which are dangerous to the mother, as

metrorrhagies, retroversion, &c. Siebold, according to Kilian, (*Die Operative Geburtshilfe*, vol. 1, p. 880) practises it in ascites, hydrothorax, &c.; and M. Costa, (*Revue Medicale*, 1827, tom. 1, p. 343,) thinks it necessary in diseases of the heart. Conquest (*Outlines of Midwifery, &c.*), Ingleby in his work on Uterine Hemorrhage, Busch (*Lehobuch der Geburtskunde*, 2d edit. 1833), and other authorities have also recommended it in cases entirely independent of pelvic distortion. My limits will not permit me to discuss the propriety of its adoption in the various morbid conditions just alluded to, but it is evidently the only rational means of relieving the woman who has the misfortune to be affected with diminution of the natural dimensions of the pelvis, and of rescuing her infant from inevitable destruction. The operative methods which have been proposed and practised for the induction of premature labour are very numerous, but the one most usually had recourse to, and upon which the greatest reliance can be placed, is the sudden evacuation of the *Liq. Amnii* either manually or instrumentally. Some writers of celebrity have advised its gradual discharge, but the majority have decided in favour of the former, as by the sudden vacuity of the uterus, that organ is more likely to take on a brisk parturient action, by which means there will be a greater probability of saving the life of the infant. I consider also that there can be no objection to the previous administration of the Ergot, according to the formula, and on the very respectable authority of Dr. F. H. Ramsbottom, and I am inclined to believe, that in some cases it may (*per se*) produce the desired effect. I may add in conclusion another mode of procedure which appears to be in high repute with the practitioners of the French school, although I cannot recommend it on my own personal experience. Velpeau (*Traité complet de l'art des accouchemens*, Tome 2, p. 413) thus mentions it. "*La dilatation au moyen d'un morceau d'éponge, comme la imaginé M. Kluge, est d'un effet beaucoup plus certain. L'irritation qui en résulte est permanente, progressive, régulière, et soutenue par la pression qu'exerce l'espèce de tampon qu'on maintient en même temps dans le vagin. Sous l'influence d'une pareille excitation, la matrice entre bientôt en action, et il est difficile que le travail n'acquière pas rapidement une énergie suffisante.*"

MADRAS MILITARY HOSPITAL.

Communicated by W. Rose, Esq., Assistant Surgeon to the Madras Army.

Ulcers on the Penis—Extensive Disease of the Colon.

A. B., private of the 54th regiment, was admitted into the Madras Military Hospital with intractable ulcers of the penis, and placed under my care by Dr. Milligen, surgeon in charge of that institution.

On examination there were three ulcers on the dorsal aspect of the penis, one of the size of a double-fanum or fourpenny piece, the other two smaller, they were all superficial, of an indolent character, with white jagged edges, and exhibiting a few unhealthy granulations, the base rather indurated, and somewhat of a purplish hue. On the mucous lining of the prepuce and the glans-penis there were two or three smaller sores, but nearly of the same character as the external ones. General health much impaired, tongue clean, pulse 70, regular and small, appetite pretty good, bowels open, stools natural, no pain of abdomen or free pressure, has no other complaint whatsoever, and denies having ever had chancre, bubo, gonorrhea, or any other form of venereal.

From the abstract of his case sent with him it appears that the ulcers have been of two years' standing, during which time he has been treated in different hospitals, the ulcers sometimes cicatrizing in one part of the penis and breaking out in another, every variety of topical applications that could be devised has been had recourse to, connected with those remedies calculated to improve the general health, all of which, however, have been unsuccessful.

He has been latterly suspected of *malingering*, and to have kept up this ulcerated state of the penis for the sake of procuring his discharge, as it is well known that soldiers have often resorted to extraordinary means to attain this end; but the man's previous character has been good, he has been several years in India, and was always found a steady and efficient soldier, his habits temperate and frugal, so much so, that he has saved from his pay a considerable sum of money, the greater part of which he left by will to a charitable institution at Madras, and the remainder with some other trifling property to be divided between two of his comrades, to which will he requested me

to become a witness. He has been latterly staying at the military hospital at Poonamalee and St. Thomas's Mount, for the benefit of the air, his general health has of late improved a little, but the local affection continues much the same.

The attention of the Inspector of Hospitals, in his late tour, was directed to this case by the surgeon in charge, and in consequence of its extraordinary nature, and the suspicion with which the poor fellow was regarded by all the medical officers under whose charge he has been latterly placed, he ordered the man to be transferred to the military hospital at Madras, in order to have him more completely under his own *surveillance*.

R.—Argenti nitratis, gr. iv.

Oqræ distillatæ, ʒi. M.

Small pledgets of lint soaked in the lotion to be applied to the ulcers, and the entire penis afterwards enveloped in an emollient poultice.

R.—Pil. hydrargyri, g. iv.

Ext. hyoscyami, gr. x.

Fiant pilulæ tres hora somni sumendæ, olei ricini, ʒss. cras mane.

Half diet.

Nov. 11th.—Spent rather a comfortable night, slept pretty well; bowels opened teniar, stools yellow and of good consistence. Complains of the ulcers being rather painful this morning, but they look cleaner and more healthy; a bougie was passed into the bladder without difficulty, no appearance of stricture, passes water freely, urine copious and clear, and deposits no sediment, no pains of lumbar region.

The hospital serjeant, a very active man, and one or two of the assistants, were directed to observe him closely without exciting any suspicion on his part, if possible, or allowing him to suppose that he was the object of any sort of *espionage*.

R.—Hydrargyri proto-iodureti, gr. i.

Extracti hyoscyami, gr. x.

Fiant pilulæ tres una ter die capiendæ.

Habeat ter die

decocti sarsæ compositi, ʒiv.

Continuatur lotio nit. argenti.

Applicetur cataplasma anodynum in loco emollientis.

15th.—Since last report the largest of the ulcers has improved much, its circumference considerably diminished, and the granulations appear small and healthy, the others retain their usual appearance, and still continue painful, particularly of a night. Bowels regular, no pain of abdomen, evacuations natural, but the appe-

tite is considerably fallen off, and his general health deteriorates daily.

He has been carried on the beach, in a palankeen, for two or three hours every day, since his admission into the hospital, he says he likes the air and exercise, and that he always feels better after it.

Perstat.

20th.—The process of cicatrization has been entirely arrested for the last day or two, absorption of the newly-formed parts has taken place, and the principal ulcer is now, if anything, larger than before, and presents a very irritable appearance, the others remain stationary. General health still retrograding, appetite continues bad, sleeps tolerably well, Bowels open regularly every day; alvine dejections healthy.

Perstat.

A glass of sherry wine daily.

25th.—Ulcers continue much the same as on last report, but are not altogether so irritable. Appetite somewhat improved, appears more cheerful; tongue pretty clean, and rather pale; general health somewhat improved, has had two glasses of sherry daily since the 22d. Continues to take his palankeen exercise on the beach as usual; in other respects as before.

Cont. omnia,

28th.—On the removal of the poultice and dressings this morning, the ulcers presented a much more irritable appearance, and were covered with a thin layer of dark fluid blood, says he does not feel so well as on yesterday. Appetite rather worse—tongue pale, and rather coated—pulse too weak and small—bowels regular—in other respects, as before.

Entering the hospital this morning by a private door, close to his bed, I observed him laying on his back, the lower extremities flexed, and both hands under the covers, apparently as if engaged in interfering with the dressings of the penis; on seeing me, he appeared much confused, withdrew his hands immediately, and changed his position.

This circumstance in connection with the deteriorated appearance of the ulcerations strengthened the suspicions which was entertained against him, and I accused him of improper interference with the parts, exercised with the view of preventing their healing—the poor fellow assured me that he never made any such attempt, shed tears, and appeared very much affected.

Cont. omnia.

30th.—Continues much the same as on

last report, but the ulcers are somewhat less irritable.

Perstat.

Dec. 5th.—Diarrhea came on yesterday evening about 8 o' clock; has had several motions during the night; at first feculent, but latterly of a serous flaky character, without any particular fetor, and attended with an irresistible inclination to strain. Considerable pain immediately over the pubis, and extending to the left iliac region—tongue red and coated—pulse 100, small and compressible: complains of great prostration of strength and depression of spirits—skin cool—ulcers much in the same state as on last report.

Applicentur hirudines viginti quatuor hypogastrio statim, foveatur abdomen bene, et postea applicatur emplastrum epispasticum.

Rep.—Hydrargyri chloridi,

Pulveris ipecacuanhæ, āā gr. iii.

Fiat pilulæ duæ hora somni sumendæ.

Habeat olei Ricini ꝯss.

Cras primomane.

Omittantur cœtera preter lotionem, et cataplasmata—

Spoon diet.

6th.—Has had several motions during the night, copious, and of a fluid consistence, containing mucous and blood, of a darker colour than yesterday, and attended with much straining—no appetite—pain of hypogastrium not so severe as before, skin rather warm, and the whole surface of the body covered with a profuse perspiration, considerable thirst, pulse scarcely altered: in other respects, as in last report.

R.—Pulveris opii, gr. i.

Ipecacuanhæ.

Acaciæ, āā gr. iij.

M fiant pilulæ duæ quarta quaque hora capiendæ.

Cont. fomenta.

Vesperi.—Continues much the same as in the morning's report.

R.—Pulveris opii, gr. i.

Hydrargyri chloridi, gr. iij.

Pulveris ipecacuanhæ, gr. iij.

Fiant pilulæ duæ hora somni sumendæ.

Olei Resini ꝯss cras mane.

7th.—Spent a restless night, has had several calls to stool, alvine dejections copious, and composed of a bloody serum, which has very aptly been compared to water in which beef has been washed, or macerated. Tenesmus urgent, passes urine in small quantity, pain of hypogas-

trium and left iliac region still continues, though not so severe as at first. Pulse still 100, small and compressible—great depression of spirits. Thirst and anorexia still continue as before. The ulcers appear of a more dusky colour, and bleed on the slightest touch.

Rep.—Hirudines, xx.

Fomenta et postea.

Empl. epispasticum ut antea.

Cont. cœtera.

Vesperi.—Purged frequently during the day, alvine dejections of the same character as in the evening's report, but there appears a considerable quantity of dark flaky matter suspended in them. Pain of hypogastrium much relieved.

Rep.—Pilulæ hora somni.

8th.—Had some sleep last night, but was disturbed by frequent calls to stool, evacuations much changed in appearance, being of a dark brown chocolate colour, and accompanied with the most intolerable fetor, some of them have passed involuntarily during the night, pain of hypogastrium much relieved. The tenesmus still continues, great prostration of strength, pulse as before, tongue white, and coated, in other respects same as in last report.

Cont. pilulæ ter die capiendæ, et fomenta.

Vesperi.—Bowels acted on only two or three times in the course of the day, alvine dejections of the same character as in the morning's report. Tenesmus still distressing—urine scanty—pain of hypogastrium much relieved. Pulse 120, small and compressible, hiccup came on during the day, and distresses him much; ulcer still of a dusky colour, and very irritable, great prostration of strength and depression of spirits.

Capiat omni hora cochleare largum julepi moschatæ.

Rep.—Pilulæ anodyne, H.S.

R.—Pulveris opii, gr. iv.

Saponis ꝯj.

Fiat suppositorium.

9th.—Died at 5 o' clock this morning, after having spent the night in the greatest torture.

Autopsy 12 hours after death.

Body much wasted, penis shrivelled, ulcers contracted and black. On dividing the common integuments, there was a considerable quantity of serum in the cavity of the abdomen. Omentum shrunk, and of a firmer feel than usual. Liver rather small and indurated, but in other respects healthy; the stomach presented its normal appearance, small intestines sound.

The great intestines throughout their entire extent, presented the highest degree of lividity: on slitting them open, several gangrenous patches, four or five inches long, were observed: the calibre of the gut much diminished, and contained a considerable quantity of extravasated grumous blood. The villos coat perfectly disorganised throughout, and besmeared with bloody mucus mixed with specks of pus. The entire intestine was so much altered in tenacity, so brittle in texture, as not to admit of being freely handled without the risk of rupturing it.

This case is remarkable in so much as a disease of such formidable extent, and of such long duration should advance so slowly, yet so surely to a fatal termination, without manifesting, until within a few days previous to the catastrophe, any of the usual symptoms attendant on such an affection. There was no pain of abdomen on free pressure, bowels regularly open, alvine dejections natural, nothing in fact which could aid in forming a correct diagnosis. I am not aware myself, nor are any of my friends with whom I have communicated on the subject, of any case on record of ulceration of the penis symptomatic of disease of the alimentary canal. In the present case it is very evident that the obstinacy which the affections of the penis manifested, was entirely dependent on the formidable disease so far removed from it.

REVUE MEDICALE.

On the employment of mercurial inunction in External Inflammation.

Mr. Serre, of Uzes presented some time ago to the Society of Medicine of Paris, an essay written by him, and entitled, "A new special and abortive (abortix) treatment of inflammation of the skin, of the cellular tissue, of the veins, of the capillary, sanguineous and lymphatic vessels, &c. (We suppose for the sake of the author, and of common sense we are to understand the term *abortix* in an active sense). An analysis of this brochure appeared in the July number of the *Revue Medicale* of the present year. The author commenced his experiments on the efficacy of mercury in 1826, and having continued his experiments of this therapeutic agent up to the present year, he found it to produce in various inflammations effects as

successful as they were prompt, so prompt as completely to check the progress of the disease. He found the disease to be arrested, and as it were to miscarry in the space of from 24 to 48 hours. Not even blood letting when it succeeds, acts more promptly; He came to the conclusion that when the disease does not yield in this time, no other therapeutic agent could have succeeded better, and that there was every reason to expect suppuration, or some other destructive termination. So that according to the author, mercury becomes a valuable touch-stone in the hands of the practitioner who is anxious to know beforehand whether such an inflammation will terminate in resolution, or whether it will go on to disorganization. The preparation of mercury employed by the author, and the only one on which he places any reliance, is the strong mercurial ointment (*l'onquent mercuriel double*). It must be of a deep grey colour, well charged with mercury. If it present a dull appearance when rubbed on the hand, it is good; if it have a shining appearance, it is bad. The dose is to be proportioned to the intensity of the inflammation; *i. e.*, the more severe the inflammation, the greater is the quantity of mercury to be employed. In all cases the entire of the part affected and a little beyond it is to be covered with mercurial ointment. Then gentle friction is to be employed with the hand for eight or ten minutes, unless the presence of pain render such a manœuvre insupportable to the patient; this being done, the part is to be covered with a dry linen cloth, and the friction is to be renewed every two hours, and even oftener if the surface is of small extent; as in that case salivation is not to be apprehended. M. Serre has never seen salivation come on in his patients; he feels satisfied that the antiphlogistic effect invariably precedes salivation. At the sitting of the academy a wish was expressed that other experimentalists should try the powers of mercury in arresting inflammation. Among others M. Lisfranc made several trials of it in the surgical ward of the Pitié, and found, that when administered according to M. Serre's formula, mercurial ointment in general fulfils the end proposed; but that it sometimes produces salivation. According to M. Lisfranc, also, it is chiefly in intense and deep-seated inflammation of the subcutaneous tissues that copious applications of mercurial ointment succeed, more especially when it is extended one

or two lines beyond the part affected, but in slight and superficial inflammation, as in Erysipelas, this therapeutic agent is found most frequently to fail. Several of the practitioners, as M. M. Velpeau, Blandin, &c., concur in acknowledging the efficacy attributed by our author to mercurial inunction in inflammation; M. Bouilland, however, considers such inunctions dangerous in all cases of inflammation accompanied with fever.

M. Serre's mode of accounting for the action of mercury is this; it increases, he says, the powers of the stomach, develops a real febrile state, and gives to the blood a buffy appearance. It excites the encephalon forcibly, and produces mania and amaurosis; it inflames the iris, the salivary glands, and the bronchi; it ulcerates and tumefies the mucous membrane of the mouth, irritates the intestines, the penis, the glands of the groin; it encloses the energy of the dermoid system, which it reddens by its external application; it causes sciatica, inflames the bones, the periosteum, and the neighbouring tissue, Erysipelas, and especially that of the face, sometimes appears to be occasioned sympathetically by the action of mercury on the digestive organs. Thus he considers mercury to act as an irritant.

M. Segond, one of the commission appointed to report on the merits of M. Serre's brochure, objects to this conclusion, viz. its action being of an irritating nature. He conceives that mercury changes the constitution of the blood, the globules of which it rarefies and attenuates, at the same that it excites the contractile power of the capillary system, two effects directly opposed to inflammation. It is because it modifies the organization of the fluids changed by the inflammatory process, that it acts so directly, and so powerfully, when it is applied to the seat of the disease. The positive and direct proof of the influence of mercury on the blood is by no means impossible; for if a person be bled before the introduction of this metal, the blood is found to be richer, than if the vein was not opened till some days after its fusion with the circulating mass, admitting, however, that the medicine has been prescribed in a sufficiently large dose. On the other hand, if this treatment be for a long time persevered in, it will produce that state designated *mercurial scorbutus*, in which the blood is very pale, serous, and much impoverished. If

this treatment were prescribed for the cure of anæmia, cachexies in general, and divers chronic diseases, you will, says M. Segond, soon have water substituted for blood, and your patients will soon cease to live.

With respect to the fever produced by mercury, it depends according to M. Segond, on the unusual composition of the blood, as happens in anæmia and chlorosis. M. Serre concludes his paper by pointing out the circumstances in which mercurial inunction must inevitably fail.

For our part we cannot help observing that this endeavour to ascertain *how* mercury or any other medicinal agent acts in the removal of disease, is a very useless, and a very unprofitable task. The old and hackneyed maxim that the co-existence of two diseases in the system at one and the same time is impossible, was just as good a mode of accounting for the action of mercury, as any that has been more recently proposed. How false such an assertion is, the veriest tyro in medicine is now well aware. All we know about it is, that it removes or mitigates the disease. But the *how* and the *why* it produces this effect, however *scientific* and philosophic the enquiry may appear, is all mere humbug. There are certain states of disease which we know mercury generally removes or relieves. Let us ascertain by careful observation the various circumstances which may exert a favourable or unfavourable influence on the medicinal action of this substance. When we have ascertained thus far, we know all we can know, all that we need know, and all that is worth knowing.

ACADEMIE ROYALE DE MEDICINE.

LITHOTRITY ON A CHILD 40 MONTHS OLD.

Mr. Segales stated before the academy the case of a little boy, 40 months old, on whom he had operated for stone by lithotritry.

This child a native of Montreuil, near Paris, presented for the last seven months the symptoms of stone, among others a frequent desire to void his urine, acute pain, loud cries on passing it, and particularly towards the termination of voiding it, an almost constant purging, and, finally, a falling of the rectum at each discharge of urine.

M. Segalas, after having ascertained

the presence of the foreign body, introduced a lithotrite, without any other preparation than the introduction for some minutes of a wax bougie into the urethra; he instantly seized a calculus *ten* lines in diameter, and broke it by the combined aid of pressure and percussion.

Four sittings sufficed completely to destroy the stone, which consisted of oxalate of lime. No unpleasant accident occurred during any of them, and in the interval between them, the little patient went regularly to school, and ran about and played as he had been wont to do. Since the operation he has regained his complexion and flesh, and presents all the appearance of the best health.

TREATMENT OF UTERINE POLYPI.

By M. PECOT.

Read by M. Capuron.

A woman, 39 years of age, had had a child by her first marriage 18 years ago; marrying a second time, she again became pregnant, and her accouchement went on so well, that in the course of twelve days she resumed all her usual occupations. On the fifteenth day, there suddenly came on a hemorrhage which obliged her to keep to bed, and reduced her to a state of extreme weakness.

M. Pecot having been called in, examined the patient, and found the cervix uteri nearly in the same state as immediately after her accouchement. He carried his hand into the uterus, and discovered there a fleshy, smooth mass, which he ascertained to be a polypus. He wished to draw it out, and to detach it by pressure. Immediately the hemorrhage returned more profusely than ever: the patient lost all consciousness, and became convulsed. Upon this M. Pecot, considering only the danger in which his patient was placed, returned his hand into vagina, seized the polypus, and tore it away. It was the size of an egg.

On the removal of the polypus the blood ceased to flow, the patient recovered her consciousness, and soon recovered sufficiently well to nurse her child.

M. Pecot made this communication in order to show, that if there are polypi where the ligature and incision may be preferable, there are others where tearing them away is more applicable; such as that which presents itself immediately, or a little time after, lying in.

M. Capuron differed from M. Pecot. On the one hand he stated, that ten days

after lying-in the vagina, vulva, and uterus are so perfectly returned to their natural state, that it is impossible to distinguish a recent lying-in from one of long standing. And yet, says M. Capuron, M. Pecot did not see the woman, who formed the subject of this case, till fifteen or twenty days after her lying in; and how then was he able to introduce his hand into the uterus? and admitting that the uterus was in a state for receiving the hand, how was it that it did not contract on the hand so as to paralyse the fingers, and, consequently, prevent the manœuvre necessary for disengaging it from the polypus which it contained? The fact, as stated by M. Pecot, was not denied by the objector, it was only supposed to be an exceptional one. It is not difficult to conceive that when a woman is exhausted by hemorrhage, all the organs must become very much relaxed, and this state of relaxation might allow the performance of certain turns, which, under other circumstances, would have been impracticable.

On M. Capuron being asked whether M. Pecot proposed tearing off the mass as a general or an exceptional method, M. Capuron answered, that M. Pecot did not propose the operation as applicable to all polypi, but only to small, soft polypi, and to such as present themselves immediately after lying in. Even in such cases M. Capuron would give the preference to excision.

M. Sanson here stated a case which fell under his own observation; that of a woman, 30 years of age, who, during her pregnancy, had had several attacks of hemorrhage. When she came to her full time she had another attack, which threw her into a half syncope. M. S. prescribed the ergot, and proceeded to deliver her. On introducing the hand into the uterus, he discovered a fleshy mass, a polypus; he twisted it, it gave way, and the mother and child did well.

CLINICAL REPORTS.

EDINBURGH ROYAL INFIRMARY.

Dropsy—Abdominal and Pelvic Disease—Clinical remarks.

M. M., a female, fifty three years of age, was admitted into the hospital on the sixth of July. She is married; and has had nine children. The catamenia continued regular until within five months of admission. They intermitted for two

periods: and then returned; and she continued to have a discharge for some months. During that time she became gradually weaker; but her health, in other respects, was not affected. Flooding then came on, continued for eight days, was arrested by topical applications, and succeeded by a leucorrhæal discharge, which has continued till the present time. Weakness has kept her in bed constantly. Two months ago, she observed her urine to be diminished in quantity, with a high colour, and depositing a copious sediment. Swelling then attacked her feet, and gradually involved the whole of the inferior limbs; and her abdomen also became tumid. She has had medical attendance from a dispensary, for six months; but without experiencing any alleviation of her symptoms. She had, for six months, pain in the left iliac region: but it is now completely gone. A fortnight ago, she had pain in the right side; but it soon yielded to a sinapism. Pulse, a hundred and four; respirations thirty in the minute, tongue red, much thirst, moderate appetite. Ordered to have a tepid bath in the evening; and to drink freely of solution of cream of tartar.

July 7.—Slept well—pulse 90; rather weak. Has had two motions, of a dark colour; but less so than formerly. Her face is pale, with an expression of languor. Is much emaciated, and complains of general debility. Urine passed unconsciously. The abdomen is tympanitic in the upper part; and there is distinct fluctuation in the lower. It is free from pain on pressure. She can now lie easily on either side, and without her shoulders being propped up; but when first attacked, she had pain at the inferior angle of the right scapula, and in the right side of the abdomen, increased by turning to that side. Ordered to take, in an appropriate vehicle, ten drops of tincture of digitalis, three times a day; a draught every night, containing twenty drops of laudanum, and forty of spirit of nitrous æther; three ounces of sherry daily, with hot water and sugar; four ounces of steak for dinner; and sweet milk, instead of buttermilk.

10.—Since the last report, the digitalis has been increased to four times a day. The daily amount of urine is between one and two pounds. The œdema is now extending to the upper extremities. Tongue clean, glistening florid, and dry in the centre. Digitalis to be given five times a day.

14.—The debility increases, with occasional pains in the abdomen. Digitalis increased to twenty-three drops three times a day; and the wine to six ounces.

16.—General debility and languor of the circulation increase. The urine is still very scanty; and as the digitalis does no good, it is ordered to be omitted; and ten drops of the tincture of squills to be given in its stead, three times a day: and thirty drops of spirit of nitrous æther, in water. four times a day

17.—The pulse becomes more feeble; with increase of the œdema, and general debility. Urine about a pound daily. Has dyspnoea on being raised: and the respiration is at all times heaving. The patient lies with her head low; and on either side indifferently. Free from cough. Has felt nausea for several days. Let the squills be given four times a day; and the wine increased to half-a-pint.

19.—Yesterday the æther was ordered to be given six times daily; and the dose of the tincture of squills to be increased to fifteen drops. The patient has had a bad night, and complains of cardialgia. The urine was retained; but was passed after the administration of an injection; two motions have since been passed in bed. The features are shrunk; debility and emaciation rapidly increase: pulse very feeble; surface cold, especially of the extremities. Wine and æther to be continued; squills to be omitted; two ounces of gin to be given, and warm water and sugar; heat to be applied to the extremities. The dose of gin and water was repeated at night: but she continued to sink, and died early next morning.

On dissection, serum was found effused copiously in the abdomen, and in both sides of the chest. The glands of the mediastinum were much enlarged and hardened; as were also those of the mesentery, which was studded with large white tubercles. No distinct appearance of disease in the kidneys internally; though externally they are slightly granular. The liver was mottled. The pelvis presented a great mass of diseases. It was lined throughout with a deposition of white matter. The uterus was slightly enlarged; hardened in structure; and presented an albuminous deposit. A similar deposit was observed on the bladder, which was thickened; and the cavity of which was much diminished by a hard, malignant fungus, growing from its neck. There was ulceration about the os uteri, and upper part of the vagina. Across

the ascending vena cava, extended a chain of glands very much enlarged; which, it is probable, retarded the circulation. The heart was healthy; rather smaller than usual. There were some pleuritic adhesion, but no condensation of the lungs, or tubercles in them.

Clinical Remarks by the attending Physician.—Part of the complaints under which this patient laboured, were obvious; and part were obscure. The ascites and anasarca were very plain; the hydrothorax was doubtful, as the symptoms of it were not present. If the effusion be limited to one side of the chest, the patient can in general lie only on that side; but if it extend to both sides, he can seldom lie down on the back, or on either side; but in this case the patient could do both. We might have discovered the effused fluid by auscultation and percussion; but as there was no doubt of the proper treatment, it would not have been right to harass the patient. The tympanitis we observed in the epigastrium, is very common in such cases.

We had here to treat the dropsy; for there was no acute vague affection requiring remedies. The great question in all dropsical cases, is the *cause* of the effusion; for that regulates the practice and the prognosis. Dropsy arises either from inflammatory action, or from venous congestion. If a tumour press on a vein, the blood cannot pass from the arteries to the veins; and an increased action of the exhalents takes place, causing dropsy. An obstruction of any larger vessels, by any cause whatever, will produce the same effect. Disease of the heart will produce it, by producing congestion in the veins, from the regurgitation of the blood into them; and so will the obstruction of an artery, in the same way. But mere weakness will cause it: as from turgescence of the lower limbs from standing long. The disorganization of any viscus that transmits much blood, will produce venous congestions. But every kind of disease does not impede the circulation. Thus we often have disease of the liver without dropsy; though in other cases we have ascites from the difficult transmission of the blood; or anasarca, from pressure on the veins. Diseases of the kidney or spleen, will likewise produce dropsy; in the case of the latter, probably from impeded circulation of the blood; but in the case of the former, it is by preventing fluid from being thrown out of the system; and the same effect

follows, for the same reason, when the functions of the skin are impeded. If a tumour presses on a large vein, it may produce a dropsical enlargement, far beyond the size of the tumour itself; and the diagnosis will be rendered more difficult by the complication.

In the case before us, there was no satisfactory evidence of diseased liver; these were wandering pains; but they were transient. If the substance of the liver be diseased without the peritoneal covering being affected, no pain is produced by lying on the left side; there was great weakness originating in deranged catamenia, followed by leucorrhœa; the latter being of a very debilitating nature. I think dropsy is almost always occasioned by increased exhalation; but if the cause be not known, we endeavour to cure it by increasing the absorption; it is in this way that purgatives, diaphoretics, sudorifics, and diuretics act; if the patient be young and robust, we prefer purgatives; if old and weak, diuretics; and digitalis acts better in debilitated than in robust persons. In debilitated persons, likewise, tonics are useful; such as steel bitters, and the cold bath. If the dropsy be of an inflammatory kind, we must bleed and purge; the latter being also useful in promoting an evacuation of the fluid. We employed diuretics in the

NORTH LONDON HOSPITAL.

THE LITHOTRITY CASE.

The committee are still proceeding with their enquiries, but it is anticipated that in consequence of their limited powers, and the great delicacy of the investigation, that it will become imperative to bring the whole matter before a general meeting of the governors.

TO CORRESPONDENTS.

Zoologist.—The time of his sailing is not yet fixed,—the arrangements are complicated. New York is the next place for the theatrical exhibitions of the great Northern Tragedian.

W. I. L.—The proceeding would be most dangerous; twelve months, with public exposure, would be the consequence.

It is one of the many official duties of the Inspector for England and Scotland, to visit all dissecting rooms, ad libitum.

LECTURES ON DISEASES OF THE SKIN,

Annually delivered in Paris,

By M. BIETT,

Reported by MM. Cazenave and Schedel.

BULLÆ.—BLEBS.

This disease consists in elevations of the epiderm larger than vesicles, and formed by an effusion of serum, or sero-purulent fluid. Blebs are generally circular, their base is large, and their size from that of a pea to that of a bird's egg: and these characters distinguish them from vesicles, which are much smaller.

The bullous inflammations are two in number—pemphigus and rupia.

Rupia was classed by Bateman among the vesiculæ, but for some years past M. Biett has placed it among the bullous affections. In some diseases of the skin, different from this order, we see analogous lesions; but then their development is altogether accidental. Thus in the variety of herpes termed *zona*, we find some of the vesicles are so much larger than others, that they closely resemble bullæ. But in that disease the vesicles are much more numerous, and want all the characters of bullous inflammation. This appearance in erysipelas is marked by very different symptoms.

Bullous inflammations may be acute, but they are generally chronic, and they may affect every part of the body by successive development; they often attack extensive surfaces, but it rarely happens they cover the skin simultaneously. They appear most frequently on the inferior extremities. Their duration is for one or two weeks, but they may continue for months, or for an indefinite period.

Symptoms.—The appearance of bullæ

is often preceded by more or less vivid redness; but in most cases there is no erythematous redness. The blebs generally appear small at first, and gradually enlarge; and, in most cases are fully developed in forty-eight hours. They are tense at the commencement, but soon become flattened, in proportion as the effused fluid thickens; and in some cases they burst. They open in all cases more or less promptly according to the thickness of the epiderm, their distention, their seat, and the movements of the patient; and they are replaced by crusts which are sometimes very thick, and sometimes very thin. The bullæ developed on the face are generally very small, they open very speedily, and are followed by crusts, which are sometimes analogous to those of impetigo.

The bullæ are, in some cases, replaced by ulcerations, which are more or less superficial; and these are deep in rupia.

Causes.—The causes of bullous diseases are, in general, difficult to be appreciated, but they appear, in the great majority of cases, in debilitated constitutions.

Diagnosis.—It is in general easy to distinguish these inflammations. Bullæ are larger than vesicles, but the diagnosis is more difficult when the former have been broken, and are replaced by crusts of greater or less thickness. Nevertheless, the peculiar characters of each species are sufficient to distinguish them, and more particularly the traces which bullæ leave on the skin.

Prognosis.—Bullous inflammations are sometimes severe, when they have continued for a long time in persons enfeebled by age, or of a delicate constitution; and in such cases they generally accompany some chronic disease in some internal organ, and often of the liver. They sometimes require an antiphlogistic treatment, at other times the contrary, as onics, chabybeate preparations, and all

means for the improvement and restoration of health. Local applications are seldom necessary, though simple cerate, ointments of lead and zinc, are sometimes used with advantage. The disease, like many others of the skin, generally disappears by regulating the bowels and improving digestion.

PEMPHIGUS.

The term Pemphigus is derived from *πυμπίξ* bulla, and is applied to a disease, to blebs, on different parts of the body, varying in size, but usually very large, and sometimes of the diameter of two inches or more, filled with a very limpid serosity, which finally becomes redish, often isolated, but very numerous, or prolonged by successive eruptions, forming thin crusts and suppurative ulcerations.

Willan only admits the existence of chronic pemphigus, which he terms pompholix, consisting of bullæ without surrounding inflammation, and without fever. Bateman agreed with Willan that there was no acute pemphigus, while Plumbe describes the acute form of the disease.

Nevertheless, M. Gilbert in his excellent monograph on pemphigus describes with great precision acute pemphigus, and such cases have also been observed by M. Biett.

There are two forms of pemphigus, the acute and chronic.

The acute pemphigus may be partial, and occupy but a certain region, but it generally attacks a larger surface, and sometimes appears all over the body. In these cases the bullæ are almost always separated from each other, and they are only confluent here and there.

The precursory symptoms are slight, and only consist in a general feeling of indisposition, accompanied by vivid itching of the skin, and a slight acceleration of the pulse. The skin is dry and burning; there is thirst, anorexia, and shivering, and the pulse becomes frequent. This state continues twenty-four or forty-eight hours. The eruption now commences and consists in small, red, and circular spots, which rapidly increase and form bullæ, the serosity of which occupies the whole, or only a part, of the red surface; the red spots become bullæ after the lapse of some hours. The bullæ in some cases, cover the whole of the inflamed surface, and then we only observe small, transparent, and isolated tumours, more or less numerous, and the size of which varies from that of a pea, to that

of a large hazel nut; and in other cases, on the contrary, the epidermis is not raised in all of the red spots of the skin, but only in the centre, and in a variable extent: thus in a spot as large as the circumference of a six-pence, we only observe on its centre, a bulla of the size of a pea, whilst in other cases, an areola of some lines only surrounds the serous collection. In some cases we observe, here and there, erythematous spots on which bullæ are not developed; but on passing the finger over them, we perceive a slight tumefaction, and if you rub them, the epidermis is separated with great facility, and then a slight effusion of serosity under this membrane. The redness of the areolæ which are more or less large, is very vivid in the first days of the disease, while that of the spots without bullæ is much less so; the skin remains sound between the spots. In some cases the bullæ unite, and form a tumour as large as a goose's egg.

When bullæ have acquired their full development, they contain a citrine serosity, they fade, and that fluid becomes turbid. They sometimes burst within twenty-four or forty-eight hours. They are then replaced by small thin brownish crusts, which begin to form before the redness has disappeared, and sometimes there are whitish, small dry scales, as if epidermic. The general symptoms are sometimes very slight, and scarcely confine the patient to bed; but in other cases they are very severe. There was a patient in the hospital of St. Louis in whom this affection was accompanied, not only with gastro-intestinal irritation, but also by pulmonary catarrh, ophthalmia, and very acute urethritis. The tongue was much tumefied, and the lips covered with blackish crusts. All these symptoms, as well as the eruption, completely disappeared, in the space of one month.

The ordinary duration of acute pemphigus is less; it varies from one to three weeks. Acute pemphigus sometimes affects children: the symptoms are precisely the same. With regard to *pemphigus infantilis* or *gangrenæus*, it seems rather to belong to *rupia* or *scarlatina*. The *pompholix solitarius* of Willan seems to be a variety of acute pemphigus. The development of the bullæ is preceded by a creeping sensation; its progress is rapid, and the epidermis is very soon raised by several ounces of serosity. The bulla bursts in the space of forty-eight hours, and leaves a slight excoriation. A day or two after another bullæ

raises near the first one, and follows the same course. Two or three are often thus developed successively, and thus the disease may continue eight or ten days.

This variety is exceedingly rare: it may also exist in a chronic state, and M. Biett has pointed out a very interesting example in his clinical lectures.

Chronic pemphigus (pompholix diutinus, Willan) is a more common disease than acute pemphigus. It is observed in adults, and often in men advanced in life, more rarely in women.

This affection sometimes occurs simultaneously in all parts of the body; at other times it is confined to a small extent of surface. We do not observe in this disease, those constant febrile symptoms that attend pemphigus; they never occur unless the bullous eruption is very extensive, and successive eruptions may continue for an indefinite period.

A few days before the eruption appears the patient sometimes feels a slight degree of lassitude and depression, with pains in the limbs; but these symptoms are very slight, and most frequently attract but little attention. A variable number of small red points then supervene accompanied with a slight creeping sensation. The epidermis is raised in the middle of each little spot; the base enlarges more and more, so as often to form in the space of a few hours, bullæ of the size of a hazel nut or even of a walnut, and generally irregular. The distention becomes greater, and at the end of two or three days, the bullæ, have often increased to the size of an egg, and even larger. In consequence either of this distention or the movements of the patient, some of them break, and the citrine serosity that they contain escapes; then the epidermis wrinkles, and becomes depressed: or detached in some part, it is desquamated from the inflamed surface, leaving a portion uncovered; or else being completely removed, it leaves a more or less extensive surface exposed, which is red, painful and slightly excoriated, around which the skin is wrinkled, causing slight epidermic exfoliation. At the expiration of three or four days, the bullæ that have not been broken lose their transparency, the liquid they contain becomes reddish, and they fade, leaving the epidermis relaxed; being macerated by the serosity, it becomes of a whitish colour, and opaque, forming little brownish, flat and rather thickish crusts.

New bullæ appear at the side of the

old ones and follow the same course; and thus it is not unusual to see, on the same individual, bullæ distended by transparent citrine serosity, thickish lamellated crusts and irregular red spots, more or less extensive, and slightly excoriated. Finally the skin of the patient on whom all these degrees may be observed, from the formation of the bullæ to their entire disappearance, presents quite a peculiar aspect. Such is the most common progress of chronic pemphigus, which may thus continue, even for months.

In some very rare cases pemphigus affects the whole surface of the skin at once. The bullæ are confluent; they unite, the liquid thickens and becomes as it were purulent, and the whole body is soon covered with yellowish crusts, which might be mistaken for *impetigo*, these crusts are rather thick, and the greater portion present in their circumference, and in their form, something that shows they are the consequences of bullæ. Thus some of them, being exceedingly thin, seem to fall off from the centre, while the circumference forms wrinkles like those that surrounds the bullæ. They almost constitute a continued envelope, whose intersections are formed by scales that lie one over the other. This variety is confined to the face, which is itself a common seat of the pemphigus. The development of the first bullæ is some times preceded by circular red spots, as in acute pemphigus; but the eruptions that succeed do not present the same phenomena, and *vice versa*; at other times the secondary eruptions may present erythematous areolæ.

The disease sometimes fixes as it were on a particular part; thus there was a patient in M. Biett's wards, about thirty years of age, who had been affected from infancy with pemphigus, sometimes on one part and sometimes on another; he had on the lower part of the legs, a portion of the skin of a red purple like that usually seen after atonic ulcers on those parts. These parts had been for many years the seat of pemphigous bullæ, some of which were the size of an almond, and others that of a large nut; and sometimes they were even as large as the palm of the hand. In this last case, the derm was very considerably denuded, and the exposed surface had all the appearance of a large atonic ulcer, which was slowly cicatrising; but this was not the case, for often in the course of two days this surface would be completely

healed; new bullæ would be developed there, and their disappearance be followed by the same phenomena.

In severe cases, the patient is obliged to remain in bed; but fever is rarely present; on the contrary, when pemphigus is less extensive, the patients are not confined to bed, and bullæ are successively developed on different parts for an indefinite period. Pemphigus may exist with several different eruptions; those with which it is most usually complicated are herpes and prurigo. In the latter complication (pompholix pruriginosus of Willan) the patient suffers from very intense itching. Chronic pemphigus may be complicated with many chronic diseases of the internal viscera.

From what has been said of the progress of pemphigus, we may judge how indefinite its duration is, it may continue from one, two, or three weeks to months, and even years. It is often developed in summer, and disappears towards the last month of autumn.

Pemphigus generally terminates favourably, sometimes in death, which is commonly the result of complications more or less severe; and it is often the result of dropsy, either general dropsy, or that of one of the large cavities, and is frequently observed in old men, who have been for several years subject to pemphigus; or else it terminates in chronic inflammation of the digestive apparatus.

Necropsy.—There has been several autopsies, at the hospital St. Louis, of patients affected with bullæ, and we have never observed these bullæ which are said to exist on the mucous membranes, and particularly on the pharynx; most frequently, on the contrary, we have found these membranes pale, and serum effused in the chest. We have in several cases found enlarged liver, and M. Biett has often observed this anatomical lesion co-exist with pemphigus.

Causes.—Pemphigus may occur at any age, but adults and old men are particularly liable to its attacks; it is, however, sometimes observed in women, but they are much less liable to it than males. This disease affects some patients very frequently at irregular intervals; in other cases the bullæ of chronic pemphigus are successively developed for an indefinite period. Sometimes it seems to be endemic, and is observed to affect several at the same time.

Acute Pemphigus often shows itself in those who are much exposed to the summer sun; changes of diet, excesses, den-

titution, &c., seem in some cases to exert a marked influence on its development; it only attacks young persons.

Chronic Pemphigus, on the contrary, generally attacks old men, and those of a broken down constitution. Unwholesome and scanty diet, excessive labour, low and damp habitations evidently predispose to this disease. It is frequently developed after chronic, rheumatismal affections, or those of the abdominal viscera.

Diagnosis.—The presence of bullæ, which are generally isolated, succeeded by a thin lamellated crust that covers the denuded surface, will always distinguish pemphigus from any other cutaneous disease.

Rupia simplex may be recognized by the small number of bullæ, which are followed by real ulceration, and thick projecting crusts.

The skin is sometimes raised by pus in ecthyma, but the fluid is purulent, and not serous. The raised epidermis has a brownish centre, and on other parts of the body there will be found pustules of ecthyma in a less advanced stage.

In herpes the vesicles are always in groups on a red inflamed surface, whilst the bullæ of pemphigus are, in the greater number of cases, isolated and without any inflammation surrounding them. In some very rare cases, however, a few bullæ of acute pemphigus are here and there agglomerated, and the disease very much resembles the groups of herpes phlyctenodes; but then, on other parts, isolated bullæ with their distinctive characters will be found; and besides these groups are an agglomeration of bullæ, which, though small, are always more voluminous than the vesicles that constitute herpes.

LECTURES ON SURGERY.

By JOHN HUNTER, F.R.S.

Of simple Fractures.

A fracture is the solution of continuity of a bone, whereby more or less of a cavity or space is allowed between the broken parts. It often, if not always, happens that the surrounding soft parts are also torn by the broken ends of the bone. On the surface of this broken or torn part are the mouths of many ruptured vessels, which immediately fill the cavity with blood. This is the first stage of the bond of union. This blood, hav-

ing the living principle in it, unites with the torn surfaces, in the same manner as in ingrafting the living parts of animals. An inflammation generally comes on, similar to that which produces adhesions where there is no ruptured vessel, which is of service in this case for the better union of surrounding parts, where extravasated blood cannot enter, by which means the callus becomes larger than it would otherwise be. Vessels are either continued from the old parts into this extravasated blood, or it forms new vessels in its own substance; this substance then goes through the regular stages of ossification, becoming first cartilaginous and then bony. Thus new parts are formed and old ones united without the occurrence of any considerable inflammation, and all owing to this circumstance of the extravasated blood being preserved, and allowed to retain its living powers. All the surgeon has to do in such cases is to put the parts as much into their natural situation as possible, and to keep them there by art in the easiest way to the patient that he can. The same idea and the same practice is extended to all unions by the first intention.

The position of the patients themselves when the fracture is in the lower extremities, (abstracted from the nature of the fracture itself,) has been of late a consideration. It has been a question whether they should lie on their backs or on their sides. I am inclined to prefer the back; for, from the experience of one patient, who had the same thigh broken twice, lying on the back was the easiest, though it was the last, method of lying; and I conceive that it is a position that can be borne longer than that on the side.

The pain arising from fracture is but little, only from the bones either tearing or wounding the soft parts. The inflammation is of course but little, if the parts have not been violently torn.

Of compound Fractures.—If the violence of the fracture has continued the laceration through the skin, so as to have allowed part of the blood to escape, and to have exposed the remainder sufficiently long to allow it to lose its living principle, so as to become an extraneous body, unfit for the purposes of union, then the suppurative inflammation must take place, and granulations finish the union which the blood was incapable of doing. In this case the granulations become the origin and seat of formation of the callus, and go through the regular changes until they become ossified, as was the case with

extravasated blood in simple fracture. In these cases considerable fever and inflammation, proportioned to the local injury come on.

There are two cases which partake of the nature both of simple and compound fracture. The first is, where the injury was a simple fracture at first, but afterwards becomes a compound, which I shall call the simple compound fracture; the other is when the fracture is a compound one at first, but the external wound so small, and the soft part having sustained so little injury, as to require very little different treatment from what happens in the simple fracture; and this kind I call a compound simple fracture.

Of the simple Compound Fracture.—This is owing, in some cases, to some part of the extravasated blood losing its living principle, and then acting as an extraneous body; in others it is owing to ulceration. In these cases we see inflammation come on, at first, as in simple fracture, with that mildness which generally attends such cases; but some days after a stimulus is given by the broken pieces of bone, or by the blood which has lost its living principle, or from the parts being beyond the power of union by the first attention, and the suppurative inflammation comes on.

The cases which I have seen of this kind have been much less dangerous than fractures that were compound from the first. The only reason I can assign for this is, that the whole of the blood produced from the lacerated parts does not lose the living principle, so that a considerable portion becomes so much a part of the living solids during the first few days as to be able to keep its ground, only a portion of it acting to produce the suppurative inflammation, which is therefore less.

The treatment of the simple compound fracture is very simple: the limb may be bound up in general as in a simple fracture, with splints and a roller, only leaving a free space for the change of dressing and to keep the parts clean.

Of the Compound Simple Fracture.—The effect of this is similar to the foregoing, though the cause is different. There are cases of compound fracture where the wound in the skin is but very little at first. If the broken ends of the bone have not done much mischief to the soft parts, and only made a small wound in the skin, they may be treated as simple fractures, which gives us an opportunity of retaining the uniting matter. By immediately closing up the wound with a bit of stick-

ing-plaster, or a little lint soaked in the blood and allowed to dry on it, the greater portion of the wounded parts and broken ends of the bone will unite by the first intention, and only those parts of the solids which are exposed will suppurate. This small suppuration will oblige the surgeon to leave the wound in the skin free from bandage, in order to be enabled to look at it occasionally; though, from some accounts, it might seem that even this was not necessary. This mode of treating it as a simple fracture obliges it to heal as such. This practice has been followed even when the laceration in the skin was considerable; but I have not seen a sufficient number of cases to say how far it may be extended.

Inflammation, Suppuration, and Ulceration of circumscribed Cavities.—All circumscribed cavities, as the pleura, peritoneum, &c., admit of the three inflammations. They may be formed into true and distinct abscesses by adhesions inclosing the matter, as in common abscess. If the inflammation does not stop at the adhesive, then suppuration follows, and ulceration also becomes necessary for the exit of the matter, which is an extraneous substance. A material circumstance happens in the inflammation of cavities containing vital parts, which is that very little sympathy exists between the surrounding part and the parts contained, whence the inflammation of the one is not always continued to the other: thus inflammation of the peritoneal coat of the abdomen and of the intestine may exist without inflammation of the inner coat of the intestine. But this does not hold good universally, for inflammation of the tunica vaginalis spread through the whole body of the testis.

Inflammation of the Pleura.—This membrane is more subject to inflammation than any other investing membrane. Probably this does not arise from any difference of structure, but from its contact with the lungs. Perhaps there is hardly one in fifty who, at the age of fifty, is without adhesion of the lungs to the pleura. We often find the lungs adhering to the whole surface of the pleura lining the thorax, and it does not seem necessary that inflammation should take place on both surfaces to produce adhesion. Abscesses may be formed here, either having the matter inclosed in a particular bag or diffused through the whole side, forming one large abscess; hence true and false empyema.

Empyema.—The cavity of the chest is

subject to the two diseases of other circumscribed cavities, dropy, and inflammation and suppuration, or empyema. These two kinds of disease will have some of their symptoms very different, though the symptoms arising from the ultimate effect, namely, the collection of fluid in the chest, will be nearly the same in both. But as this cavity has connexions with parts whose symptoms when diseased will be very different from those of this cavity simply, and as those parts will sympathize with the diseases of this cavity, we shall find that a complication of symptoms will often take place which may mislead the judgment so much as to make us suspect that the sympathizer is the seat of the disease.

This sympathizer is the heart; and as a disease of this part has produced symptoms which have been lately called angina pectoris, we find that it requires particular attention to be paid to the specific symptoms of empyema to separate them from those of the heart.

The general cavity of the chest is divided into two distinct cavities; therefore whatever disease affects one simply, cannot affect the other by its having affected this.

Water may collect in the cavity of the chest almost at once, without giving much previous notice. It may be the consequence of various causes, as cold, fever, &c. The symptoms arising from the presence of a fluid are either peculiar, common, or sympathetic, which last may or may not occur.

The first true specific or peculiar symptom arising from an extraneous fluid, in some considerable quantity, in the cavity of the chest, is difficulty of breathing, which is always an attendant, and is distinguished from difficulty of breathing from other causes by this, that the patient is always able to breathe much better in certain positions. This position will vary according to circumstances: if water is only on one side, the person can lie on that side, and on that side only; if on both sides, he can lie on his back, not horizontally, but with the chest raised as much as possible. He feels the fluctuation of the fluid within the chest whenever he moves, especially when he raises himself up. I have heard patients often say that they could hear the fluid move. The fluid is felt pressing like a weight on the diaphragm. An anasarctous habit often takes place, and sometimes ascites. These two last symptoms would seem to arise from a universal irritable debility.

The second, or common symptoms with other diseases, of those parts are difficulty of breathing, and of expanding the chest: great lowness and oppression; a feeling of suffocation or of dissolution.

The third, or sympathetic, symptoms are often great irregularity of the pulse, palpitations, fluttering.

When the symptoms are known to arise from the presence of a fluid in the chest, it should in general be let out by an operation called paracentesis thoracis, which is only making an opening into the thorax and allowing the fluid to flow out. The wound should be made to unite by the first intention. The fluid to be evacuated may be of various kinds: as blood from a ruptured vessel, or wound made with a ball or cutting instrument; or extravasated serum, as in hydrops pectoris; or pus, the consequence of inflammation.

Whatever the fluid is which is to be discharged, I have always found suppuration take place in all the operations I have seen performed; for when the discharge was nothing at first but serum, (as water in ascites,) yet afterwards it gradually changed into pus. This arose simply from keeping the external wound open. I am inclined to think that nothing could have saved these patients but resolution of the inflammation, and the parts falling back into their natural disposition. This, as I have mentioned, sometimes takes place in common abscesses, especially those of a scrofulous kind, and in the present cases it might the more readily take place, as there is here no change of structure or granulation of the whole surface of the pleura or lungs. However, wounds have been made into the cavity of the thorax, suppuration has taken place, and yet the patient has got well; but how this has been brought about I cannot tell. General Murray, to whom I have often expressed a wish to peep into his chest, has been twice wounded in this way. I tried the experiment by shooting a dog; but both Nature and the dog cheated me, for I intended to keep open the wound until the whole surface of the pleura had taken on suppuration, when I meant to let Nature have her way and cure the dog as she pleased, and then I intended to kill the dog and see what she had done. But the dog would always lie on the wounded side; and when, after death, I examined it, I found the lungs had adhered to the wound and prevented the inflammation spreading over the surface of the lungs. The wound after evacuation, therefore, should be united as quickly as possible,

to prevent the whole pleura from suppurating, which would destroy the patient in nineteen cases out of twenty.

Inflammation of the Pericardium.—The cavity of the pericardium is not so apt to produce universal adhesions as that of many other cavities. When it goes no further than adhesion the patient lives, although this produces many disagreeable symptoms, as palpitation of the heart, irregularity of the pulse, great oppression and faintings, which in general produce a bad state of health, a great debility, and symptoms which have gone by the name of angina pectoris. If the inflammation approaches to suppuration, it will certainly kill.

Emphysema.—It will not be improper here to say something of the treatment of patients affected with emphysema arising from a wound in the lungs by a fractured rib, for if any surgical operation is necessary, great caution is required not to make the wound communicate immediately with the cavity of the thorax, in order to avoid the mischief above described.

If the lungs are wounded by a fractured rib, we know that the pleura must be wounded, and that there must be a communication between the cells of the lungs and the cavity of the thorax. There is also a communication between this cavity and the common cellular membrane of the body by the wound in the pleura. The air escapes from the lungs into the cavity of the thorax, and in the act of respiration is squeezed into the cellular membrane of the body. The internal wound does not inflame so quickly as the external, because the internal depends on extravasated blood for the renewal or adhesion of parts; and the wound of the lungs, from its being in contact with the air, may be considered as an external wound, while that of the pleura is an internal one: the former will therefore probably heal sooner than the latter, whereby the air will be confined in the cavity.

The operation for the relief of this disease is making a perforation into the cavity for the relief of this disease, which operation should be religiously avoided, because it will produce the suppurative inflammation all over the internal cavities, and most probably make the wound in the lungs ulcerate. If an external opening is necessary, it should be made at some distance from the fractured rib, and never on the rib itself. If this is not attended to, it will make what was at first a simple a compound fracture, which

probably would produce the same effect as an incision at once into the cavity of the thorax; or if it did not produce this evil, would produce adhesive inflammation quickly about the fractured rib, which would prevent any future escape of air from the pleura, which should be allowed; and for the same reason the patient should not have a roller bandage put on, as this would cause an impediment to the respiration by the other lung, and, by preventing the escape of the air, cause the whole contents of the thorax to be pressed to the other side.

Peritoneal Inflammation.—This inflammation is attended with great pain, not of the colicky kind, but a violent soreness or tenderness on external pressure. The fever, or sympathy of the constitution, arises much higher than if it arose from the inflammation of a common part, and runs through all its stages much sooner than another part. When the immediate cause of these constitutional symptoms is not known, and the effects are violent, it has been called a fever, and the chief attention has been directed to checking this fever; but the symptoms are merely the consequence of the inflammation in a part by which the constitution is easily affected; so that if it were possible to restore the healing disposition to the cavity of the abdomen, the other symptoms would vanish and health be restored. A diarrhoea sometimes comes on, but at other times there is costiveness, both of which I am inclined to think may be considered as sympathetic affections.

It is perhaps almost impossible at first to say what the inflammation is, whether the true inflammation or the erysipelatous because we are only guided by the constitutional symptoms, not by the appearances. A person in seemingly tolerable health attacked at once with so violent a local disease will be at first roused, which will make it appear a truly inflammatory complaint; but if it is erysipelatous he soon sinks. Still at first the apparent indication would be bleeding, and that largely; but if it is of the erysipelatous kind we may be led by those symptoms beyond the quantity suitable to the constitution. Yet I do not know what I can do better: I should be inclined to reduce the patient to the lowest pitch rather than allow suppuration to take place, for that would certainly kill. In whatever light we consider an inflammation of the peritoneum that is capable of producing suppuration, it is one of the most dangerous diseases we can meet with. How

far, in such cases, it might appear desirable to make an opening into the abdomen, and throw in warm water repeatedly to wash away the matter, I will not undertake at present to determine.

Peritoneal inflammation after lying-in.—Inflammation often attacks some part or the whole of the peritoneum in women some days after childbirth, and hence has been called puerperal fever, from supposing it to be a fever peculiar to that state, and the inflammation of the peritoneum a consequence of this fever, whereas the fever is only a sympathetic symptom of the inflammation; but as this inflammation is connected with vital parts, the sympathetic fever is so much the more violent and dangerous. I believe I am the first who formed this idea of this disease.

Why such a disease should occur after so natural an operation is not easily explained. It does not arise from an inflammation of the substance of the uterus first taking place, as we might at first naturally expect; for if the uterus did inflame in consequence of delivery, there would be no more necessity for the peritoneum of that viscus to inflame than for the peritoneum of the intestine to inflame when the intestine is itself inflamed, which it seldom does; and if the peritoneum of the uterus inflamed in consequence of inflammation of the uterus, that is not a necessary cause why the whole peritoneum should inflame, excepting the inflammation was carried so far as to produce suppuration on that part of the peritoneum. But the substance of the uterus generally appears as sound as in those who have no such disease; however, although the uterus is to appearance sound, yet it may be in such a state as to give the same stimulus of imperfection as if it were entirely removed or not existing. To illustrate this we may bring forward the circumstance of two cocks' combs that were frozen and thrown off as dead sloughs, for I suppose from analogy that the frozen parts were still alive, and if so we may see that a living part may be so circumstanced as to give the stimulus of death to the parts with which it is connected. That the inflammation of the peritoneum arises from the stimulus of imperfection is also evident, because if a man is wounded in the belly with a sword which has also wounded one of the intestines, if the wound in the abdomen is closed, and unites by the first intention, the wound in the intestine will unite with some part

with which it comes in contact, either by extravasated blood or the adhesive inflammation, and no further trouble will ensue, because the stimulus of imperfection has not been given. But if a man is wounded in the belly, and there is no wound of the viscera, yet if the wound is kept from healing by the first intention, the whole peritoneum becomes inflamed immediately, not from the spreading of inflammation by the continuity of surface, but the consciousness of imperfection in the membrane itself, by which the whole is brought into the same action. It is probable that the uterus suddenly contracting, the neighbouring parts, becoming sensible, as it were, of the loss of a part they have been accustomed to, inflame. Sometimes adhesion will take place, and a circumscribed abscess will be formed in the lateral and lower part of the belly, and probably the inflammation was chiefly in the round or broad ligament: first there is hardness and pain, then prominence and fluctuation, when it may be safely opened.

LECTURES ON OBSTETRICY, AND DISEASES OF WOMEN AND CHILDREN.

Now in course of delivery at the
NORTH LONDON SCHOOL OF
MEDICINE.

CHARLOTTE STREET, BLOOMSBURY SQUARE.

By MICHAEL RYAN, M.D., &c. &c.

Human Oology—Physiology of the Fœtus:—Development—Nutrition and Circulation.

I now proceed to illustrate human oology from the engravings of Maygrier, Lizars, Velpeau, Breschet, Granville, Coste, Sprar, and those published by myself in the London Medical and Surgical Journal, 1836, from the twelfth day of embryonic existence to the commencement and completion of the development of the placenta; and I shall next shew you engravings representing the circulation of the human fœtus, and that of the four classes of vertebral animals, splendidly executed by M. Martin St. Ange. I have also before me a number of preparations chiefly collected from the inferior classes of the animal kingdom, illustrative of the oology of the

hen's egg, of the mouse, rat, cat, rabbit, bitch, sheep, cow, mare, and lastly, of our own species; and all present the closest analogy, if not almost a perfect identity in the development of comparative and human oology. (*Plates and preparations exhibited.*) All the investigations of physiologists, naturalists and comparative anatomists on the reproduction of organized beings, or the vegetable and animal kingdoms, have been undertaken with a view of elucidating the mysterious functions of human generation and oology. The former we have already considered, and the latter now claims our serious attention and study.

The term *embryo* is applied to the germ during the first three months of utero-gestation, or until its different parts are distinct from each other: it is called *fœtus* during the remainder of its sojourn in the uterus, and *infant* after birth, and until the seventh year when childhood commences. The application of the word child to the fœtus in utero is physiologically incorrect.

Much discrepancy of opinion exists among physiologists as to the period after conception, in which the ovule or embryo is visible. Hippocrates said, the ovum was visible on the sixth day; Mauriceau on the seventh day; Meckel, on the fifth; Pockels, Sir E. Home, and Bauer, on the eighth; and Haller, from the fifteenth to the twenty-first. Velpau dissents from all these writers, and denies that the present state of science is such, as to enable us to fix on the exact moment of human conception, or to prove that the embryo will descend into the uterus of the same animals at the same period after different conceptions. The exact moment at which the human germ is impregnated, and at which it appears in the uterus after its vivification, is as yet involved in utter darkness; and the researches of two thousand years have not yet penetrated the mystery which surrounds it. The transmission of life by parents is as incomprehensible to physiologists, as its nature and cessation. Delicacy forbids a rigid inquiry on the subject, and the opportunities of examining the ovaries immediately after conception are so rare, that there never was, nor perhaps will be, a physiologist who could avail himself of them. Hence the almost insurmountable barrier to the investigation of human oology from the instant of conception, and the necessity of referring to comparative anatomy for the elucidation of the subject. This science shews the closest ana-

logy between, indeed we might say, the identity of ovology in all viviparous and oviparous animals as was already stated.

The ancients applied the term *yovv* semen, to the product of conception during the first six days. The nine following days they called it *κυνμα*, *fœtus*, then embryo during twelve days, and they employed the word *παιδιον* to designate the *fœtus* to the forty-fifth day, and these four epochs were characterized in two verses:—

Sex in lacte dies, ter sunt in sanguine
terni,
Bis seni carnem, ter seni membra figu-
rant.

Hippocrates De Nat. Pueri

Pockels asserts that he examined four ova between the eighth and sixteenth day; and Beclard says, the ovum is visible when it measures only three lines in diameter.

According to Meckel, the ovum can be distinctly seen on the fifteenth day after conception; it is six or eight lines in diameter, is pyriform, elongated, curved, large, and round at the extremity, which appears to be the head, fixed to the membranes by the opposite extremity which is small: it offers a homogenous appearance, and with difficulty a white fibre is seen, which is said to be the spinal marrow. (Velpeau.)

Sir E. Home describes it at the eighth day of existence, as a vesicular, glutinous, pellucid oval body, attached to the fundus uteri; that it is composed of two oval bodies joined by neck, the one the head, the other the trunk. (Phil. Trans. 1817 Med. Chir. Trans vol. ii.) M. Velpeau remarks that there is nothing to prove, that the corpuscle described by Home was an ovum more than anything else. (Traite des Accouch. 1835.)

The experiments of Grnaf, Nuck, Davenport, Haighton, and Cruikshank, demonstrate, that the impregnated ovum of inferior animals does not descend into the uterus for some days after conception.

M. Velpeau describes an ovum of twelve days old. A midwife was on the last day of menstruation, when her husband returned from Rouen, where he had passed two months. Conjugal intimacy occurred next morning, and on the thirteenth day, this woman who was the mother of six children, aborted. The ovule which she sent me could not be more or less than twelve days old. The embryo was very distinct, as well as the vesicles and all the membranes.

According to the observations of this author, 1, the spinal cord is the fundamental part of the body; 2, that this axis appears before all other organs; 3, that it so early exists for a long time; 4, that its form does not differ very essentially from what it is at other periods of intra-uterine life; 5, that until the twentieth or some days more, the embryo is not straight, nor swelled in the middle; 6, that the head and neck form less than half its length; 7, that its curvature approaches nearer to a circle, the less it is developed; 8, that the dispositions of its internal circumference differ but slightly from those at a later period, whilst its contour or cavity deserves the most serious attention.

M. Velpeau also informs us, that before the end of the third week the embryo is elongated, and he believes that it first consists of the cerebro-spinal system; it appears to him, from numerous recent observations, that the vertebral column is the fundamental part of the body, and that all other parts proceed from this as branches do from a tree. He dissents from Tiedemann, Meckel, Serres, and Geoffroy-Saint-Hilaire, who think the organic evolution is from the sides towards the median line, which is the more generally received opinion.

It is now held that each organ is double at first, but as development advances the two lateral parts are joined together. It is said by the last distinguished author that if any impediment is given to the growth of organs, as when an artery does not supply proper materials to an organ, such organ will be imperfectly developed, and thus monstrosity produced. He considers the influence of the mother's mind and corporeal exertions on the *fœtus*, as sufficient causes of deformity in the early stage of foetal development. This theory, though ingenious, is by no means satisfactorily proved, nor is it generally received at present.

Functions of the Embryo and Fœtus.

The sensibility of the *fœtus* in utero must be admitted, though the latter is not exposed to external objects. Its motions are often violent and troublesome towards the completion of the term of gestation, and are purely instinctive. Its calorificity is less than that of the adult. (Edwards.)

Nutrition.—Of all the questions of physiology this has been perhaps the most disputed. Some have placed the source of nutrition, in the water of the amnios, which surrounds the embryo, more

than in the placenta; others in the vesicula umbilicalis and allantoides; more in the gelatin of the cori, and some in the decidua or epithorion.

Harvey and Diemerbroeck (*Anat. corp. Human.*) considered the water of the amnios highly nutritive and lacetous; and with Rudbeck, Haller, Darwin, La Courrée (*De Nutrit. Fœt. in utero—1655*), maintained it passed by the mouth to the stomach; while Alcmœon, Boheraave, Buffon, Levret, and Van-den-Bosh alleged it was absorbed by the skin. These opinions are, however, refuted by the fact, that in cases of imperforation of the œsophagus, stomach, and intestines, and in acephalous monsters, and also when the infant is born with all the outlets impervious, it is fully developed. (Dubois, *Desgrangages*, Burton's *Mid.* p. p. 96—116, Velpeau p. 195.) Bartholin and Morlanne have known the fœtus to survive in the uterus after the escape of the waters; while Velpeau had seen a case at the Hotel Dieu, in April, 1834, in which the fœtus lived more than a month in the womb under similar circumstances (*Op. Cit.*), and Burton saw an infant born, Jan. 12, 1750, without any waters. (*Op. Cit.* p. 103.) I have often observed infants fully developed in cases in which there was very little amniotic fluid, perhaps not an ounce, and labours of this kind are termed dry by women and midwives. It would be uninteresting to notice all the physiological reveries upon this and other parts of my subject; but I cannot help inserting a few more upon this point. Lobstein held the amniotic fluid was partly passed by the genitals; Oslander, Oken, and Muller, that it was absorbed and modified by the mammæ then conveyed to the thymus gland, and finally to the thoracic duct; while Schurigius, David, Rœderer, Scheele, Winslow, Heroldt, Declard, and Geoffroy-Saint-Hilaire, believe it to enter the trachia and bronchi, and to be there elaborated for the purposes of nutrition. The general and received opinion of almost all physiologists is, that at first, alimentation is in the ovum itself, as in the hen's egg, and after a certain time, that the placenta is the source of nutrition to the fœtus. It has been said that the placenta is a respiratory organ to the fœtus, supplies it with oxygen, and receives the blood of the mother. (*Joerg Journal des Progrès des Sciences*, t. ix.)

During the early period of intra-uterine life, the embryo is nourished by the umbilical vesicle, which is continuous with

the intestinal tube, absorbs its own fluid, which is carried by the omphalo-mesenteric vein to the heart of the embryo. The analogy of these vessels to those of the yolk of the galinaceous egg renders this opinion extremely probable. The absence of the meconium in acephalous cases (Elben), which, according to others, was the residuum of digestion, was considered an argument in favour of the passage of the amniotic fluid into the stomach. Meconium is formed by the bile, and is only absent when the liver is wanting. (Tiedemann.) The human female nourishes her offspring with her blood, through the medium of placenta; while the fœtus possesses an organ for the further depuration of the blood, and the liver is that organ. (Bichat and others.) Tiedemann and Gmeiin considered it the same in the adult. The researches of Dr. Stoker of Dublin, in his *Pathology* upon this point, are exceedingly interesting and satisfactory. Of this, however, I shall speak more fully hereafter, when I have described the function of the placenta.

The circulation of the placenta is also differently explained. Some say, the fœtal arteries deposit the blood in the cells of the placenta, whence it is absorbed by the maternal veins, and carried to the maternal lungs to be vivified, and afterwards brought by the arteries to the placenta. Others maintain, that a portion of the blood deposited by the umbilical arteries, is absorbed by the veins of that name, and returns to the fœtus. M. Velpeau raises a formidable objection to the first opinion. He says if the blood of the umbilical arteries is deposited in the placental sinuses, it must evidently mix with that of the uterine arteries, which is effused in the same place; it is therefore necessary to suppose that the absorbent mouths of the umbilical vein possess the faculty of choosing the arterial blood from this mixture, as the uterine veins do not take up but the venous blood. On the other hand, an injection will pass with the greatest facility from the arteries into the veins of the placenta, without effusing itself upon the uterine surface of that body, and therefore the blood of the fœtus is not taken up by the uterus. It appears from the results of all anatomical injections, whether made from the maternal or fœtal vessels, and even from both simultaneously, that there are certain portions of the placenta uninjected, and therefore there is not a direct communication between the circulation

of the human female and the fœtus in the womb. Moreover, it is well known to every practical obstetrician that the pulse of a woman during the early stage of parturition, and in some cases during the whole of this process will be natural, varying from 70 to 78, while that of the fontanelle of the fœtus, or of the umbilical cord will be nearly double the number, and therefore the circulation of the mother and of the fœtus is not continuous or direct, or to use a more scientific term is not synchronous. Any obstetrician can determine this fact. It is a wise ordination of nature that there should not be a direct circulation between the womb and the ovule or future being, when imperceptible to the human eye, and when the mental emotions or ordinary exertions of the mother would accelerate her circulation so much as to derange or destroy the offspring in the first moments, hours, or days of its existence. You should remember the remarks made upon the placenta in a former lecture, in which you will find solid objections against the former reasoning and conclusions.

M. Velpeau remarks, and I fully agree with him, that experiments with injections on the dead body, do not prove the actual state of living parts. Thus, when a very fine injection is thrown from the arteries of the pelvis of a dead body, the injecting matter appears on the mucous surface of the intestines; introduced by the vena portæ, it not only returns by the hepatic arteries and veins, but by the excretory ducts of the bile. If forced through the renal artery, it not only passes into the emulgent vein, but also into the pelvis, and then into the urethra. Notwithstanding these facts, we cannot conclude that during life the blood continually transudes into the alimentary canal, or that it passes from the vessels of the liver into the hepatic ducts, or from the kidneys into the urethra. Professor Burns, who admits the vascular continuity between the placenta and the womb, has not prevented Dr. Blundell or Dr. Horner from denying a direct circulation between the mother and fœtus, nor M. Baer, from establishing the principle that in mammiferæ, the vessels of the mother are not continuous with those of the embryo. Here is a preparation shewing the placenta partly separated from the uterus, but the points of union are so intimate that it is impossible to distinguish the line of demarcation. The uterine sinuses are distinct over the surface from which the placenta

is separated. In cases in which the placenta is expelled entire, we often find that on looking at its uterine surface, a fine membrane covers it, and this will be very evident by placing the placenta under water, and blowing on its surface with a blow-pipe. These facts prove that the mode of transmission of blood from the uterus to the placenta is not direct, nor even clearly understood. Some are of opinion that the blood enters by simple porosities, or by a kind of imbibition, or that it is absorbed by the radicles of the umbilical vein. (Blumenbach Inst. Physiol.) This conclusion is liable to objections, as the experiments of Autenreith demonstrate, that the blood of the fœtus has not the same appearance as that of the mother. It is more rosaceous, then becomes redder, and blacker, and is of the same colour in the veins and arteries. Tiedemann and others have proved that it contains a much greater proportion of serum than in the adult, which is less coagulable. Everything proves that the composition of the fœtal blood is different from that of the adult. Lauth, Junior, has arrived at the following conclusions:—1, that there are between the decidua and the terminations of the vessels of the placenta, vascular filaments, which he thinks are lymphatics; 2, that these vessels are the only ones which can immediately communicate with the uterine ramifications; 3, that they are of two kinds, some taking up materials which have undergone an elaboration, and have thus become fit to nourish the fœtus; the others which proceed from the placenta to the uterus, removing from the blood of the fœtus such principles as can no longer be of any use to it.

M. Martin St. Ange, whose extensive researches in comparative anatomy on the circulation of the blood in the human fœtus, and in four classes of vertebral animals, received the prizes of the Académie des Sciences in 1831-32, is of opinion, "that the circulation between the uterus and placenta is performed by endosmos or imbibition, viz: that the porous placental ramifications inspire the fluids deposited in the cells of the uterus, which fluids, in passing through the placenta, an organ of hæmatosis, acquire qualities for the nutrition of the organs of the fœtus, and consequently I am induced to deny the immediate communication between the vessels of the uterus and those of the placenta." (Translation by T. W. Jones, M. D.) M. Velpeau arrives at the same conclusion which

most generally received. According to this inextinguishable author, the fœtus derives nutrition from the different sources. It is like a vegetable which imbibes from the circumambient humidities. The envelope on its periphery, is a true cellular sponge, which absorbs in the tube or womb, those nutritive principles which develop the vesicles, so that the embryo nourishes itself like the chick in the egg, or like a plant from the principles in its cotyledons. The fluid contained in the umbilical vesicle gradually becomes thicker. The emulsive substance of the allantois is gradually absorbed. The vessels of the cord form about the end of the second month, and the placenta becomes developed for the evolution of the fœtus. This spongy mass imbibes nutritive principles from the womb, which are converted into a fluid more or less like blood, and this is absorbed by the roots of the umbilical vein. The placenta extracts materials from the womb which form the fluids of the fœtus, as the liver, kidneys, and seminal gland extract bile, urine and spermatic fluid from their vessels, and as trees and plants extract from the soil, the principles of the numerous substances which compose them.

M. Velpeau is inclined to suppose that the arterial blood of the fœtus undergoes its changes by a molecular action in the placenta, which though inexplicable may be still correct. He thinks it may be compared to the capillary system after birth; to what takes place in secretory organs, and in the lung itself. The fluids of the ovum are in immediate contact with those of the woman; but a change may take place analogous to that in the lungs between the atmospheric air and the venous blood.

OBSERVATIONS ON DR. ABRAHAM COLLES'S WORK "ON THE VENEREAL DISEASE, AND ON THE USE OF MERCURY."

By RICHARD CARMICHAEL, M.R.I.A.,

Honorary member of the Royal Academy, of Medicine of France, &c., &c., and consulting surgeon of the Richmond Surgical Hospital, &c. &c.

If the "Practical observations on the Venereal disease, and the use of mercury," lately published, had come from the pen of a person less influential than that of

my friend, Doctor A. Colles, I should have allowed them to pass without any remarks; but his doctrines are so much in opposition to those which I espouse, that although he has not honoured me so far as to notice any of my published opinions on the subject, yet I feel that his observations have been in many places so pointedly opposed to them, that I should be deficient, not only in that just portion of amour propre, which every man ought to possess, but in my duty towards the public, were I to allow his to pass unheeded, and to permit others to suppose that I had changed my mind, or acquiesced in doctrines which have not even the allurements of novelty to recommend them.

I trust that the observations I am about to make will be found devoid of all the acrimony which a desire to achieve a triumph is so likely to induce, but that they will be made in that cool spirit of philosophical investigation, where the object alone is to ascertain a truth of considerable practical importance; and I beg particularly of the author, not to consider them in the light of an attack upon his opinions, but in that of a defence of my own.

The first passage, in the import of which I cannot agree, occurs in the first chapter, which treats on the "Natural History of the Venereal Disease." In it we find John Hunter eulogized in the terms he so amply deserves, as having ascertained many important facts relative to the natural history of the venereal disease not previously known. But then, as the author observes, he left much for his successors to achieve, and exclaims, "does it not appear strange, that subsequent writers have not made some efforts to supply these deficiencies." He then proceeds to account for the little progress that has been made in this inquiry, as arising from the universal exhibition of mercury, which interferes with the natural progress of venereal complaints; for every practitioner is so impressed, he observes, with the sense of duty to do all in his power for the relief of his patient, that he cannot, consistently with that feeling, withhold such medicine, or refrain from such means as may be best adapted to the case. Now this conscientious feeling has, no doubt, prevented our author from taking any steps towards ascertaining the natural progress of venereal complaints, when not interfered with; but as a feeling, perhaps as strong, has prevented others from having recourse to mercury

in many forms of the venereal disease, so we must look to the observations of the latter, or to those who abstain altogether from the use of mercury, for information on the point in question. And I would here beg leave to ask, has no useful additional information in the natural history of those diseases been obtained since Hunter's time, by those practitioners who refrain from the use of mercury? Is not the classification alone of the various forms of venereal disease, grounded on the nature of the eruption, a great and important step towards a just knowledge of their natural history? In Hunter's work, we find these eruptions all jumbled together under the general term of copper-coloured blotches, which is as little significant of their character as the term *dartre*, so generally applied by our neighbours to every variety of cutaneous disease. In Hunter on the venereal, we find no mention of papulæ, pustules, tubercles, rupia, psoriasis, or lepra; all those forms of eruption, indicative of different forms of the disease, and often requiring different modes of treatment, are all classed under the one general and undistinguishable term of copper-colored scaly blotches. Now Hunter is not to be accused of want of discrimination for this omission; because, at the time in which he lived, there was but little precise knowledge, and no accuracy of nomenclature, respecting cutaneous eruptions. But when the profession became enlightened on this subject, chiefly by the labours of Dr. Willan, the information thus obtained was applied with manifest utility towards a just classification of the different forms of venereal disease.

That a classification, grounded on the character of the eruption, is not only in accordance with nature but the most practically useful one which could be devised, is apparent from the following circumstances:—

1st, When a practitioner meets with a patient affected with a papular eruption, either in its early stage, when it presents itself in the form of pimples with accumulated heads, containing matter; or in its advanced stage, when the spots have desquamated, and present one of the appearances which Hunter calls copper-coloured blotches, he may be certain that he has only a disease of easy management to contend with, and that under suitable treatment, he may assure his patient with confidence of a certain and speedy recovery.

2dly. If we meet with a pustular eruption which terminates in superficial ulcers and not in desquamation, we may be certain that we have a much more formidable disease to manage.

3rdly. If there is offered to our consideration a case of pustular eruption, mixed with tubercles, which terminate in deep ulcers which spread with a phagedænic margin, and form those crusts termed rupia, we may be certain that we have the most unmanageable and destructive form of venereal disease to contend with. For under the most judicious mode of treatment, we too often fail in curing the malady, which annually destroys numbers, after enduring a lingering and loathsome catalogue of disgusting ailments. For it is in this form of the disease that we meet with extensive ulceration engaging the uvula, tonsils, and back of the pharynx where it lies upon the bodies of the vertebrae, ulceration of the nares, destruction of the bones of the nose, and also ulceration of the larynx, the usual precursor of laryngeal phthisis.

4thly. The scaly eruption comprising psoriasis and lepra, is a form of the disease which is in general manageable; for unlike the pustular and phagedænic forms of venereal, it yields with certainty and quickness to the influence of mercury. It may, however, be accompanied by deep ulceration of the tonsils, and very obstinate nodes; but whether ulceration of the larynx and of the nares attends it, is more than I can say, never having witnessed it. This form of the disease: which, from the term "copper-coloured scaly blotches," was most frequently met with in Hunter's time, is now comparatively seldom to be seen. It is often confounded with other forms of venereal eruption, because papulæ and pustules, in their desquamating declining stage, when the virulence of the disease is considerably exhausted assume a scaly, copper-coloured appearance; and even rupia evinces the same tendency, when the disease is on the wane. But I have never seen an instance (although Mr. Colles adverts to several) of "a papular or scaly eruption degenerating into rupia."

The tendency of all venereal eruptions is, as the disease is becoming exhausted, and is gradually yielding to the powers of the constitution, to become scaly. And when in this state, no matter in what form the eruption commenced, I never saw mercury do harm, but always observed the most decided and quick amendment

to follow its adoption,—a general fact which must be a great comfort to those who are either too indolent, or too sceptical, to think it of any consequence to pay attention to the precise character of the eruption.

From the facts above stated, I have a right to deny the justice of the sarcasm of our author, that all who treated of venereal disease since Hunter's time, have added no additional information relative to its natural history. It is a most important practical point, and, coupled with the natural history of venereal complaints, to be able by an accurate diagnosis, grounded on the character of the eruption, to prognosticate the probable event; to be able to state whether the patient will recover in a short time; or whether he may linger for years, and finally sink under the disease; and also from the nature of the eruption to be able to decide on the most appropriate mode of treatment.

I have not in these observations on the natural history of venereal diseases, insisted upon the much disputed point of a particular form of primary ulcer being followed by a particular or corresponding form of eruption. And I have refrained from doing so, because, though my opinions remain unshaken on this head, and are supported by a host of observations, yet as it is still *sub judice*, I am unwilling to assume it as a fact established in the natural history of venereal diseases.

But notwithstanding this concession, and that Dr Colles declares, "that after a long and careful observation, he had not been able to trace particular forms of eruption to particular forms of primary ulcers," I must also declare, that nothing is more decidedly connected, in my mind, than the links which exist between gonorrhœa virulenta, a patchy excoriation of the glands and prepuce, and the simple fungous-looking ulcer without induration, with the secondary symptoms—papular eruption and all its concomitants, as laid down in my work on venereal diseases; and again, the connection which exists between the primary phagedænic or sloughing ulcer, with venereal rupia and all its dreaded companions, is equally evident.

That the papular and phagedænic forms of venereal disease, as described in my work, combine in each a concatenation of symptoms both primary and secondary, totally dissimilar in appearance in character, in duration, and in susceptibility of being acted upon by medicine, is ob-

vious to any man even of a limited experience, and must be acknowledged as such by every candid mind solicitous after truth,

Dr. Colles's reasons for dissenting from this doctrine, I shall give in his own words:—"Firstly," he says. "I have not unfrequently observed varieties of eruption exist together in the same individual; for example, I have seen small venereal lichen on the face, while a large form of papular eruption occupied the trunk and the extremities; sometimes also, I have found spots of a pustular character scattered through a general crop of the papular eruptions. Secondly, I have noticed, as a very frequent occurrence, that when the first eruption has been removed, either by the use of mercury, or by other means, that the second crop has proved of a different kind; thus when the first eruption was of that small pimply kind which resembles measles, it has been succeeded by a papular eruption, and this again by a pustular crop. And thirdly, by injudicious treatment; for example, by the excessive use of mercury in bad habits, any one other form of eruption may be made to degenerate into one which is most obstinate and severe, namely, that of rupia."

To these observations I reply, that small papulæ on the face and large ones on the trunk, in the same individual, do not evince any difference in the nature of the eruption on these two parts, but only a difference in its intensity. The same objection might be urged against the identity of the itch, small-pox, or any other eruption, because it happens to be more severe in any one part of the body than on another. Some explanation is perhaps required with respect to the nomenclature of venereal eruptions. Papulæ have constantly accumulated heads containing matter, which some might call pustules: but the true diagnostic distinction between venereal papulæ and pustules is, that the former end in desquamation, the latter in superficial ulcers.

If a case presented itself in which pustules that terminated in ulcers were mixed with papulæ, I would say the patient was afflicted with the pustular eruption; always designating it by the term which signified the most severe and dangerous spots which appear on the patient. For in the pustular eruption we often meet with papulæ, and in the phagedænic eruption we often see the rupia, which marks the disease, intermixed with

both papulæ and pustules; but the first, in my judgment, indicates in each form, the true nature of the eruption.

In the same manner, in small-pox, we often observe papulæ intermixed with the pustules, which latter constitute the characteristic signs of the disease, for no person thinks of calling small-pox a papular, but a pustular, eruption.

With respect to the second objection, I may briefly observe, that the *tendency* of all venereal eruptions in re-appearing, either a second, third, or fourth time, is to assume the scaly form. But although I have been many years attending to the natural history and the progress of this class of diseases, I cannot call to my recollection a single instance, even under "injudicious treatment, and the excessive use of mercury," of a papular eruption being succeeded by a pustular crop, or this last by rupia.

The successive crops of both the papular and pustular eruptions have, as I have just said, an obvious tendency to assume the scaly character, in which they appear like copper-coloured blotches, and even rupia itself has the same tendency; but with this modification, that the spots exhibit the appearance of raised rounded tubercles, of a scaly dark red or copper colour, of which we possess many excellent delineations amongst the admirable collection of drawings belonging to the Richmond Surgical Hospital.

At page 76, I find the following observation—"We shall now consider the proper treatment for a case of true venereal ulcer, the Hunterian chancre:—The local treatment should, in my opinion, be confined to the most bland and mild applications, such as cannot in any manner alter the features of the ulcer, for I am certain that many useful indications which may serve to guide us in the administration of mercury, are to be derived from observing the changes which these ulcers undergo through the agency of that medicine; these changes, and their corresponding indications, I shall hereafter advert to. I am further confirmed in this opinion from having observed that little or no benefit is derived from a contrary practice; thus I have known a chancre completely cut out on the first or second day after its appearance, yet the occurrence of secondary symptoms was not prevented."

I cannot agree with my esteemed contemporary in this reasoning or advice; for although he may have seen a chancre extirpated on the first or second day after

its appearance, and yet secondary symptoms not prevented, yet I have seen, on the contrary, so many hundred instances of primary venereal ulcers treated by the free application of lunar caustic, with the view of destroying a surface secreting a morbid poison, which were not followed by constitutional symptoms, that I cannot but look upon this general exemption, by the mode of treatment mentioned, as a proof that I acted on a right principle. But in order to cut off infection, the sooner it is attempted the better. We should also recollect, that during the first two or three days, and whilst the ulcer is still excavated, and secreting a thin, ichorous discharge, it is in its most virulent state, and therefore, most likely to infect the constitution. For we know, from the practice of inoculating vaccine and variolous matter, that the earlier the poison is taken, and before the matter becomes purulent, the more certain we are of imparting the poison; and therefore, it follows that the sooner we prevent an ulcer from secreting a highly infectious matter, the more likely are we to prevent the contamination of the system; and this is of more consequence than withholding our hand with the view of receiving "useful indications, which may serve to guide us in the administration of mercury."

Concerning the prevalent exhibition of mercury, Doctor Colles observes: "In my opinion, nothing can more clearly establish the claims of mercury to be considered as a *specific* for this disease, than the frequent instances of cures made by it in the hands of those who must employ it at random; and very frequently on patients as careless and incautious as the prescriber is ignorant and pretending. It is wonderful that an engine so very powerful could have been so long wielded by the hands of the inexperienced, the injudicious, the uneducated and unprincipled, and yet should not have committed more havoc than it has done." But surely Dr. Colles does not mean to assert that mercury has not committed most dreadful havoc in the hands he alludes to. There is scarcely a day that we do not witness instances either in public, or in private practice, of the injurious consequences arising from the abuse of this most powerful medicine; but I will not limit this imputation to the "injudicious, the uneducated, and the unprincipled," for I assert, that as long as mercury is blindly administered even by the judicious, the educated, and the

principled, under the deceitful and empirical notion that it is a "specific" for the cure of all venereal complaints, and not given as a medicine of unequivocal and ascertained powers, on sound pathological principles, we are not likely to improve medicine as a science, enhance our own characters, or what is of still more consequence, benefit our patients. Are we always to be swamped by the obsolete axiom, that mercury is the only and appropriate cure for every form of venereal disease? Mr. Pearson formerly escaped from the many obstacles he met with in practice that militated against this notion, by christening those refractory symptoms that did not yield to mercury, syphiloidal, or sequelæ of syphilis; Mr. Mathias by calling them mercurial; Mr. Abernethy, pseudo-syphilitic. And now Doctor Colles tells us, that when mercury fails it is because it has been "injudiciously employed;" either in too small or too large quantities; for too short or too long a time; or that the patient has not been duly prepared for its use; or that he has taken it in a negligent manner, and not under a sufficiently strict regimen. It seems never to enter into his mind that when it fails, it may be *because it is an inappropriate or injurious medicine* for the form of disease under which the patient labours; or that it has been administered at an unfavourable period, for instance, during the continuance of the eruptive fever.

Thus we find the following observations with respect to the treatment of primary ulcers:—"Although I have repeatedly stated, that when pyæmia has been established, the further use of mercury becomes comparatively safe, yet it may happen, either from the mercury being continued too long, or too largely, in a weakly system, or from a state of fever induced by other causes, that a chancre which has made some progress towards healing, will take an unfavourable turn, and assume a phagedænic or a sloughing disposition."

Now here the ulcer, it seems, unluckily began to assume a phagedænic or a sloughing disposition, "because the patient had taken mercury too long or too largely." But if our author had not been blinded by his prejudices, he would have said, because mercury is not an appropriate or fit remedy for any primary ulcer which shows a disposition either to the phagedænic, or the sloughing process; but this would be expecting too much, for it would lead to an admission that there

is a difference in primary ulcers indicating the necessity of different modes of treatment. Continuing his observations on these obdurate ulcers which so provokingly resist the infallible powers of mercury, we read, that "about twenty years ago, when I had charge of a large number of soldiers labouring under the venereal disease, who were received into the attic wards of Stevens's Hospital, I attempted the treatment of such cases by throwing in mercury largely and suddenly; but whether it was owing to the want of a judicious plan of using mercury, or to the bad habits of the men induced by intemperance and dissipation, I know not; but I freely admit that with many this practice was not successful. However the success of the two plans, that by mercury and that by the antiphlogistic regimen, was so evenly balanced at the time the military hospital was broken up, that I was quite undecided which to prefer. About this time I learned the use of the black wash, which has rendered such essential services in the early periods of this condition, that I have not since repeated the experiment of administering mercury through the constitution. Many of the cases treated with mercury were cured without the slightest destruction of any part, but this was purchased by the certain and severe sufferings of a violent salivation. Some escaped with the loss of part of the glans, and some few had the penis destroyed down to a level with the pubes: Possibly the mercurial treatment would have been the more frequently successful, had I more constantly used venesection and other evacuations as a process preparatory to the use of mercury. There is one condition of the sloughing penis, which I look upon with total despair of being able to afford any means of arresting its progress until it has destroyed the entire penis down to the pubes; I mean that condition in which the sloughing part is so soft, as to resemble melted tallow when beginning to form into a solid. I have never seen the progress of this arrested, even for a moment, by any local or constitutional means hitherto employed." And yet, at the very period alluded to by Doctor Colles, my work on venereal diseases was in the hands of every surgeon, and he would there have found a number of cases in which this form of ulcer was successfully treated, and the absolute necessity *emphatically* insisted on of abstaining altogether from the use of mercury. But I feel grateful for the candour of Doctor

Colles's admission; and although I widely differ from him in my opinions, yet I have the utmost reliance on the honesty of his statements. Thus we find, that even in his hands, mercury failed to benefit phagedænic ulcers; but surely he of all others should not attribute this failure either to a neglect of the preliminaries of "venesection and other evacuations;" or to an "injudicious plan or mode of using it;" or even to the "bad habits of the men." For it is well known that soldiers being well fed, clothed, and exercised, possess far superior constitutions to the generality of the inmates of hospitals. His reliance upon his favourite medicine, it seems, therefore, would have been sadly shaken, had he not at this time learned the use of black wash, the well-known combination of calomel and lime water. This fortunate discovery saved his confidence in the powers of mercury; and I believe, at the same time, not a few unworthy *members* of society from being reduced to mere stumps, if not uprooted altogether from their pelvic origins.

The good effects which so frequently arise from a spontaneous hæmorrhage in stopping the progress of a phagedænic ulcer, is next adverted to. This fact I particularly stated in my work, (at p. 166. second edition,) and therefore recommended (at p. 182,) the removal of the jagged and uneven edges of such an ulcer by the knife, which induces a bleeding that succeeds often in checking its further progress. But as our author does not condescend to notice the works of any man since Hunter's time, I have no right to complain of his disregarding this, and some other points of practice, which, I believe originated with myself.

In the next page, even after the ulcer is induced to heal, he recommends a course of mercury, with a view of protecting the constitution. Now I beg to protest against this practice, as I have frequently seen a phagedænic ulcer, after it had been healed, break out afresh, as soon as the mercury had affected the system, as if to evince how inimical is its use in this form of venereal disease.

In the same page, we find that a full course of mercury is recommended for the cure of chancrous excoriation—a primary affection, which I have mentioned as one of the causes of the papular eruption.

This recommendation, I acknowledge, astonished me; as I thought that such practice had been long since relinquished, having myself been in the habit of treat-

ing it with some mild astringent wash, and gentle aperients, during the last twenty-five years, a practice which usually removed the complaint in three or four days, the most obstinate case seldom extending to a week; and I found that constitutional symptoms as seldom occurred after this treatment, as when I had been in the habit of using mercury. On looking over the cases which Dr. Colles gives as illustrative of his mode of managing those ulcers, we find that Mr. W. used mercury in large quantities for the cure of this simple complaint, and that he even took five grains of blue pill, or three grains of calomel, three times a day, while he rubbed in mercurial ointment every night. The next case, (Mr. R.) who was affected with so mild an excoriation, that he was treated with cold water at first, and afterwards was put on a mercurial course, which, however, did not prevent the accession of constitutional symptoms. He however, it appears, got worse under the use of mercury, and it was laid aside in consequence of an excoriation occurring about the anus. The patient then got well, and had not any return of his venereal symptoms.

Now, those who have been dosed with a full course of mercury know full well that it is really no joke, and it appears to me to be rather too serious a measure to inflict for a complaint, which under the mild means pointed out, may be effectually cured in a few days; particularly as we find, by Dr. Colles's own showing, that mercury, however largely given, is not always successful in preventing the accession of constitutional symptoms.

Before I take my leave of his observations on primary ulcers, I must make some strictures on the following passage, which was obviously intended as a hit at my peccadilloes.

"I shall not attempt any farther description of the various primary venereal ulcers which are daily to be met with; much less shall I undertake any classification of their endless varieties, or of the course with which each peculiar form has been supposed to run. They will be found to differ so constantly, that very rarely shall we find any two of them to correspond accurately with each other; not merely at their commencement do they present such dissimilar characters, but in their different stages towards healing they will be also found to deviate most strangely from each other, more particularly so when they have been treated by mercury."

Now, although I perfectly agree with our author that it would be impossible to describe the endless varieties of appearances which ulcers present, because every ulcer may be modified by age, constitution, mode of living, local and constitutional treatment, (particularly by irritating applications and mercury,) yet I contend there are at least four classes of venereal primary ulcers exhibiting, *ab initio*, distinct and characteristic appearances: 1st, the mild fungous-looking ulcer, devoid of induration or phagedæna; 2nd, the ulcer with raised defined edges and smooth surface, without granulation; 3rd, the phagedænic and sloughing ulcer; and 4th, the ulcer with a hardened base, or the true syphilitic chancre of Hunter. Now these four classes of ulcers may be so altered by the causes I have mentioned as to present interminable varieties: yet when we remove the inflammation, and wait until the mercurial irritation (the most common causes of these varieties) subside, we will in almost all cases be able to recognize, in the ulcer under consideration, one or other of these four venereal classes.

We now come to the chapter which treats of venereal affections of the throat, and we find that our author attributes the great variety of ulcers in this part, to the manner in which mercury has been employed. But it is better to let him speak for himself.

"In my judgment, the great varieties in the appearances and nature of venereal sore throats, are occasioned by the manner in which mercury has been used, either for the cure of primary, or for the treatment of the secondary symptoms. No doubt when mercury is used injudiciously, and in a manner unsuited to the general health and condition of a patient, we shall find that it causes more mischief, and produces more strange changes in the venereal ulcers of the throat, if the patient be of a highly scrofulous, or of a very delicate habit, than if he be of a vigorous and healthy constitution."

Now this conclusion of our author is completely subverted by the facts which the anti-mercurial treatment has enabled us to observe; and therefore, as I before said it is only amongst the anti-mercurialists that we can learn any thing certain about the natural history of the disease. For we meet with great varieties of venereal sore throats in those cases where not a grain of mercury had been used, and varying in mildness or severity in correspondence with that of the eruption which

precedes or accompanies them. These have already been noticed in this paper, and sufficiently enlarged upon in my work on venereal diseases.

But I acknowledge that the injudicious use of mercury in cases unfitted for exhibition multiplies *ad infinitum*, not only the variety but the severity of the ulceration. And when our author recommends a course of mercury for every venereal sore throat (for he does not acknowledge distinctions) "of eight or ten weeks' duration," we may readily conclude what the result must be in the popular or phagedænic form of the disease. In the first it is not only unnecessary and injurious, but in the latter such a sweeping recommendation is absolutely destructive.

The case of James Johnson, admitted Jan. 10th, is an excellent sample of the phagedænic venereal disease: rupia, and dark-brown scabs on the forehead, eyebrows, and nose, and scattered over the entire body. "The arches of the palate, uvula, and tonsils deeply ulcerated; the entire surface of the pharynx converted into, or covered by a soft slough, like half-boiled flummary, great emaciation, and weakness." This man was repeatedly salivated, before he was admitted into Stevens's Hospital, in other institutions. He was treated with sarsaparilla, nitrous acid, and lotions of nitrate of silver. On the 26th, ten grains of mercurial ointment were ordered to be rubbed in; the other medicines to be continued.

Feb. 6th The ten grains of ointment were used only every second night, when diarrhoea set in, and the usual remedies for it were directed. We are not told whether the ointment was continued; but we find the ulcers were nearly healed; and though he swallowed well, the fluid regurgitated through his nostrils whenever he drinks; and that for ten days past has complained of pains, &c., profuse night sweats, sleeps badly, appetite declining." The author then observes, "it is unnecessary to prosecute the details farther." I believe not. And this is an instance selected as an illustration of the successful exhibition of mercury. Verily, a man must have unbounded faith in his panacea, who could produce the treatment of this case as an inducement worthy of imitation. The amendment is attributed obviously to the ten grains of mercurial ointment rubbed in every night for ten nights, and afterwards only every second night, although, at the same time, sarsaparilla, nitrous acid, and strong local remedies were employed.

The case of an apothecary, which follows, who had a similar ulcer of his throat, so deep and extensive as to cause exfoliation of the ring of the first vertebra, is as strong an illustration as I could wish of the ill effects of mercury in this form of the disease. But I shall not make farther observations upon these and many other cases equally to my purpose; but merely mention my surprise, that if a judicious use of mercury is capable of curing the phagedænic venereal disease, how it happens that we are seldom without some cases of this form of the malady in the Richmond Hospital, which had been previously many months in Stevens's Hospital, where, no doubt, mercury had been tried in the most "judicious manner." Now, I do not mention this by way of triumph, but as a fact, to show that mercury is not the appropriate remedy for this form of venereal disease; nay, that it is positively injurious and destructive.

In reply to this, I perhaps may be told that many patients are admitted into Stevens's from the Richmond Hospital—unsuccessful instances of the non-mercurial treatment. If so, I shall not feel in the slightest degree hurt by such rejoinder; only premising this, that we of the Richmond are only so far non-mercurialists, that we do not give mercury in every form, or in every stage of venereal complaints, nor in any, except those few in which its use may be resorted to with advantage, as distinctly pointed out in my work.

In chapter X, our author contends for the use of mercury in venereal hectic fever, and also in that fever which precedes and accompanies venereal eruptions. His words are: "I believe it is a pretty prevalent opinion at the present day, that when a venereal eruption is coming out, we should withhold mercury until the eruptions be completed, lest we interfere with or interrupt that process. Another reason for withholding this medicine in such cases is, that the fever which accompanies the eruption is considered as unfriendly to the anti-venereal action of mercury. Now I am convinced by repeated observations, that this rule not only may be departed from, but that it cannot be followed with advantage to the patient."

This doctrine is supported by some cases, in all of which mercury was given during the eruptive fever in minute doses; for instance, two or three grains of blue pill once or twice a day, or ten grains of ointment rubbed in every night, or only

every second night, are the doses he prescribes. When he speaks of hectic fever, I presume he alludes to that fever which is an attendant upon those constitutional symptoms which harass and wear out a frame already nearly exhausted by useless efforts to overcome the disease. Now under such circumstances, if the eruption were scaly, and thus indicating that the disease was obviously on the decline. I should not feel the slightest objection to the cautious exhibition of mercury, having, however, first tried sarsaparilla in conjunction with the hydriodate of potash; which latter medicine I consider the most powerful auxiliary for the cure of the constitutional symptoms of the phagedænic disease, that has come into notice since I last published on the venereal. But as to the propriety of exciting mercurial action, whilst an eruption is making its appearance, attended with an eruptive fever, I decidedly dissent, for the following reasons:

1st. Repeated observation has convinced me, that we lose instead of gaining time by doing so. For if the eruption is suddenly checked by the exhibition of mercury, cold, or any other cause, it will most probably return again and again in successive crops; a circumstance, of which Doctor Colles must himself have met frequent instances, and which, I recollect, we witnessed more than once together in consultation, upon cases which he considered at the time, very harassing and perplexing, as the patient had previously taken the specific in great abundance.

2ndly. In suppressing the eruption suddenly by the exhibition of mercury, the patient is much more liable to nodes and affections of the deep-seated parts, than if a contrary practice had been followed; a fact which is strongly supported by the published reports of the surgeons of the British Army, on the non-mercurial treatment; and for these reasons I dissent altogether from the four conclusions which the author lays before his reader at p. 226, in favour of the exhibition of mercury during the eruptive fever.

The cases detailed as illustrating the beneficial effects of mercury under those circumstances cannot be considered as affording any support to his position, for before the small doses given could affect the system, the eruptive fever had most probably declined. Our author himself seems, from the following passage, somewhat aware of the injurious effects of

mercury during the eruptive fever:—"These two febrile states, viz. that of hectic and exhaustion, and that of the eruptive fever, require that the mercury should be administered in a manner peculiarly suited to such conditions. Were we to use mercury with these as we do with venereal patients in general, I believe we should commit most serious mischief. In these cases we should not commence with a larger dose than ten gr. of ungt. hydr. fort. every morning, or with an equivalent of blue pill; that is about gr. iij. mane nocteque."

And in the next page we find him stating that three or four drachms of ointment are sufficient to produce the most salutary effects; for not only, he observes, "are the secondary symptoms dispersed by this small quantity, but the general health is proportionally improved, so that the patient rapidly acquires health and strength."

It is amusing to find that M. Divergie, chief surgeon of the Gros-Caillon, an advocate for the anti-mercurial treatment exhibited the same minute doses of mercury as our author, but altogether under another motive. M. Divergie gave them in finesse, to satisfy such patients as imagined they could not be cured without that remedy: not that he had himself the slightest faith that such doses would be of any advantage; but it is better to let him speak for himself.

"When at the close of 1814, I became attached as senior surgeon to the Val de Grace, I was very desirous to make trials for arriving at the same result in the cure of recent venereal symptoms, by rejecting the employment of mercurial remedies. The principles explained in the works then published on the subject, and so accordant with the facts observed by myself, were assurances that I should succeed. But more than one obstacle prevented me from making conveniently, in the treatment of the venereal cases, the trials for which I was so anxious. Here as every where else, mercury under three forms, ointment, liquor, and pills, formed in general the treatment of the primary affections. Physicians and patients showed themselves equally persuaded that this metal was the only remedy against these distempers. To propose publicly a reform would have been equivalent to provoking an anathema against me. I was therefore obliged to proceed with reserve.

"Nevertheless, from 1819 to the month of April, 1835, when I quitted the divi-

sion of the venereal cases, aided by most of the pupils, I had several opportunities of introducing freely in the treatment of this class of patients, the improvements suggested by experience and reasoning. Those who, already victims of the effects of mercury, refused to take more, when symptoms recently contracted brought them again to the hospital, fell naturally under my care. As to those who believed that mercury was the true specific, I began mercurial frictions in small doses, one drachm every two or three days, after the acute stage was over. Already sparingly nutritive regimen, local blood-lettings, and rest had effected an important modification. Time passed; the cure advanced; and seven or eight drachms of mercurial ointment were sufficient to put these soldiers in a condition to quit the hospital after an abode of thirty or thirty-four days. Those, on the contrary, who were subjected to the ordinary mercurial treatment, used from four to five ounces of ointment, without counting the pills of Belloste (Ratier's Formulary, p. 123) taken in the interval between the frictions, and left the hospital only after fifty-five or sixty days. When the patients suffered themselves to be guided without anxiety as to the mode of treatment, I suppressed altogether the mercurial preparations; and I arrived nevertheless at the same end; that of curing the patient more rapidly than by the ordinary method. Instructed by so many observations agreeing with those afforded by my civil practice, I no longer doubted that recent syphilis might also be cured by simple and rational treatment. From this time mercury performed only a secondary part in my practice in the city. I soon renounced it entirely, and treated my patients by the antiphlogistic method."

The remainder of M. Divergie's communication consists in giving the result of his anti-mercurial practice from 1814 to 1835, and is chiefly composed of tables of the various classes of venereal symptoms thus cured, amounting to several thousands to which I beg to refer the reader as a most important document. The difference between M. Divergie and Doctor Colles, in exhibiting these minute doses of mercury, appears to be this—that the former deceived his patients for their advantage—the latter deceives himself to the advantage of no one.

In a work just published by Doctor Oppenheim, "On the Treatment of the Venereal Disease without Mercury, toge-

ther with a notice of the antiphlogistic treatment of the disease pursued in the General Hospital at Hamburg," we find that the author is a decided advocate for this mode of treatment, and was amongst the first who introduced it into the German hospitals.

"He believes that it can be shewn from historical data, that since the period when mercury became to be universally esteemed the proper remedy for the venereal disease, the latter has increased in the obstinacy and violence of its symptoms; and he maintains, that when the treatment of it by antiphlogistic remedies alone shall be generally adopted, the beneficial effects produced upon the present as well as the future generation, will be scarcely less than those produced from the discovery of vaccination!

"Notwithstanding the foregoing facts and observations (all relating to the antiphlogistic mode of treatment) it has been almost universally believed that syphilis can be effectually cured only by specifics, at the head of which was ranked, and still is ranked by many, mercury. That numerous other remedies and plans of treatment have, at different periods, been proposed, will be seen from the previous chapters of this work. Diet, depletion, and abstinence, have, indeed, always been considered as necessary adjuvants to insure even the efficacy of their presumed specific."

For this notice of Dr. Oppenheim's work, we are indebted to the American Journal of Medical Science, as it has not as yet been translated into the English language. From it we find a host of evidence in addition to that afforded by the surgeons of the British army, in favour of the antiphlogistic mode of treatment; and I would beg particularly to call the attention of Dr. Colles to the shrewd observations which I have marked in italics. I have now quoted the opinions and practice, recently published, of two most influential personages, the one in France and the other in Germany, directly opposed to those of our author, whose great object seems to be, to bring us back to the old orthodox faith—that there is no cure for a venereal disease but mercury; and that those modern heresies which have led some foolish people to recommend any other means, have induced incalculable mischief upon society. Now although it seems, from various passages, that our author's faith remains unshaken in the *specific* powers of this mineral, yet he has disco-

vered that one-sixth, one-twelfth, nay a twenty-fourth part of the doses he was formerly in the habit of prescribing, will prove as effectual a remedy as the original quantum; thus we find in many cases detailed, particularly of the phagedænic venereal disease, characterised by rupia, that ten grains of the ointment rubbed in every night, or every second night, or three grains of blue pill every night, or every second night, will be sufficient to cure the disease. I feel no objection to allow our author to ride his hobby as hard as he pleases, provided it produces no worse results than this practice. I know how strongly he is wedded to early opinions and associations, and that I might as well attempt to shake a pious Mussulman from his faith, that there is no God but Allah, and that Mahomet is his prophet, as to endeavour to dissuade my friend from his belief in the infallible powers of mercury over every other form and stage of venereal complaints—a belief which may aptly be parodied by a doctrine, the orthodoxy of which he will not dispute, that to overcome these maladies, there is no God but Mercury and Abraham is his prophet.

In chapter XI., "On the treatment of Syphilis in Scrofulous patients," I find that Dr. Colles still perseveres in the notion, that those enlarged cervical glands which occur for the first time, with the other symptoms of secondary venereal, are scrofulous. In my work on the former disease, I pointed out their occurrence as analogous and similar to that which takes place in other exanthemata; for all the different forms of the venereal appertain to this class of diseases. He asks, when these glands appear, "how are we to treat this complicated case?" and then he thus replies to himself: "my answer is, that we are to proceed exactly in the same manner as if the venereal symptoms were uncombined with any such affection;"—and my answer would be precisely the same, although I do not consider the case to be at all complicated—the swelling of the cervical glands having arisen from the venereal poison, and not from any scrofulous diathesis. But in a truly scrofulous subject, with a predisposition to tubercular phthisis, Hunter, in my opinion, was perfectly right in deprecating the use of mercury, particularly when given, as the author recommends in such cases, so as to excite a smart pyæmia. Several instances are adduced, however, of the success of the mercurial

practice; but I rather imagine that the enlarged glands had, in those successful cases, a venereal origin.

Chapter XV. is dedicated to the consideration of non-mercurial treatment of syphilis; of course our author is not likely to approve of it, but allows that "fewer of the non-mercurial patients complained of affections of the bones, than those who had been ineffectually treated by mercury." Such an admission from Dr. Colles cannot but be esteemed of value. He also "acknowledges, that the profession is highly indebted to those who have lately introduced the non-mercurial plan of treatment, for we have not only acquired a second line of treatment for venereal cases, but, what is of the highest value, we have been released from an inveterate and deep-rooted error—from an unfounded conviction that the venereal disease could not be cured by the innate powers of the system, unless aided by mercury. I need not add, that all the opinions and practices consequent on this prejudice have been subverted."

Now I agree perfectly with him as to the obligations which we owe to non-mercurialists; but I differ nearly as much in theory and practice from this class of practitioners, as I do from the downright mercurialist. I look upon mercury as a most useful medicine for particular forms and particular stages of venereal diseases according to the system laid down in my work, which I have now pursued, both in private and public practice, upwards of twenty-five years, and never had occasion to regret my adoption of it. But the decided non-mercurialist, in his faults of omission, is perhaps equally erroneous, though not equally injurious to society as the decided mercurialist, who with one fell swoop, and without compunction, blindly consigns every venereal case to his powerful, and when thus indiscriminately employed, destructive *specific*.

At the conclusion of Dr. Colles's work, is an interesting chapter "On the use of Mercury in affections of the Nervous System," which he commences with the following observation: "Every surgeon who has been engaged in the practice of his profession during the last twenty years, cannot fail to have remarked the following fact; viz. that during that period, mercury has been applied much more frequently to the cure of certain diseases, than it formerly was, although its powers over these had not been previously acknowledged. How to account for the increasing partiality to this medi-

cine, for the cure of other diseases, while its use in venereal complaints, for which it had so long been considered a specific, has within the same period of time been by many practitioners objected to, and by some totally abandoned, is a problem not easily to be solved." He then conjectures that the general application of this medicine to diseases not venereal, has been owing to the salutary effects of which it evinced in the treatment of the Walcheren fever. I should rather attribute it to the well known beneficial effects of mercury upon inflammation of the iris, for the first intimation of which we are indebted to Dr. Farre, in his letter to the late much lamented J. C. Saunders, on the disorganizing effects of mercury, published upwards of twenty-five years ago; It was this first opened my eyes to the benefits likely to result from its application in all inflammatory complaints, and from that period I have been in the habit of employing it wherever I suspected the existence of internal inflammation.

In peritonitis, pleuritis, meningitis, periostitis, and lastly, in synovitis, its great utility is firmly established. In the last, or inflammation of the joints, my friend Dr. O'Beirne has put beyond a doubt, the vast advantages which result from a quick mercurialization of the system, in a paper inserted in the 5th volume of the Dublin Medical and Surgical Journal, and in the 5th vol. of the same publication, for September, 1833, I inserted a paper on "*Inflammatory Affections of the Brain and its Membranes*," containing six remarkable cases of head affections, including apoplexy and paralysis, five of which were treated successfully by bleeding, mercurializing the system, and the counter stimulus of tartar emetic ointment to the head. The unsuccessful case, the first detailed, would probably also have had a fortunate termination, were it not for the wilfulness of the patient, who discontinued the medicine and my attendance, at two distinct intervals, on finding, as he thought, sufficient relief and amendment from the means employed.

Amongst observations I made at the time on the cases detailed, is the following:—"In the treatment of inflammatory affections of the brain and its membranes, next to blood-letting, in efficacy, stands, in my opinion, mercurialization of the system. The beneficial effects of this process in stopping the progress of inflammation of membranous parts, is most satisfactorily demonstrated every day by

the exhibition of mercury for iritis. Frequently, in this affection, the pain, change of colour, and deposition of lymph on the iris, occasioned by the inflammation, begin to disappear, even before the mercury has had time to evince its usual effects on the gums of the patient."

Since that publication, I have met with a considerable number of cases of apoplexy, recent epilepsy, and paralysis, which have established, in my opinion, the value of this mode of treatment. In inflammation of the brain or its meninges, from accident, it affords our best safeguard in protecting the patient against the formation of matter and its other consequences: and this mode of treating all accidents of the head, in which internal inflammation is suspected, has been acted on with such success in the Richmond Hospital during the last four years, as to insure a continuation of this practice. I have this moment in conjunction with Mr. Kavanagh, under my care, a young lady residing at Kingstown, who has recovered by this treatment from an attack of paraplegia, by which she had totally lost all power over the sphincter of the bladder and the lower extremities. This young lady had been previously subject to most intense headaches, which sufficiently indicated the seat of the disease.

I therefore hailed with pleasure the confirmation of my opinions and practice contained in this section of Dr. Colles's work, in which is detailed some remarkable cases of hemiplegia, of confusion of the intellect, with tendency to apoplexy, gastrodynia, and epilepsy, treated successfully with mercury and tartarized ointment.

But notwithstanding this general adoption of mercury, for inflammation of membranous and parenchymatous tissues, I have been informed by some eminent apothecaries of this city, of long standing, that on a rough calculation there is not a tenth of the quantity of that medicine ordered now, compared to its employment twenty years ago; a fact which demonstrates the great diminution of mercury in the treatment of venereal complaints. Another fact is, I believe, also admitted by the seniors of the surgical profession, viz. that we do not now meet in the same proportion as formerly, extreme cases of broken down constitutions from the combined effects of venereal and its presumed antidote. We have, therefore, reason to conclude that the treatment of the disease is, by the majority of practitioners, better understood than it was twenty years ago;

but it must be admitted that in general practice there is still great room for improvement.

Notwithstanding that Dr. Colles and I disagree upon many points, both in theory and practice, respecting venereal complaints, yet there are several upon which I give my unqualified assent. For instance, I agree with him, contrary to the opinion of Hunter, "that constitutional symptoms are capable of infecting and communicating the disease." In addition to the testimony adduced by Dr. Colles on this head, I have met with several instances of new married women, whose moral character set them above suspicion, who received the disease from their husbands, who at the time of connexion had no primary, but had secondary symptoms; and in no other way could I account for children before the age of puberty becoming diseased in consequence of lying in the same beds with persons labouring under constitutional eruptions or ulceration.

His rules for conducting a mercurial course, where such is advisable, are excellent; and his mode of fumigating by mercurial candles, ingenious and suitable.

The chapter which treats of the venereal disease in infants, also contains much novel, useful, and interesting information.

His mode of treating a chancre at the orifice of the urethra with a strong escharotic, such as the white muriate of antimony, is decisive and most useful, particularly when the ulcer is of a phagedænic character; and when stricture of the orifice occurs after cicatrization of the ulcer, his peculiar mode of treating the stricture, as detailed at p. 95, is ingenious, and, I make no doubt, effectual. I also perfectly agree with him, contrary to the opinion of Hunter, that chancres sometimes occur in the urethra; but this was proved long since by the experiments detailed by Benjamin Bell.

Chapter IV. is on a "*Disease of the Lymphatic Glands of the Groin attended with peculiar Symptoms.*" In this affection one or more of the lymphatic glands of the lower or femoral range are generally the seat of the disease, of which I have met with in many instances. It is always attendant upon a delicate constitution, and rapid pulse. In every case of this description, I have been led to suspect the existence, or at least a strong tendency to tubercular phthisis; and always directed my patients to the sea-side, and to observe those attentions calculated to improve the general health: and I per-

fectly agree with the author, that mercury in such a case would be injudicious and most probably destructive.—On the whole I am happy in stating my opinion, that this treatise contains many useful practical lessons; and there is no surgeon, however extensive his practice may have been, who will not be benefitted by a perusal of a work obviously the production of a man of extensive experience and undoubted talent for observation.

AND

Surgical Journal.

Saturday, October 28th, 1837.

MEDICAL EDUCATION IN LONDON.

THE metropolis has presented during the last few weeks, as far at least as the medical schools are concerned, a good deal of bustle. The general impression is, that the number of students is rather diminished than increased, when compared with that of last season; there has, however, been no diminution in the zeal and activity of the teachers, in using their best exertions to entrap as many of "the lads green, raw, and fresh from the country," as they possibly could contrive. During the recess, no school has surpassed in activity and assiduity that of the Professors of the Brodian College. They advertised their attractive establishment in every provincial newspaper; and when their celebrated lectures were about to commence, handbills were profusely circulated by active agents in the suburban districts. These praise-worthy efforts have not, however, succeeded to the extent which might have been reasonably expected, or anxiously desired; and we have every reason to believe, that Mr. Lane and the other professors of St. George's Hospital School, have in no

way suffered from the intrigues of Kinnerton Street.

The benefits which the medical student will derive from the reduction of the attendance fee of the Westminster Hospital, can not be supposed to be fully appreciated this session, while at the same time the loss of Mr. Guthrie's *gratis* lectures must also have no small influence on the Westminster School.

We regret to pass by the meritorious institution of Charing Cross, without being able to announce any new and interesting feature, we exempt only the retirement of the venerable and experienced Dr. Shearman from the chair of the theory and practice of medicine, whose place is now amply filled by Dr. Chowne, ably assisted by that eminent practitioner, Dr. Weatherhead.

Except the Brodian professors, the medical staff of King's College have been the most energetic in their labours to procure pupils; but, we regret to say, with their usual want of success. There is a general impression amongst the professors, that their existence as a medical school, solely depends on having attached to it an hospital; and had Dr. Partridge been able to negotiate with the council of Lincoln's Inn, and obtain another RECOGNITION for the Charing Cross Hospital, they might have expected better things. The complete discomfiture of his colleague and fellow-labourer, Mr. Howship, in all their endeavours to obtain a second recognition, was a death-blow to the Joint Stock Company in the Strand; and their only remaining hope, slender as it may be, is to induce one of the medical officers of the hospital to resign, and thus create a vacancy for the ingenious and erudite Professor Todd.

It will be recollected, that at Bartholomew's Hospital School, there was a great falling off in the number of students last

session ; but this year there is the appearance of a more plentiful harvest, which will be a great source of delight to some of the rapacious staff of Smithfield.

The Royal Hospital of St. Thomas, notwithstanding the support of the illustrious Travers, still remains in a state of great "constitutional irritation," which competent general practitioners confidently affirm, will speedily terminate in a fatal collapse of the whole system.

At the noble hospital of the philanthropist Guy, all is prosperity and sunshine ; and it is but justice to the eminent individuals connected with this unrivalled institution to state, that in number and respectability of students, it takes the lead of all the medical schools of the metropolis. Besides the great advantages of a large practical seminary, and attractive museum, on which the funds of the hospital have been most amply and liberally bestowed, for the advancement of science and the interests of the sick poor, a morbid anatomist of unrivalled skill as a curator, and nicety in preserving morbid specimens ; a zealous professor of anatomy, whose alluring manners and urbanity of disposition, along with some important *radical* changes ; among others, the gaseous illumination of the dissecting rooms, and his true spirit of reform ; operative surgeons of the first eminence, physicians of the most profound learning, all these combined into one great and harmonious whole, has justly laid the foundation of the eminence, reputation, and success of the school of Guy's Hospital.

The singular success of the professors of Guy's has not diminished the fame of the Graingerian academy, nor has the loss which it has sustained in the retirement of Dr. Whiting to his gastro-panadrian manufactory, injured the establishment to the extent to which some might have anticipated ; and this may be legi-

timately attributed to the *reflex motatory* system of the modern Sydenhamian professor for the Boroughonian and northern divisions of London, whose lectures, from being published in the "independent journal," give to the student a very superior advantage, as he is enabled to ponder over, with the midnight oil, those various interesting and instructive discourses orally delivered by the eminent prototype of one of the most renowned fathers of medical science.

The prosperity of the Borough schools may, to a certain extent, account for the unpropitious forebodings of the Gower Company. University College has, indeed, for some time past, had much to contend with. The loss of two professors, on whom alone its reputation rested, having been inadequately repaired, the unpardonable tragical scenes which have been enacted in its hospital, the *experimental* system of clinical instruction, the serious jarrings and disputes amongst some of the professors and the students, and the various intrigues connected with the professors' chairs, have all contributed to cast a cloud of obloquy on this ill-fated institution.

The theatrical exhibitions of operations on which they endeavoured to raise a reputation, or rather to increase their funds, we have never ceased to repudiate ; and the experimental system of clinical instruction deserves to be no less severely censured, and the exhibitions of animal magnetism have even called forth the animadversions of, and have been severely stigmatized by, the public press. Independent of the unkindly, nay, uncharitable, feelings by which men are actuated, to select the sick poor as victims of their experiments, the system of performing experiments in the use of new remedies, is not only quite uninformative to the student, but is much to be reprobated. Our

materia medica affords abundant stores of remedial means, the effects of which the student ought first to learn before he attempts to study those which are comparatively but little understood; and he who professes to give clinical instructions ought to direct the youthful mind exclusively to observe the effects of such medicines in the treatment of disease, the safety of whose administration has received the sanction of the most eminent practitioners of this as well as of former generations. Whilst such an example of an experimental system must be highly prejudicial to youth, we are far from con-
 ending that rational trials should not be made of new remedies, but those should only be employed by men who have a consummate knowledge of the use and mode of administering the more ordinary medicines.

WORKING OF THE ANATOMY BILL.

It is satisfactory to state, that there is a plentiful supply of subjects to all the schools, which is to be attributed to the vigilance of the Inspector of Anatomy in counteracting the fraudulent abuses which were formerly so prevalent in certain schools, and received the sanction of an anatomical committee.

THE STUDENT'S MANUAL.

No. II.

ORGANIC DISEASES.

Much mystery has been connected with the treatment of diseases; but of this mystery we shall endeavour to divest it. This we shall do by not attempting to pry into the nature of the first link in the chain of diseased action. Indeed we do not know the intimate nature of a single disease, we only know its effects. We do not understand the real nature

even of the healthy functions of the body, such as secretion and digestion, much less can we pretend to understand its morbid actions or diseases. Of inflammation, for instance, we only know the effects. We see the changes which occur in the inflamed part, that it becomes redder, that its vessels are enlarged, and the circulation quickened; but the nature of these effects we do not comprehend. They may be produced by other causes. By friction, for instance, a part will be reddened, its vessels enlarged, and the circulation quickened, without any inflammation at all. Dissection will not reveal the nature of a disease, but only its effects; and if it should be very violent and quickly fatal, dissection reveals nothing. Angina pectoris is looked upon by some eminent physicians as depending on spasm of the heart, and here dissection tells nothing; for muscular contraction, in which spasm consists, is a vital action, and therefore no spasm can be found after death. Again, certain parts of the brain are essential to life, and if they suffer severely life is quickly destroyed, without leaving any traces for dissection to reveal. Inflammation on the brain, if very quickly fatal, eludes discovery on dissection. Hydrocephalus is the result of inflammation in an advanced stage; and if quickly fatal the only morbid appearance will be fulness of the veins; whereas, if longer protracted, there will be more decided appearances; so that, in this case, the more violent the disease the less of it will be revealed by dissection.

Anatomy, how excellent and useful soever it may be, will not teach us how to cure diseases; for this, experience is necessary. Anatomy will not teach us that jalap causes purging, or antimony vomiting. The changes to which diseases are naturally liable are sometimes attributed to the remedies employed; many diseases are liable to spontaneous change and cessation, and in this way physicians and their remedies have sometimes gained undeserved reputation. Formerly, every disease had a list of remedies opposite to it, and he was the best physician who could remember most of them; sometimes not only scores but hundreds of ingredients were made into a compound, the efficacy of which was thereby thought to be increased. A cure is not always the object of treatment, for if the disease should not be of a curable nature, attempts at effecting a cure are injurious, for the best remedies do injury in cases

to which they are not appropriate. Many diseases are altogether incurable; such as cancer, the disorganization of parts, and fever, if the stage be too far advanced, and in the latter case, the means which were applicable at first would be hurtful, such as bleeding, for instance; the treatment in these cases must be palliative. If diseases have become habitual, and are not violent, it is not always proper to attempt their removal, for the system has become accustomed to them. This applies to habitual hemorrhage (as from piles), cutaneous affections, &c. The system may here, perhaps, require the stimulus which the disease affords. Gout in the joints may be cured, but it is not always advisable to do so, for we should be exposing the patient to a greater evil by curing the lesser. As a general rule, however, we cannot cure a disease too soon. Various and even opposite means have been adopted for this purpose. The inflammation resulting from a burn, for instance, is sometimes treated by cold, and at other times by stimulants. Ophthalmia is another example. Both succeed at times; and it is not easy to decide which is best. There must be a principle on which they succeed, although that principle is not ascertained. This subject is treated in a rational and common-sense style in Dr. Billings's "First Principles of Medicine." Bleeding cures many diseases, not by weakening the patient, for it cures the weak as well as the strong, though we do not say it is equally proper for them. Purgatives will sometimes cure diseases which are not apparently connected with the intestines, such as ophthalmia; and vomiting likewise cures diseases not connected with the stomach; a blister will cure many diseases, not by removing any thing noxious from the system, but by counter-irritation. This is understood to act by making an impression on the system, so as to induce a new action, which tends to stop the disordered action on which the disease depends. We do not expect to restore the healthy action in any disease in the first instance, for we have no power to do this, but we change the action of the part, hoping that the healthy action will be resumed. To do this, we must make an impression on the part affected, so as to induce it to change its action; to effect this we employ various means, such as cold, heat, and medicinal drugs. We cannot always succeed in stopping the diseased action, as the tendency to it in the system may be too strong for us, but if it could, all diseases

might be cured. The disposition to epilepsy is so strong, where it has once taken place, that we cannot cure it once out of ten times; for it depends on an unsound state of a part of the brain, which state we cannot remove. It is the same with mania and other chronic diseases of the brain. For stopping diseased action in the venereal disease no remedy can be relied on but mercury; though there are many remedies the action of which are more powerful. There is a difference observable in the cases of different patients in similar circumstances, owing to the disposition to disease differing in them, this throws an uncertainty over our prognosis, in which probability is all that can be attained.

The treatment of a disease is called *local*, if applied to the part affected; and *general*, if applied to other parts. We may use either, or combine both. Local treatment would, at first sight, appear to be the best, but there are many parts which cannot be reached, such as the brain, the heart, and (but imperfectly) the lungs; and yet we can often treat diseases of these organs better than those of parts within our reach. Thus a blister is often applied to the back with the view of curing the brain, and even the lower extremities have been recommended to be blistered for the same purpose; this is on account of these parts being connected by what is called sympathy; so that we can reach one by means of the other. This is what is meant by counter-irritation, the exciting of one disease in order to cure another. We ascertain this by long experience, for we should not suspect it without. Our best remedies act on this principle. Purgatives, for instance, often act, not by carrying anything out of the system, but by exciting an artificial disease in the intestinal canal, in order to relieve another disease. We must always take care that this new disease which we excite, is not worse than the old one. Even blood-letting may be classed with remedies which act on this principle; it influences all the actions of the system, and therefore we hope it may influence the diseased one. Some patients will not bear our more powerful remedies, such as bleeding and blistering. We must take into consideration all the circumstances of the case. In diseases of the urinary organs blistering is improper, on account of its tendency to produce strangury.

We have divided all diseases into organic or functional. At present we are

engaged with diseases of the first class, and we shall consider them in the following order:—1. Diseases of the nostrils. 2. Diseases of the eyes. 3. Diseases of the ears. 4. Diseases of the mouth. 5. Diseases of the respiratory system. 6. Diseases of the digestive system. 7. Diseases of the urinary system. 8. Diseases of the genital organs in the male. 9. Diseases of the genital organs in the female. 10. Diseases of the mammary organs. 11. Diseases of the glands. 12. Diseases of the skin. 13. Diseases of the osseous system. 14. Diseases of the muscular system. 15. Diseases of the nervous system. 16. Diseases of the vascular system. 17. Fevers.

We commence with diseases of the nostrils.

Catarrh.—Cullen places this disease among the profluvia. He has two species:—1. Catarrh from cold. 2. Catarrh from contagion. It is no longer, however, held to be contagious, but epidemic. It occurs particularly in infancy, old age, and debility from any cause. It is most dangerous when it occurs in infants; for it prevents their sucking. It is symptomatic of measles, small-pox, and worms, and is excited by septic poisons, such as various fishes. In common cases confine to the house, and to low diet, and use diuretics; when epidemic, it is known by the name of *influenza*, which is often fatal. In the first stage, if the inflammatory symptoms are urgent, use venesection. It obtained its name from the Italians, because its cause not being known, it was supposed to depend on the influence of the stars. Sydenham attributed it to a vapour arising from the bowels of the earth; and some modern physicians ascribe it to a miasm generated at the surface of the earth. The doctrine of its being communicated by contagion is opposed to the fact of its occurring in nations very little connected with each other; and it never occurs without travelling over a great part of the world. It got from India to China, though there is very little intercourse between them; nor could it have been communicated from India to Russia by personal intercourse, unless it was conveyed by a caravan, which, by a journey of so many hundred miles, is not likely. Its progress differs much from that of contagion in the rapidity with which it takes place. A sloop sailed from Portsmouth with a hundred and forty-five men, within eight hours sixty men were attacked with influenza, and the next day they put back from

want of healthy men to work the ship. There was no evidence that any were sick when they sailed, they seemed to have got it at sea, and every man in the ship was attacked. This looks like malaria, for it is too rapid for contagion. On one occasion the influenza went through London, and was completely at an end in three weeks. Such contagion as this was never heard of. It is generally mild; but from the great number of persons attacked, the deaths are very numerous. It is generally attended with bronchitis, but differs from that disease, as it generally occurs, in not leaving behind it a disposition to tubercular consumption, or, if tubercles exist in the lungs, rousing them into activity. The catarrh which is produced by exposure to cold, if slight, is relieved by the secretion which takes place, after a few hours or days, from the mucous membrane of the nostrils. Sometimes the inflammation extends to the frontal sinuses, and then we have occasional stinging pains in that region, especially on taking snuff. Every time a pinch of the latter is taken, a man (though in health) gets a temporary catarrh. Bronchitis and croup generally begin with catarrh.

Disease of the Antrum.—There is a phlegmonous inflammation of the mucous membrane of the nose, which sometimes extends into the antrum of Highmore. It is distinguished from neuralgia of the face (*tic douloureux*) by the heat, swelling, and redness being constant; by the swelling in the nose; the suppuration; and the hectic fever which comes on. When matter has formed in the antrum, it must be evacuated. The first molar tooth used to be drawn for this purpose, and a perforation made through the socket; but that is seldom done now, Mr. Liston having introduced a plan of penetrating the cavity through the anterior wall. Sometimes this disease of the antrum is idiopathic; but it is generally from inflammation extending into it from the neighbouring parts,—especially the scheidarian membrane. In the natural state, the interior of the cavity is only moistened with a little mucus; but the inflammation produces a great quantity of vitiated secretion, by which the bone is painfully distended. The communication with the nostril is very small at all times, and when inflamed, the membrane which lines the passage becomes so thickened as to obliterate it altogether. The symptoms are very severe; the cheek being much swelled, and shooting pains

being felt, from the teeth up to the temples. If left alone, the matter will work its way out sometimes into the nostrils, but generally through the anterior wall of the cavity, which gives way. Sometimes the teeth fall out and the pus escapes in that way; or, if they be extracted, it may flow through their sockets. This pus is very fetid,—especially if there be disease of the bone. Sometimes the antrum is the seat of a chronic abscess which gradually expands the cavity; and then if the sides of it be pressed upon, they yield with a noise like the crackling of parchment. Although small in its natural state, the antrum may become so enlarged as to hold several ounces of fluid. Sometimes it extends as far as the external angle of the frontal bone. It may be caused by blows on the cheek. If not evacuated, the lining membrane may slough, and even the bone be destroyed. An objection to the old method of perforating through the socket of a tooth, was the difficulty of getting an opening large enough; and if the teeth are sound, it would be wrong to remove any of them. It is better to separate the soft parts from the gum, and to perforate the bone at the point corresponding to the interval between the sockets of the canine and the third molar teeth. The discharge dries up, and the parts recover themselves; sometimes returning to their original state. When the inflammation is in its early stage, suppuration may sometimes be prevented by a free abstraction of blood locally. A good way of effecting this, is by applying leeches inside the nostril. Desault's instruments for effecting the perforation, are like small chisels. He recommends that a hole should be made large enough to admit the little finger. He incises the mucous membrane first, and then cuts through the bone, as in Liston's operation; all being performed inside the mouth, and thus no scar being produced externally. If the distension, and consequent deformity, have been very great, a bandage will assist in restoring the parts to their natural state.

But the antrum is liable to a more serious disease—that of polypus (tumours; which are different from those in the nasal passages; and if removed, are speedily reproduced. Polypi of a similar kind sometimes occur in the frontal sinuses. They cause great swelling of the face, pain, loosening of the teeth, and sometimes a discharge from the nostrils of a bloody sanies. The humour soon

gets into the nose, and into the orbit, by destroying its inferior wall; and ultimately spreads into the fauces. The discharge is then swallowed, which may cause diarrhoea, and kill the patient; but if not, he is carried off by the repeated hæmorrhage, or by hectic. The disease is far advanced before the patient applies for medical assistance; and even if discovered earlier, it is doubtful whether any operation could be employed with advantage. Some have applied the trephine to the bone; extirpated the tumour; and applied the escharotics, or the cautery afterwards. It is an operation, however, which cannot be recommended; for it does not appear that life has been prolonged by it. The way in which it is performed, is by making an incision from the angle of the eye to that of the lips; turning back the flap; and then the trephining the bone, and scooping out the tumour. Some have recommended extirpation of the superior maxillary bone; but it is not in this disease it is to be employed. The enterprising surgeon, Mr. Lizars, once attempted it after tying the common carotid of that side; but so much hæmorrhage ensued, that he was compelled to desist. In a week afterwards he tried again; after tying the common trunk of the temporal and internal maxillary arteries, on the other side; but there was again so much blood lost, that he was obliged to give it up. In another case he succeeded in extirpating the bone, but the man died in a few days.

Nasal Polypi.—The polypi which occur in the nostrils are of three kinds. 1. Grey polypus; which is merely the hypertrophied mucous membrane. 2. Red polypus. This, which is the true polypus, is vascular sarcoma. 3. Black polypus. This is scirrhus, and generally occurs in the front part of the nostrils; while the red occurs most at the back. To the latter, which is also called the soft polypus, caustic is applied. In the case of the black, or scirrhus polypus, we administer iron, conium, or arsenic; using the arsenic paste as a local application. The grey polypi are benign humours, covered with the mucous membrane of the nose. They seldom occur singly, being generally in clusters, filling up one or other of the cavities of the nostrils. They are supplied with blood-vessels and nerves, though not very sensible; and generally hang by a narrow neck. When they first begin to grow, the person feels as if he had caught

"a cold in the head;" the passage of the air through the nostrils is impeded; and this causes a change in the voice. As the disease advances, the nasal duct becomes stopped up; which gives rise to lachrymation. Sometimes the Eustachian tube is filled up; and then deafness is produced. This occurred in a gentleman who was operated on by Mr. Liston, and who said that though he went to church, for the sake of setting a good example, he had not heard what the clergyman said for twenty-five years. He recovered his hearing after the operation.

There is no application known that will check the growth of these polypi. The different modes which have been employed to extirpate them, are the forceps, scissors, ligatures, and caustics. There is also what is called "a twisted tractor;" and Monro uses a knife in a sheath. The most usual instrument employed, is the forceps; but the common large polypi forceps are much too big. It is best to hold them with a small pair of toothed forceps, with one hand, while you pass up another pair, with the other, to pull them out. Small strong forceps are best for twisting them out. A hook is not so well; for if it should slip, it may lacerate the nostrils. You must not pull directly outward, or you may bring away parts of the bones, or dislodge the ethmoid; and it is believed that abscess within the skull, has sometimes been occasioned by this latter accident. When laid hold of with the forceps, the polyp often burst and discharge a fluid; and then the bag which contained the latter may be pulled out. Tear the polyp away by twisting them; and do not expect to get rid of them all at one operation; for in a day or two you may find the nostrils as full as ever. This is not from any new growth, but from the polypi which before cramped for want of room, have now become developed. Curved knives, and an instrument shaped like a crotchet, have been recommended, and in some cases they are useful. Escharotics are of doubtful service, owing to the danger of causing exfoliation of the bone. A little red precipitate on lint, is employed by some skilful surgeons, in particular cases.

Some recommend the ligature; but it is only advisable when the tumours grow backwards into the mouth; and the cases in which it is necessary are very rare. When, however, they do grow backwards into the fauces, it is a very troublesome

case. Sometimes they degenerate, and assume a malignant character; but not often. But though innocent, yet if large they may impede deglutition. Here the application of a ligature is necessary but not easy. You can obtain no material advantage from any mechanical contrivance; a piece of catheter will do very well to apply the ligature with; though an instrument has been invented with a double tube. Put your finger into the mouth, as far as the polypus; pass a loop of catgut or wire through the nostril, till you can see it in the forceps; expand the loop with your finger, and put it round the base of the polypus; draw the ends of the ligature through a canula, or the piece of catheter, or the tubes, and fasten them together; tighten them from time to time, and you will get rid of the polypus in from thirty to forty hours.

Ulceration of the Nasal Cartilages—

There is no doubt that the cartilages of the nose may be destroyed by ulceration, beginning in the surface of the mucous membrane. This membrane is inflamed every day, without ill consequences; but it does sometimes go on to the destruction of the cartilages. In some cases a blow on the nose causes so much inflammation, that the septum is destroyed. In one case, after a blow, the mucous membrane of the nostrils swelled up and protruded; so that it was mistaken for a polypus. On being punctured, a great quantity of fetid pus was evacuated. When the columna nasi ulcerates away, the nose becomes disgustingly deformed. The extremity is flattened; the nasal openings are wide, and in one case the point of the nose was firmly adherent to the lip. In this case Mr. Liston proposed an operation, which he has since often practised. He first detached the tip of the nose,—made a raw surface for the attachment of the new columna; then holding up the upper lip, he passed a bistoury completely through it, and carried it down to its free edge; and making a parallel incision in the same way, a strip of the upper lip was provided for the new columna. This was raised, by cutting its frenum; its free edge was pared, and when the bleeding had ceased, it was turned up, and fastened to the tip of the nose with a needle and twisted silk. The mucous surface which is thus turned outwards, soon becomes cutaneous. The divided lip must also be brought together with pins, and twisted sutures, as in the operation for hare lip.

REVIEWS.

The Student's Pocket Guide to the College of Surgeons; embracing the Ligaments, Bones, Muscles, Eye, Skin, Arteries, &c.; and all Questions in Anatomy, Physiology, and Surgery usually asked of Candidates. By FORBES WINSLOW, M.R.C.S. J. T. Cox.

A Manual of Practical Midwifery, including Diseases of Women; in accordance with Burns, Denman, Gooch, Dewees, Blundell, Davis, Ryan, &c. By FORBES WINSLOW.

One Thousand Latin Prescriptions. By GEORGE FUTVOYE. Sold by all Booksellers.

A literal Translation of the Pharmacopœia of the Royal College of Physicians of London. 1836. By GEO. FUTVOYE.

The Student's Companion to Apothecaries Hall, or the London Pharmacopœia of 1836, in question and answer. By EDWARD OLLIVER, M.R.C.S. &c, London, 1837, J. Churchill.

This is the age for waistcoat pocket editions of medical works. The whole of the art and science of medicine is now professed to be contained in a few little volumes, which one may carry in his waistcoat pocket without the slightest inconvenience; such is the march of bibliopolic ntellect.

It is our duty, however, to warn students against the great majority of these publications, as most of them are imperfect, and inaccurate, and some of them worse than useless. They are generally written and compiled by young men "just let loose from School," who are totally incompetent for the proper execution of authorship, and who publish for the purpose of claiming the privilege of giving private instruction. Having given our opinion of this class of works, we have now to notice those more immediately before us.

The Pocket Guide to the College of Surgeons is an imperfect production, without scientific order, and much too concise. On perusing its title, it will be observed that the author commences with the ligaments, and thus differs from the arrangement of all anatomical teachers. There are other faults, such as there are two arteries in the body, &c.

The Manual of Practical Midwifery is

still more concise and imperfect, indeed the title is a misnomer. The author gives the orteology of the pelvis—the symptoms and diseases of pregnancy—abortion—division of labours, the descriptions of which are too concise, and to students must be unintelligible. The whole of the work is too superficial even for the merest tyro.

One Thousand Latin Prescriptions contain every day formulæ, and few of the new medicines. The work can only be useful to those who have to learn the reading of prescriptions.

A Literal Translation of the Pharmacopœia, is an accurate, and well executed version. It is the cheapest translation extant.

The Student's Companion to Apothecaries Hall is a useful manual for candidates. It presents the chemical compositions and decompositions of the preparations in the new pharmacopœia, and greatly facilitates the study of pharmacy.

TO CORRESPONDENTS.

A. P.—The additional extortion fee of ten pounds, by the North London Hospital staff cannot be dispensed with. The fee to the Westminster Hospital is ten pounds less, and the certificate is as good.

J. D.—We believe that the gratis lectures of Sir Benjamin Brodie, are given to none who do not pay the Hospital fee, which is fifty pounds.

T. J.—In point of law, the coroner was justified in his decision.

A Dissecting Pupil.—Every lecturer on anatomy is obliged to have a licence from the Secretary of State for the Home Department, for the particular places where dissections are made. If this law be not complied with, the student, as well as the teacher, is liable to fine and imprisonment.

North London Student.—The two subjects at present exhibiting in the dissecting-room of Gower Street, are merely intended as a clap-trap. It ought to be distinctly understood that the inspector of anatomy rigidly adheres to a *just* distribution of subjects, and the demand of all the schools is generally less than the supply.

All communications and works for review to be forwarded (carriage paid) to Dr. RYAN, 4, Charlotte-street, Bloomsbury-square.
